Overview of ASP.NET Core

Article • 06/18/2024

By Daniel Roth, Rick Anderson, and Shaun Luttin

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

ASP.NET Core is a cross-platform, high-performance, open-source framework for building modern, cloud-enabled, Internet-connected apps.

With ASP.NET Core, you can:

- Build web apps and services, Internet of Things (IoT) apps, and mobile backends.
- Use your favorite development tools on Windows, macOS, and Linux.
- Deploy to the cloud or on-premises.
- Run on .NET.

Why choose ASP.NET Core?

Millions of developers use or have used ASP.NET 4.x to create web apps. ASP.NET Core is a redesign of ASP.NET 4.x, including architectural changes that result in a leaner, more modular framework.

ASP.NET Core provides the following benefits:

- A unified story for building web UI and web APIs.
- Architected for testability.
- Razor Pages makes coding page-focused scenarios easier and more productive.
- Blazor lets you use C# in the browser alongside JavaScript. Share server-side and client-side app logic all written with .NET.
- Ability to develop and run on Windows, macOS, and Linux.
- Open-source and community-focused.
- Integration of modern, client-side frameworks and development workflows.
- Support for hosting Remote Procedure Call (RPC) services using gRPC.
- A cloud-ready, environment-based configuration system.

- Built-in dependency injection.
- A lightweight, high-performance, and modular HTTP request pipeline.
- Ability to host on the following:
  - Kestrel
  - IIS
  - HTTP.sys
  - Nginx
  - Docker
- Side-by-side versioning.
- Tooling that simplifies modern web development.

Build web APIs and web UI using ASP.NET Core MVC

ASP.NET Core MVC provides features to build web APIs and web apps:

- The Model-View-Controller (MVC) pattern helps make your web APIs and web apps testable.
- Razor Pages is a page-based programming model that makes building web UI easier and more productive.
- Razor markup provides a productive syntax for Razor Pages and MVC views.
- Tag Helpers enable server-side code to participate in creating and rendering HTML elements in Razor files.
- Built-in support for multiple data formats and content negotiation lets your web APIs reach a broad range of clients, including browsers and mobile devices.
- Model binding automatically maps data from HTTP requests to action method parameters.
- Model validation automatically performs client-side and server-side validation.

Client-side development

ASP.NET Core includes Blazor for building richly interactive web UI, and also integrates with other popular frontend JavaScript frameworks like Angular, React, Vue, and Bootstrap. For more information, see ASP.NET Core Blazor and related topics under *Client-side development*.

ASP.NET Core target frameworks

ASP.NET Core 3.x or later can only target .NET.

There are several advantages to targeting .NET, and these advantages increase with each release. Some advantages of .NET over .NET Framework include:

- Cross-platform. Runs on Windows, macOS, and Linux.
- Improved performance
- Side-by-side versioning
- New APIs
- Open source

Recommended learning path

We recommend the following sequence of tutorials for an introduction to developing ASP.NET Core apps:

1. Follow a tutorial for the app type you want to develop or maintain.

Expand table

App type	Scenario	Tutorial
Web app	New server-side web UI development	Get started with Razor Pages
Web app	Maintaining an MVC app	Get started with MVC
Web app	Client-side web UI development	Get started with Blazor
Web API	RESTful HTTP services	Create a web API†
Remote Procedure Call app	Contract-first services using Protocol Buffers	Get started with a gRPC service
Real-time app	Bidirectional communication between servers and connected clients	Get started with SignalR

2. Follow a tutorial that shows how to do basic data access.

Expand table

Scenario	Tutorial
New development	Razor Pages with Entity Framework Core
Maintaining an MVC app	MVC with Entity Framework Core

3. Read an overview of ASP.NET Core fundamentals that apply to all app types.

4. Browse the table of contents for other topics of interest.

†There's also an interactive web API tutorial. No local installation of development tools is required. The code runs in an Azure Cloud Shell in your browser, and curl is used for testing.

Migrate from .NET Framework

For a reference guide to migrating ASP.NET 4.x apps to ASP.NET Core, see Update from ASP.NET to ASP.NET Core.

How to download a sample

Many of the articles and tutorials include links to sample code.

1. Download the ASP.NET repository zip file.
2. Unzip the `AspNetCore.Docs-main.zip` file.
3. To access an article's sample app in the unzipped repository, use the URL in the article's sample link to help you navigate to the sample's folder. Usually, an article's sample link appears at the top of the article with the link text *View or download sample code*.

Preprocessor directives in sample code

To demonstrate multiple scenarios, sample apps use the `#define` and `#if-#else/#elif-#endif` preprocessor directives to selectively compile and run different sections of sample code. For those samples that make use of this approach, set the `#define` directive at the top of the C# files to define the symbol associated with the scenario that you want to run. Some samples require defining the symbol at the top of multiple files in order to run a scenario.

For example, the following `#define` symbol list indicates that four scenarios are available (one scenario per symbol). The current sample configuration runs the `TemplateCode` scenario:

```
C#
```

```
#define TemplateCode // or LogFromMain or ExpandDefault or FilterInCode
```

To change the sample to run the `ExpandDefault` scenario, define the `ExpandDefault` symbol and leave the remaining symbols commented-out:

```
C#

#define ExpandDefault // TemplateCode or LogFromMain or FilterInCode
```

For more information on using C# preprocessor directives to selectively compile sections of code, see #define (C# Reference) and #if (C# Reference).

Breaking changes and security advisories

Breaking changes and security advisories are reported on the Announcements repo. Announcements can be limited to a specific version by selecting a **Label** filter.

Choose between ASP.NET 4.x and ASP.NET Core

Article • 04/10/2024

ASP.NET Core is a redesign of ASP.NET 4.x. This article lists the differences between them.

ASP.NET Core

ASP.NET Core is an open-source, cross-platform framework for building modern, cloud-based web apps on Windows, macOS, or Linux.

ASP.NET Core provides the following benefits:

- A unified story for building web UI and web APIs.
- Architected for testability.
- Razor Pages makes coding page-focused scenarios easier and more productive.
- Blazor lets you use C# in the browser alongside JavaScript. Share server-side and client-side app logic all written with .NET.
- Ability to develop and run on Windows, macOS, and Linux.
- Open-source and community-focused.
- Integration of modern, client-side frameworks and development workflows.
- Support for hosting Remote Procedure Call (RPC) services using gRPC.
- A cloud-ready, environment-based configuration system.
- Built-in dependency injection.
- A lightweight, high-performance, and modular HTTP request pipeline.
- Ability to host on the following:
  - Kestrel
  - IIS
  - HTTP.sys
  - Nginx
  - Docker
- Side-by-side versioning.
- Tooling that simplifies modern web development.

ASP.NET 4.x

ASP.NET 4.x is a mature framework that provides the services needed to build enterprise-grade, server-based web apps on Windows.

Framework selection

The following table compares ASP.NET Core to ASP.NET 4.x.

Expand table

ASP.NET Core	ASP.NET 4.x
Build for Windows, macOS, or Linux	Build for Windows
Razor Pages is the recommended approach to create a Web UI as of ASP.NET Core 2.x. See also MVC, Web API, and SignalR.	Use Web Forms, SignalR, MVC, Web API, WebHooks, or Web Pages
Multiple versions per machine	One version per machine
Develop with Visual Studio, Visual Studio for Mac, or Visual Studio Code using C# or F#	Develop with Visual Studio using C#, VB, or F#
Higher performance than ASP.NET 4.x	Good performance
Use .NET Core runtime	Use .NET Framework runtime

See ASP.NET Core targeting .NET Framework for information on ASP.NET Core 2.x support on .NET Framework.

ASP.NET Core scenarios

.NET vs. .NET Framework for server apps

Article • 06/07/2024

There are two supported .NET implementations for building server-side apps: .NET and .NET Framework. **The latest .NET version (currently .NET 8) is the preferred version of .NET to use for server development.** The reasons to continue using .NET Framework are specific and limited.

Expand table

Implementation	Included versions
.NET	.NET Core 1.0 - 3.1 .NET 5 and later versions
.NET Framework	.NET Framework 1.0 - 4.8

Choose .NET

.NET has the following advantages for server apps:

- **Works cross-platform.**

  .NET enables your web or service app to run on multiple platforms, for example, Windows, Linux, and macOS. You can also use any of these operating systems as your development workstation. Use the Visual Studio integrated development environment (IDE) on Windows, or use Visual Studio Code on macOS, Linux, or Windows. Visual Studio Code supports IntelliSense and debugging. Most third-party editors, such as Sublime, Emacs, and VI, work with .NET. These third-party editors get editor IntelliSense using Omnisharp. You can also skip the code editor and directly use the .NET CLI.

- **Lets you target microservices.**

  A microservices architecture allows a mix of technologies across a service boundary. This technology mix enables a gradual embrace of .NET for new microservices that work with other microservices or services. For example, you can mix microservices or services developed with .NET Framework, Java, Ruby, or other monolithic technologies.

  There are many infrastructure platforms available. Azure Service Fabric is designed for large and complex microservice systems. Azure App Service is a

good choice for stateless microservices. Microservices alternatives based on Docker fit any microservices approach, as explained in the next section (Supports Docker containers). All these platforms support .NET and make them ideal for hosting your microservices.

For more information about microservices architecture, see .NET Microservices: Architecture for containerized .NET apps.

- **Supports Docker containers.**

  Containers are commonly used with a microservices architecture. Containers can also be used to containerize web apps or services that follow any architectural pattern. While .NET Framework can be used on Windows containers, the modularity and lightweight nature of .NET make it a better choice for containers. When you're creating and deploying a container, the size of its image is much smaller with .NET than with .NET Framework. Because it's cross-platform, you can deploy server apps to Linux Docker containers.

  You can host Docker containers in your own Linux or Windows infrastructure or in a cloud service such as Azure Kubernetes Service. Azure Kubernetes Service can manage, orchestrate, and scale container-based applications in the cloud.

- **Is high-performance and scalable.**

  When your system needs the best possible performance and scalability, .NET and ASP.NET Core are your best options. The high-performance server runtime for Windows Server and Linux makes ASP.NET Core a top-performing web framework on TechEmpower benchmarks.

  Performance and scalability are especially relevant for microservices architectures, where hundreds of microservices might be running. With ASP.NET Core, systems run with a much lower number of servers or virtual machines (VMs), which saves costs on infrastructure and hosting.

- **Supports side-by-side .NET versions per application.**

  The .NET implementation supports side-by-side installations of different versions of the .NET runtime on the same machine. That capability allows multiple services on the same server, each on its own version of .NET. It also lowers risks and saves money in application upgrades and IT operations.

  Side-by-side installation isn't possible with .NET Framework. It's a Windows component, and only one version can exist on a machine at a time: each version of .NET Framework replaces the previous version. If you install a new app that targets

a later version of .NET Framework, you might break existing apps that run on the machine because the previous version was replaced.

- **Is more secure.**

When to choose .NET Framework

As previously mentioned, the *.NET* implementation offers significant benefits for new applications and application patterns. However, in some specific scenarios, you might need to use .NET Framework for your server apps, and .NET Framework will continue to be supported. Use .NET Framework for your server app when:

- Your app currently uses .NET Framework.

  In most cases, you don't need to migrate your existing applications to .NET. Instead, we recommend using .NET as you extend an existing app, such as writing a new web service in ASP.NET Core.

- Your app uses third-party libraries or NuGet packages that aren't available for .NET.

  .NET Standard enables sharing code across all .NET implementations, including .NET 6+. With .NET Standard 2.0, a compatibility mode allows .NET Standard and .NET projects to reference .NET Framework libraries. For more information, see Support for .NET Framework libraries.

  You should only use .NET Framework when the libraries or NuGet packages use technologies that aren't available in .NET Standard or .NET.

- Your app uses .NET Framework technologies that aren't available for .NET.

  Some .NET Framework technologies aren't available in .NET. The following list shows the most common technologies not found in .NET:
  - **ASP.NET Web Forms applications**: ASP.NET Web Forms are only available in .NET Framework. ASP.NET Core can't be used for ASP.NET Web Forms.
  - **ASP.NET Web Pages applications**: ASP.NET Web Pages aren't included in ASP.NET Core.
  - **Workflow-related services**: Windows Workflow Foundation (WF), Workflow Services (WCF + WF in a single service), and WCF Data Services (formerly known as "ADO.NET Data Services") are only available in .NET Framework.
  - **Language support**: Visual Basic and F# are supported in .NET but *not for all project types*. For a list of supported project templates, see Template options for dotnet new.

  For more information, see .NET Framework technologies unavailable in .NET.

- Your app uses a platform that doesn't support .NET.

  Some Microsoft or third-party platforms don't support .NET. Some Azure services provide an SDK not yet available for consumption on .NET. In such cases, you can use the equivalent REST API instead of the client SDK.

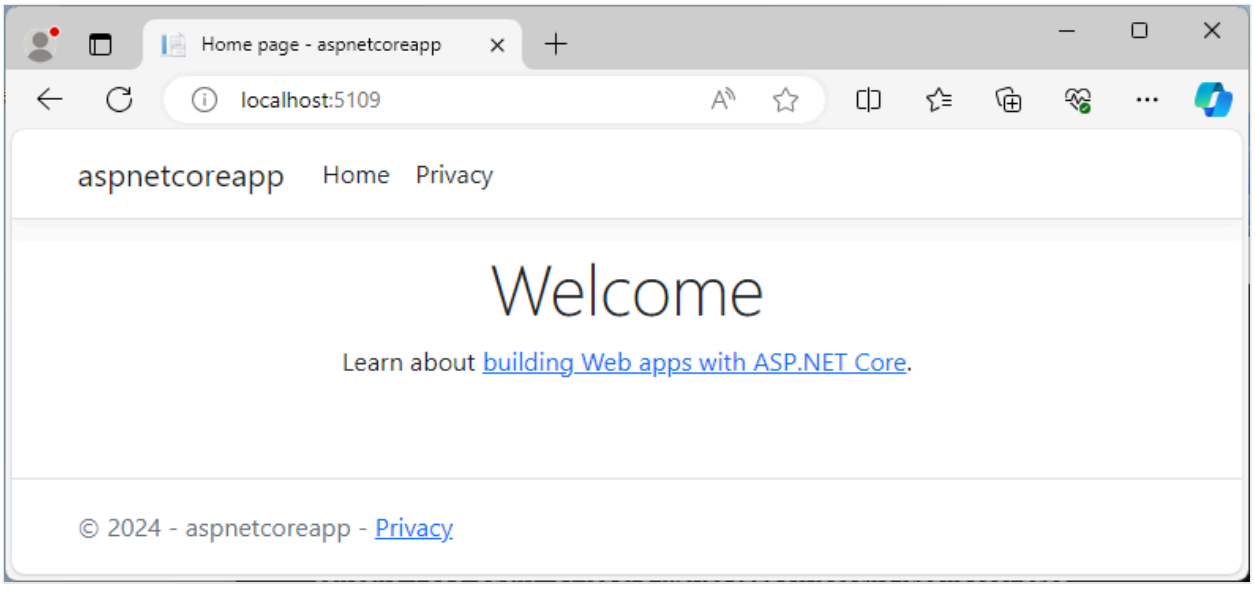
Tutorial: Get started with ASP.NET Core

Article • 09/18/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.



This tutorial shows how to create and run an ASP.NET Core web app using the .NET CLI.

For Blazor tutorials, see ASP.NET Core Blazor tutorials.

You'll learn how to:

- ✓ Create a web app project.
- ✓ Run the app.
- ✓ Edit a Razor page.

At the end, you'll have a working web app running on your local machine.

Prerequisites

.NET 8.0 SDK

Create a web app project

Open a command shell, and enter the following command:

.NET CLI

```
dotnet new webapp --output aspnetcoreapp --no-https
```

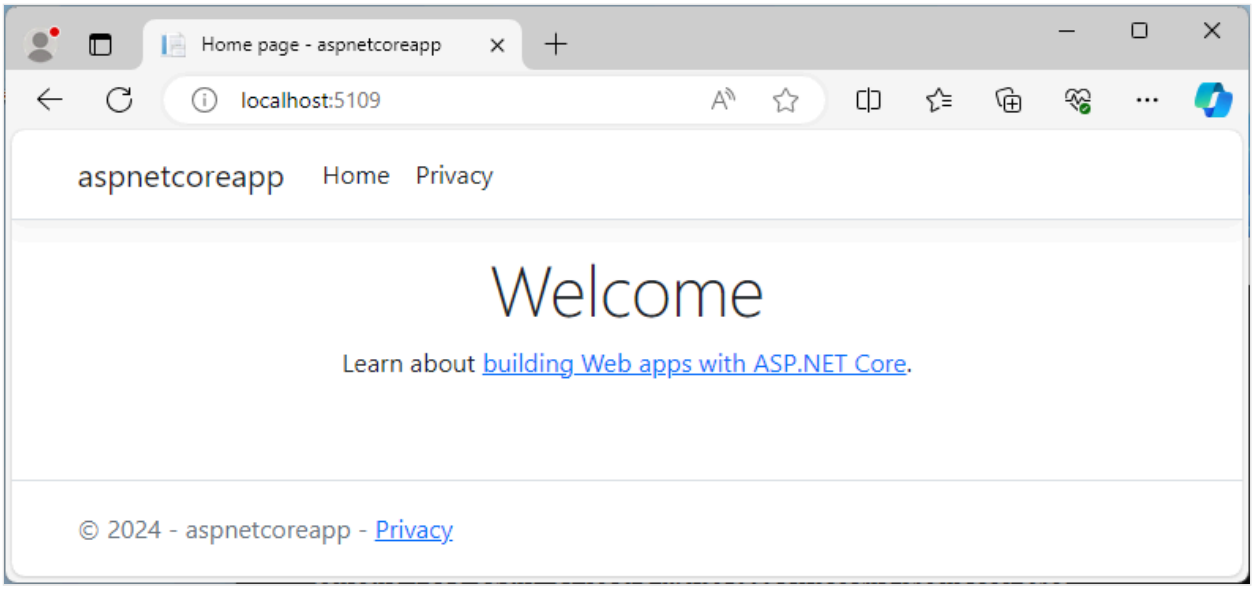
The preceding command creates a new web app project in a directory named `aspnetcoreapp`. The project doesn't use HTTPS.

Run the app

Run the following commands:

.NET CLI

```
cd aspnetcoreapp
dotnet run
```



The `run` command produces output like the following example:

Output

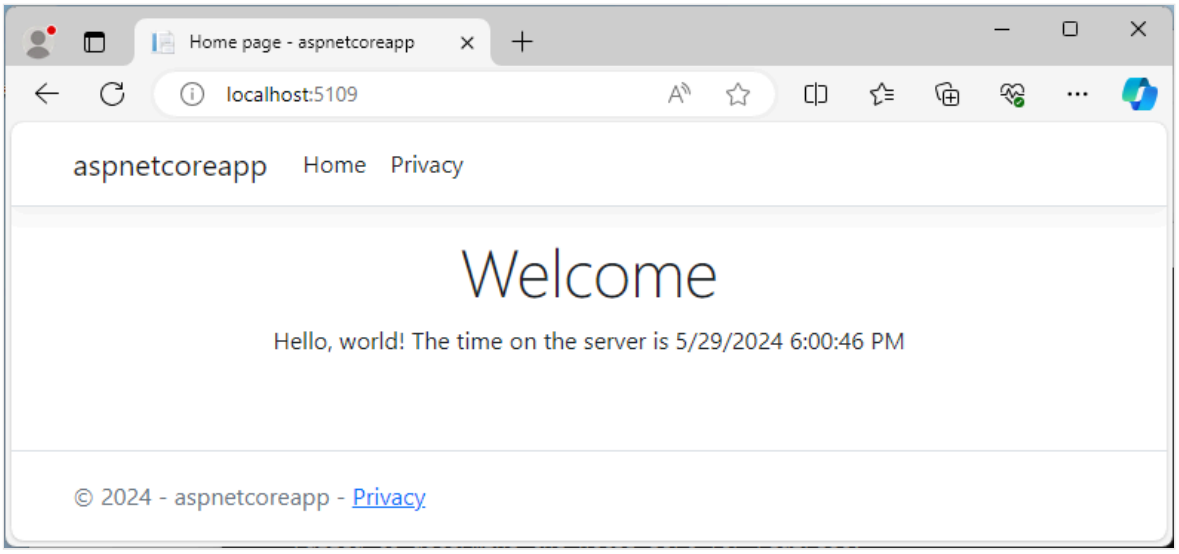
```
Building...
info: Microsoft.Hosting.Lifetime[14]
      Now listening on: http://localhost:5109
info: Microsoft.Hosting.Lifetime[0]
      Application started. Press Ctrl+C to shut down.
info: Microsoft.Hosting.Lifetime[0]
      Hosting environment: Development
info: Microsoft.Hosting.Lifetime[0]
      Content root path: C:\aspnetcoreapp
```

Open a browser and go to the URL shown in the output. In this example, the URL is `http://localhost:5109`.

The browser shows the home page.

Edit a Razor page

Change the home page:



- In the command shell, press Ctrl+C (Cmd+C in macOS) to exit the program.
- Open `Pages/Index.cshtml` in a text editor.
- Replace the line that begins with "Learn about" with the following highlighted markup and code:

CSHTML

```
@page
@model IndexModel
@{
    ViewData["Title"] = "Home page";
}

<div class="text-center">
    <h1 class="display-4">Welcome</h1>
    <p>Hello, world! The time on the server is @DateTime.Now</p>
</div>
```

- Save your changes.
- In the command shell run the `dotnet run` command again.
- In the browser, refresh the page and verify the changes are displayed.

Next steps

In this tutorial, you learned how to:

- ✓ Create a web app project.
- ✓ Run the project.
- ✓ Make a change.

To learn more about ASP.NET Core, see the following:

Overview of ASP.NET Core

What's new in ASP.NET Core 9.0

Article • 11/05/2024

This article highlights the most significant changes in ASP.NET Core 9.0 with links to relevant documentation.

This article has been updated for .NET 9 Release Candidate 2.

Blazor

This section describes new features for Blazor.

.NET MAUI Blazor Hybrid and Web App solution template

A new solution template makes it easier to create .NET MAUI native and Blazor web client apps that share the same UI. This template shows how to create client apps that maximize code reuse and target Android, iOS, Mac, Windows, and Web.

Key features of this template include:

- The ability to choose a Blazor interactive render mode for the web app.
- Automatic creation of the appropriate projects, including a Blazor Web App (global Interactive Auto rendering) and a .NET MAUI Blazor Hybrid app.
- The created projects use a shared Razor class library (RCL) to maintain the UI's Razor components.
- Sample code is included that demonstrates how to use dependency injection to provide different interface implementations for the Blazor Hybrid app and the Blazor Web App.

To get started, install the .NET 9 SDK and install the .NET MAUI workload, which contains the template:

.NET CLI

```
dotnet workload install maui
```

Create a solution from the project template in a command shell using the following command:

.NET CLI

```
dotnet new maui-blazor-web
```

The template is also available in Visual Studio.

> **Note**
>
> Currently, an exception occurs if Blazor rendering modes are defined at the per-page/component level. For more information, see BlazorWebView needs a way to enable overriding ResolveComponentForRenderMode (dotnet/aspnetcore #51235).

For more information, see Build a .NET MAUI Blazor Hybrid app with a Blazor Web App.

Static asset delivery optimization

Map Static Assets routing endpoint conventions (MapStaticAssets) is a new feature that helps optimize the delivery of static assets in any ASP.NET Core app, including Blazor apps.

For more information, see the following resources:

- The Optimize static web asset delivery section of this article.
- ASP.NET Core Blazor static files.

Detect rendering location, interactivity, and assigned render mode at runtime

We've introduced a new API designed to simplify the process of querying component states at runtime. This API provides the following capabilities:

- **Determine the current execution location of the component**: This can be particularly useful for debugging and optimizing component performance.
- **Check if the component is running in an interactive environment**: This can be helpful for components that have different behaviors based on the interactivity of their environment.
- **Retrieve the assigned render mode for the component**: Understanding the render mode can help in optimizing the rendering process and improving the overall performance of a component.

For more information, see ASP.NET Core Blazor render modes.

Improved server-side reconnection experience:

The following enhancements have been made to the default server-side reconnection experience:

- When the user navigates back to an app with a disconnected circuit, reconnection is attempted immediately rather than waiting for the duration of the next reconnect interval. This improves the user experience when navigating to an app in a browser tab that has gone to sleep.
- When a reconnection attempt reaches the server but the server has already released the circuit, a page refresh occurs automatically. This prevents the user from having to manually refresh the page if it's likely going to result in a successful reconnection.
- Reconnect timing uses a computed backoff strategy. By default, the first several reconnection attempts occur in rapid succession without a retry interval before computed delays are introduced between attempts. You can customize the retry interval behavior by specifying a function to compute the retry interval, as the following exponential backoff example demonstrates:

  JavaScript

  ```
  Blazor.start({
    circuit: {
      reconnectionOptions: {
        retryIntervalMilliseconds: (previousAttempts, maxRetries) =>
          previousAttempts >= maxRetries ? null : previousAttempts * 1000
      },
    },
  });
  ```

- The styling of the default reconnect UI has been modernized.

For more information, see ASP.NET Core Blazor SignalR guidance.

Simplified authentication state serialization for Blazor Web Apps

New APIs make it easier to add authentication to an existing Blazor Web App. When you create a new Blazor Web App with authentication using **Individual Accounts** and you enable WebAssembly-based interactivity, the project includes a custom AuthenticationStateProvider in both the server and client projects.

These providers flow the user's authentication state to the browser. Authenticating on the server rather than the client allows the app to access authentication state during prerendering and before the .NET WebAssembly runtime is initialized.

The custom AuthenticationStateProvider implementations use the Persistent Component State service (PersistentComponentState) to serialize the authentication state into HTML comments and read it back from WebAssembly to create a new AuthenticationState instance.

This works well if you've started from the Blazor Web App project template and selected the **Individual Accounts** option, but it's a lot of code to implement yourself or copy if you're trying to add authentication to an existing project. There are now APIs, which are now part of the Blazor Web App project template, that can be called in the server and client projects to add this functionality:

- `AddAuthenticationStateSerialization`: Adds the necessary services to serialize the authentication state on the server.
- `AddAuthenticationStateDeserialization`: Adds the necessary services to deserialize the authentication state in the browser.

By default, the API only serializes the server-side name and role claims for access in the browser. An option can be passed to `AddAuthenticationStateSerialization` to include all claims.

For more information, see the following sections of Secure ASP.NET Core server-side Blazor apps:

- Blazor Identity UI (Individual Accounts)
- Manage authentication state in Blazor Web Apps

Add static server-side rendering (SSR) pages to a globally-interactive Blazor Web App

With the release of .NET 9, it's now simpler to add static SSR pages to apps that adopt global interactivity.

This approach is only useful when the app has specific pages that can't work with interactive Server or WebAssembly rendering. For example, adopt this approach for pages that depend on reading/writing HTTP cookies and can only work in a request/response cycle instead of interactive rendering. For pages that work with interactive rendering, you shouldn't force them to use static SSR rendering, as it's less efficient and less responsive for the end user.

Mark any Razor component page with the new `[ExcludeFromInteractiveRouting]` attribute assigned with the `@attribute` Razor directive:

razor

```
@attribute [ExcludeFromInteractiveRouting]
```

Applying the attribute causes navigation to the page to exit from interactive routing. Inbound navigation is forced to perform a full-page reload instead resolving the page via interactive routing. The full-page reload forces the top-level root component, typically the `App` component (`App.razor`), to rerender from the server, allowing the app to switch to a different top-level render mode.

The `HttpContext.AcceptsInteractiveRouting` extension method allows the component to detect whether `[ExcludeFromInteractiveRouting]` is applied to the current page.

In the `App` component, use the pattern in the following example:

- Pages that aren't annotated with `[ExcludeFromInteractiveRouting]` default to the `InteractiveServer` render mode with global interactivity. You can replace `InteractiveServer` with `InteractiveWebAssembly` or `InteractiveAuto` to specify a different default global render mode.
- Pages annotated with `[ExcludeFromInteractiveRouting]` adopt static SSR (`PageRenderMode` is assigned `null`).

razor

```
<!DOCTYPE html>
<html>
<head>
    ...
    <HeadOutlet @rendermode="@PageRenderMode" />
</head>
<body>
    <Routes @rendermode="@PageRenderMode" />
    ...
</body>
</html>

@code {
    [CascadingParameter]
    private HttpContext HttpContext { get; set; } = default!;

    private IComponentRenderMode? PageRenderMode
        => HttpContext.AcceptsInteractiveRouting() ? InteractiveServer :
```

```
null;
}
```

An alternative to using the `HttpContext.AcceptsInteractiveRouting` extension method is to read endpoint metadata manually using `HttpContext.GetEndpoint()?.Metadata`.

This feature is covered by the reference documentation in ASP.NET Core Blazor render modes.

Constructor injection

Razor components support constructor injection.

In the following example, the partial (code-behind) class injects the `NavigationManager` service using a primary constructor:

C#

```
public partial class ConstructorInjection(NavigationManager navigation)
{
    private void HandleClick()
    {
        navigation.NavigateTo("/counter");
    }
}
```

For more information, see ASP.NET Core Blazor dependency injection.

Websocket compression for Interactive Server components

By default, Interactive Server components enable compression for WebSocket connections and set a `frame-ancestors` Content Security Policy (CSP) directive set to `'self'`, which only permits embedding the app in an `<iframe>` of the origin from which the app is served when compression is enabled or when a configuration for the WebSocket context is provided.

Compression can be disabled by setting `ConfigureWebSocketOptions` to `null`, which reduces the vulnerability of the app to attack but may result in reduced performance:

C#

```
.AddInteractiveServerRenderMode(o => o.ConfigureWebSocketOptions = null)
```

Configure a stricter `frame-ancestors` CSP with a value of `'none'` (single quotes required), which allows WebSocket compression but prevents browsers from embedding the app into any `<iframe>`:

```
C#

.AddInteractiveServerRenderMode(o => o.ContentSecurityFrameAncestorsPolicy =
"'none'")
```

For more information, see the following resources:

- ASP.NET Core Blazor SignalR guidance
- Threat mitigation guidance for ASP.NET Core Blazor interactive server-side rendering

Handle keyboard composition events in Blazor

The new `KeyboardEventArgs.IsComposing` property indicates if the keyboard event is part of a composition session. Tracking the composition state of keyboard events is crucial for handling international character input methods.

Added `OverscanCount` parameter to `QuickGrid`

The QuickGrid component now exposes an `OverscanCount` property that specifies how many additional rows are rendered before and after the visible region when virtualization is enabled.

The default `OverscanCount` is 3. The following example increases the `OverscanCount` to 4:

```
razor

<QuickGrid ItemsProvider="itemsProvider" Virtualize="true"
OverscanCount="4">
    ...
</QuickGrid>
```

`InputNumber` component supports the `type="range"` attribute

The InputNumber<TValue> component now supports the type="range" attribute, which creates a range input that supports model binding and form validation, typically rendered as a slider or dial control rather than a text box:

razor

```razor
<EditForm Model="Model" OnSubmit="Submit" FormName="EngineForm">
    <div>
        <label>
            Nacelle Count (2-6):
            <InputNumber @bind-Value="Model!.NacelleCount" max="6" min="2"
                step="1" type="range" />
        </label>
    </div>
    <div>
        <button type="submit">Submit</button>
    </div>
</EditForm>

@code {
    [SupplyParameterFromForm]
    private EngineSpecifications? Model { get; set; }

    protected override void OnInitialized() => Model ??= new();

    private void Submit() {}

    public class EngineSpecifications
    {
        [Required, Range(minimum: 2, maximum: 6)]
        public int NacelleCount { get; set; }
    }
}
```

Multiple Blazor Web Apps per server project

Support for multiple Blazor Web Apps per server project will be considered for .NET 10 (November, 2025).

For more information, see Support for multiple Blazor Web apps per server project (dotnet/aspnetcore #52216).

SignalR

This section describes new features for SignalR.

Polymorphic type support in SignalR Hubs

Hub methods can now accept a base class instead of the derived class to enable polymorphic scenarios. The base type needs to be annotated to allow polymorphism.

C#

```
public class MyHub : Hub
{
    public void Method(JsonPerson person)
    {
        if (person is JsonPersonExtended)
        {
        }
        else if (person is JsonPersonExtended2)
        {
        }
        else
        {
        }
    }
}

[JsonPolymorphic]
[JsonDerivedType(typeof(JsonPersonExtended), nameof(JsonPersonExtended))]
[JsonDerivedType(typeof(JsonPersonExtended2), nameof(JsonPersonExtended2))]
private class JsonPerson
{
    public string Name { get; set; }
    public Person Child { get; set; }
    public Person Parent { get; set; }
}

private class JsonPersonExtended : JsonPerson
{
    public int Age { get; set; }
}

private class JsonPersonExtended2 : JsonPerson
{
    public string Location { get; set; }
}
```

Improved Activities for SignalR

SignalR now has an ActivitySource named `Microsoft.AspNetCore.SignalR.Server` that emits events for hub method calls:

- Every method is its own activity, so anything that emits an activity during the hub method call is under the hub method activity.
- Hub method activities don't have a parent. This means they are not bundled under the long-running SignalR connection.

The following example uses the .NET Aspire dashboard and the OpenTelemetry packages:

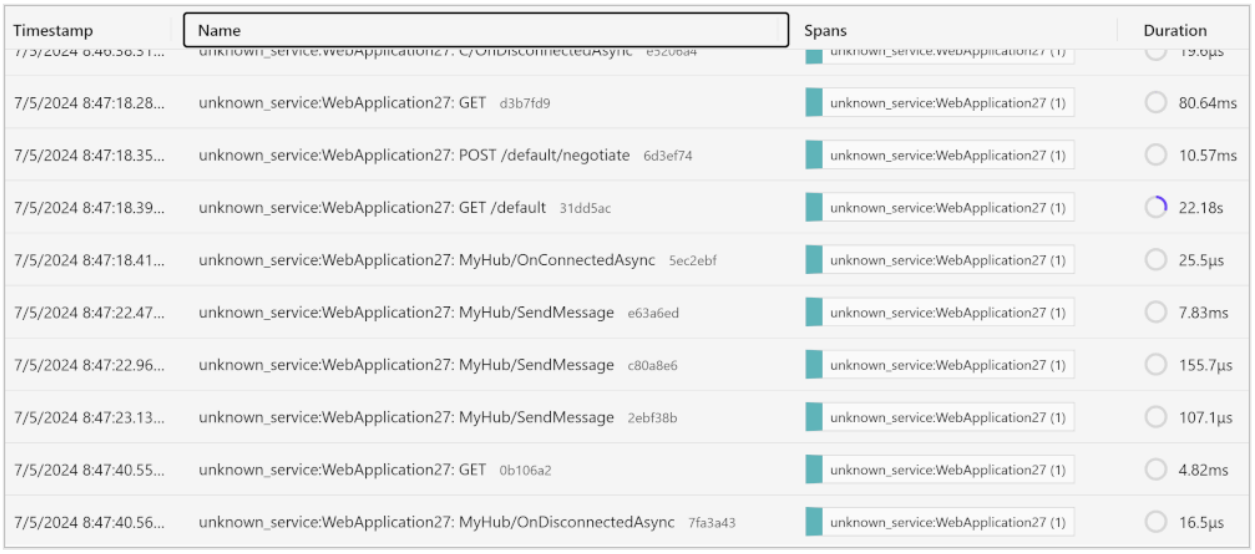
XML

```xml
<PackageReference Include="OpenTelemetry.Exporter.OpenTelemetryProtocol"
Version="1.9.0" />
<PackageReference Include="OpenTelemetry.Extensions.Hosting" Version="1.9.0"
/>
<PackageReference Include="OpenTelemetry.Instrumentation.AspNetCore"
Version="1.9.0" />
```

Add the following startup code to the `Program.cs` file:

C#

```csharp
// Set OTEL_EXPORTER_OTLP_ENDPOINT environment variable depending on where
your OTEL endpoint is
var builder = WebApplication.CreateBuilder(args);



builder.Services.AddRazorPages();
builder.Services.AddSignalR();

builder.Services.AddOpenTelemetry()
    .WithTracing(tracing =>
    {
        if (builder.Environment.IsDevelopment())
        {
            // We want to view all traces in development
            tracing.SetSampler(new AlwaysOnSampler());
        }

        tracing.AddAspNetCoreInstrumentation();
        tracing.AddSource("Microsoft.AspNetCore.SignalR.Server");
    });

builder.Services.ConfigureOpenTelemetryTracerProvider(tracing =>
tracing.AddOtlpExporter());
```

The following is example output from the Aspire Dashboard:

SignalR supports trimming and Native AOT

Continuing the Native AOT journey started in .NET 8, we have enabled trimming and native ahead-of-time (AOT) compilation support for both SignalR client and server scenarios. You can now take advantage of the performance benefits of using Native AOT in applications that use SignalR for real-time web communications.

Getting started

Install the latest .NET 9 SDK.

Create a solution from the `webapiaot` template in a command shell using the following command:

.NET CLI

```
dotnet new webapiaot -o SignalRChatAOTExample
```

Replace the contents of the `Program.cs` file with the following SignalR code:

C#

```
using Microsoft.AspNetCore.SignalR;
using System.Text.Json.Serialization;

var builder = WebApplication.CreateSlimBuilder(args);

builder.Services.AddSignalR();
builder.Services.Configure<JsonHubProtocolOptions>(o =>
{
    o.PayloadSerializerOptions.TypeInfoResolverChain.Insert(0,
AppJsonSerializerContext.Default);
```

```
});

var app = builder.Build();

app.MapHub<ChatHub>("/chatHub");
app.MapGet("/", () => Results.Content("""
<!DOCTYPE html>
<html>
<head>
    <title>SignalR Chat</title>
</head>
<body>
    <input id="userInput" placeholder="Enter your name" />
    <input id="messageInput" placeholder="Type a message" />
    <button onclick="sendMessage()">Send</button>
    <ul id="messages"></ul>

    <script src="https://cdnjs.cloudflare.com/ajax/libs/microsoft-
signalr/8.0.7/signalr.min.js"></script>
    <script>
        const connection = new signalR.HubConnectionBuilder()
            .withUrl("/chatHub")
            .build();

        connection.on("ReceiveMessage", (user, message) => {
            const li = document.createElement("li");
            li.textContent = `${user}: ${message}`;
            document.getElementById("messages").appendChild(li);
        });

        async function sendMessage() {
            const user = document.getElementById("userInput").value;
            const message = document.getElementById("messageInput").value;
            await connection.invoke("SendMessage", user, message);
        }

        connection.start().catch(err => console.error(err));
    </script>
</body>
</html>
""", "text/html"));

app.Run();

[JsonSerializable(typeof(string))]
internal partial class AppJsonSerializerContext : JsonSerializerContext { }

public class ChatHub : Hub
{
    public async Task SendMessage(string user, string message)
    {
        await Clients.All.SendAsync("ReceiveMessage", user, message);
    }
}
```

The preceding example produces a native Windows executable of 10 MB and a Linux executable of 10.9 MB.

Limitations

- Only the JSON protocol is currently supported:
  - As shown in the preceding code, apps that use JSON serialization and Native AOT must use the `System.Text.Json` Source Generator.
  - This follows the same approach as minimal APIs.
- On the SignalR server, Hub method parameters of type `IAsyncEnumerable<T>` and `ChannelReader<T>` where `T` is a ValueType (`struct`) aren't supported. Using these types results in a runtime exception at startup in development and in the published app. For more information, see SignalR: Using IAsyncEnumerable<T> and ChannelReader<T> with ValueTypes in native AOT (dotnet/aspnetcore #56179).
- Strongly typed hubs aren't supported with Native AOT (`PublishAot`). Using strongly typed hubs with Native AOT will result in warnings during build and publish, and a runtime exception. Using strongly typed hubs with trimming (`PublishedTrimmed`) is supported.
- Only `Task`, `Task<T>`, `ValueTask`, or `ValueTask<T>` are supported for async return types.

Minimal APIs

This section describes new features for minimal APIs.

Added `InternalServerError` and `InternalServerError<TValue>` to `TypedResults`

The TypedResults class is a helpful vehicle for returning strongly-typed HTTP status code-based responses from a minimal API. `TypedResults` now includes factory methods and types for returning "500 Internal Server Error" responses from endpoints. Here's an example that returns a 500 response:

C#

```
var app = WebApplication.Create();

app.MapGet("/", () => TypedResults.InternalServerError("Something went
wrong!"));
```

```
app.Run();
```

Call `ProducesProblem` and `ProducesValidationProblem` on route groups

The `ProducesProblem` and `ProducesValidationProblem` extension methods have been updated to support their use on route groups. These methods indicate that all endpoints in a route group can return `ProblemDetails` or `ValidationProblemDetails` responses for the purposes of OpenAPI metadata.

C#

```
var app = WebApplication.Create();

var todos = app.MapGroup("/todos")
    .ProducesProblem();

todos.MapGet("/", () => new Todo(1, "Create sample app", false));
todos.MapPost("/", (Todo todo) => Results.Ok(todo));

app.Run();

record Todo(int Id, string Title, boolean IsCompleted);
```

`Problem` and `ValidationProblem` result types support construction with `IEnumerable<KeyValuePair<string, object?>>` values

Prior to .NET 9, constructing Problem and ValidationProblem result types in minimal APIs required that the `errors` and `extensions` properties be initialized with an implementation of `IDictionary<string, object?>`. In this release, these construction APIs support overloads that consume `IEnumerable<KeyValuePair<string, object?>>`.

C#

```
var app = WebApplication.Create();

app.MapGet("/", () =>
{
    var extensions = new List<KeyValuePair<string, object?>> { new("test",
"value") };
    return TypedResults.Problem("This is an error with extensions",
                                                    extensions:
```

```
extensions);
});
```

Thanks to GitHub user joegoldman2 for this contribution!

OpenAPI

This section describes new features for OpenAPI

Built-in support for OpenAPI document generation

The OpenAPI specification is a standard for describing HTTP APIs. The standard allows developers to define the shape of APIs that can be plugged into client generators, server generators, testing tools, documentation, and more. In .NET 9, ASP.NET Core provides built-in support for generating OpenAPI documents representing controller-based or minimal APIs via the Microsoft.AspNetCore.OpenApi package.

The following highlighted code calls:

- `AddOpenApi` to register the required dependencies into the app's DI container.
- `MapOpenApi` to register the required OpenAPI endpoints in the app's routes.

C#

```
var builder = WebApplication.CreateBuilder();

builder.Services.AddOpenApi();

var app = builder.Build();

app.MapOpenApi();

app.MapGet("/hello/{name}", (string name) => $"Hello {name}"!);

app.Run();
```

Install the Microsoft.AspNetCore.OpenApi package in the project using the following command:

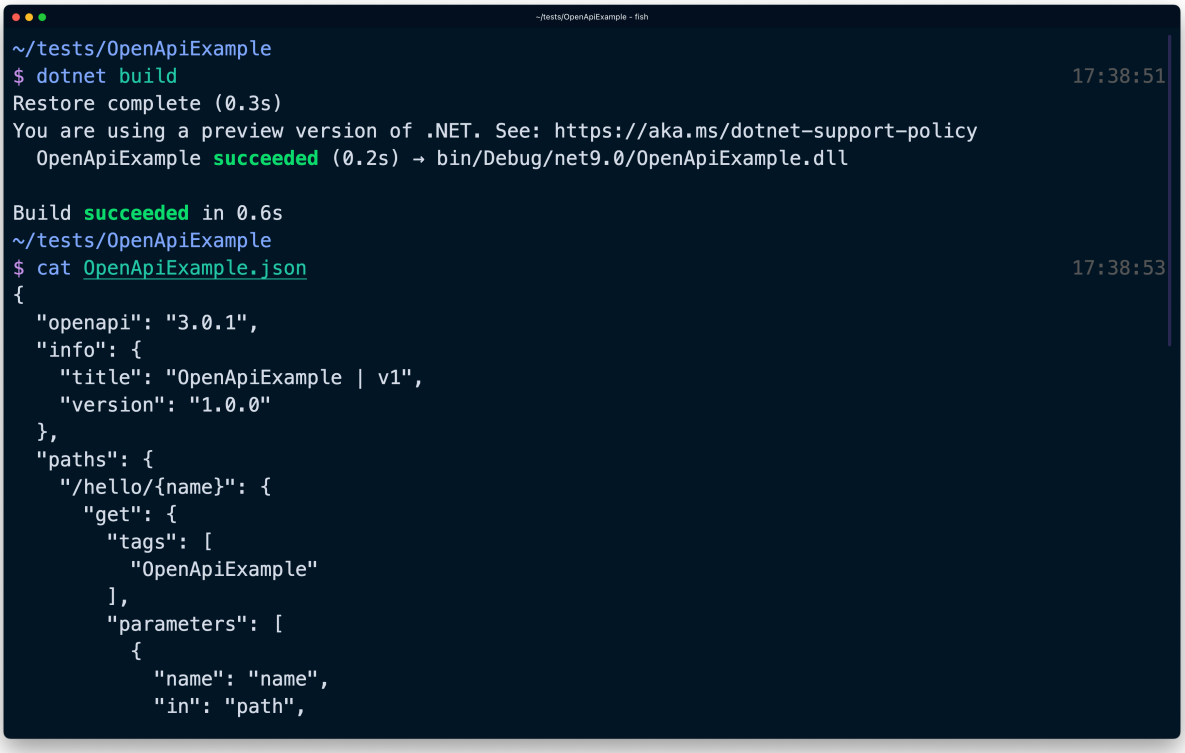
.NET CLI

```
dotnet add package Microsoft.AspNetCore.OpenApi --prerelease
```

Run the app and navigate to `openapi/v1.json` to view the generated OpenAPI document:

OpenAPI documents can also be generated at build-time by adding the Microsoft.Extensions.ApiDescription.Server package:

.NET CLI



```
dotnet add package Microsoft.Extensions.ApiDescription.Server --prerelease
```

To modify the location of the emitted OpenAPI documents, set the target path in the OpenApiDocumentsDirectory property in the app's project file:

XML

```
<PropertyGroup>
  <OpenApiDocumentsDirectory>$(MSBuildProjectDirectory)
</OpenApiDocumentsDirectory>
</PropertyGroup>
```

Run `dotnet build` and inspect the generated JSON file in the project directory.

ASP.NET Core's built-in OpenAPI document generation provides support for various customizations and options. It provides document, operation, and schema transformers and has the ability to manage multiple OpenAPI documents for the same application.

To learn more about ASP.NET Core's new OpenAPI document capabilities, see the new Microsoft.AspNetCore.OpenApi docs.

Microsoft.AspNetCore.OpenApi supports trimming and Native AOT

The new built-in OpenAPI support in ASP.NET Core now also supports trimming and Native AOT.

Get started

Create a new ASP.NET Core Web API (Native AOT) project.

```
Console

dotnet new webapiaot
```

Add the Microsoft.AspNetCore.OpenAPI package.

```
Console

dotnet add package Microsoft.AspNetCore.OpenApi --prerelease
```

For this preview, you also need to add the latest Microsoft.OpenAPI package to avoid trimming warnings.

```
Console

dotnet add package Microsoft.OpenApi
```

Update *Program.cs* to enable generating OpenAPI documents.

```
diff

+ builder.Services.AddOpenApi();

var app = builder.Build();

+ app.MapOpenApi();
```

Publish the app.

```
Console

dotnet publish
```

The app publishes using Native AOT without warnings.

Authentication and authorization

This section describes new features for authentication and authorization.

OpenIdConnectHandler adds support for Pushed Authorization Requests (PAR)

We'd like to thank Joe DeCock from Duende Software for adding Pushed Authorization Requests (PAR) to ASP.NET Core's OpenIdConnectHandler. Joe described the background and motivation for enabling PAR in his API proposal as follows:

> Pushed Authorization Requests (PAR) is a relatively new OAuth standard that improves the security of OAuth and OIDC flows by moving authorization parameters from the front channel to the back channel. Thats is, moving authorization parameters from redirect URLs in the browser to direct machine to machine http calls on the back end.
>
> This prevents a cyberattacker in the browser from:
>
> - Seeing authorization parameters, which could leak PII.
> - Tampering with those parameters. For example, the cyberattacker could change the scope of access being requested.
>
> Pushing the authorization parameters also keeps request URLs short. Authorize parameters can get very long when using more complex OAuth and OIDC features such as Rich Authorization Requests. URLs that are long cause issues in many browsers and networking infrastructures.
>
> The use of PAR is encouraged by the FAPI working group within the OpenID Foundation. For example, the FAPI2.0 Security Profile requires the use of PAR. This security profile is used by many of the groups working on open banking (primarily in Europe), in health care, and in other industries with high security requirements.
>
> PAR is supported by a number of identity providers, including
>
> - Duende IdentityServer
> - Curity
> - Keycloak
> - Authlete

For .NET 9, we have decided to enable PAR by default if the identity provider's discovery document advertises support for PAR, since it should provide enhanced security for providers that support it. The identity provider's discovery document is usually found at

`.well-known/openid-configuration`. If this causes problems, you can disable PAR via OpenIdConnectOptions.PushedAuthorizationBehavior as follows:

```
C#

builder.Services
    .AddAuthentication(options =>
    {
        options.DefaultScheme =
CookieAuthenticationDefaults.AuthenticationScheme;
        options.DefaultChallengeScheme =
OpenIdConnectDefaults.AuthenticationScheme;
    })
    .AddCookie()
    .AddOpenIdConnect("oidc", oidcOptions =>
    {
        // Other provider-specific configuration goes here.

        // The default value is PushedAuthorizationBehavior.UseIfAvailable.

        // 'OpenIdConnectOptions' does not contain a definition for
'PushedAuthorizationBehavior'
        // and no accessible extension method 'PushedAuthorizationBehavior'
accepting a first argument
        // of type 'OpenIdConnectOptions' could be found
        oidcOptions.PushedAuthorizationBehavior =
PushedAuthorizationBehavior.Disable;
    });
```

To ensure that authentication only succeeds if PAR is used, use PushedAuthorizationBehavior.Require instead. This change also introduces a new OnPushAuthorization event to OpenIdConnectEvents which can be used customize the pushed authorization request or handle it manually. See the API proposal for more details.

OIDC and OAuth Parameter Customization

The OAuth and OIDC authentication handlers now have an `AdditionalAuthorizationParameters` option to make it easier to customize authorization message parameters that are usually included as part of the redirect query string. In .NET 8 and earlier, this requires a custom OnRedirectToIdentityProvider callback or overridden BuildChallengeUrl method in a custom handler. Here's an example of .NET 8 code:

```
C#
```

```
builder.Services.AddAuthentication().AddOpenIdConnect(options =>
{
    options.Events.OnRedirectToIdentityProvider = context =>
    {
        context.ProtocolMessage.SetParameter("prompt", "login");
        context.ProtocolMessage.SetParameter("audience",
"https://api.example.com");
        return Task.CompletedTask;
    };
});
```

The preceding example can now be simplified to the following code:

C#

```
builder.Services.AddAuthentication().AddOpenIdConnect(options =>
{
    options.AdditionalAuthorizationParameters.Add("prompt", "login");
    options.AdditionalAuthorizationParameters.Add("audience",
"https://api.example.com");
});
```

Configure HTTP.sys extended authentication flags

You can now configure the HTTP_AUTH_EX_FLAG_ENABLE_KERBEROS_CREDENTIAL_CACHING and HTTP_AUTH_EX_FLAG_CAPTURE_CREDENTIAL HTTP.sys flags by using the new `EnableKerberosCredentialCaching` and `CaptureCredentials` properties on the HTTP.sys AuthenticationManager to optimize how Windows authentication is handled. For example:

C#

```
webBuilder.UseHttpSys(options =>
{
    options.Authentication.Schemes = AuthenticationSchemes.Negotiate;
    options.Authentication.EnableKerberosCredentialCaching = true;
    options.Authentication.CaptureCredentials = true;
});
```

Miscellaneous

The following sections describe miscellaneous new features.

New `HybridCache` library

> **Important**
>
> `HybridCache` is currently still in preview but will be fully released *after* .NET 9.0 in a future minor release of .NET Extensions.

The HybridCache API bridges some gaps in the existing IDistributedCache and IMemoryCache APIs. It also adds new capabilities, such as:

- **"Stampede" protection** to prevent parallel fetches of the same work.
- Configurable serialization.

`HybridCache` is designed to be a drop-in replacement for existing `IDistributedCache` and `IMemoryCache` usage, and it provides a simple API for adding new caching code. It provides a unified API for both in-process and out-of-process caching.

To see how the `HybridCache` API is simplified, compare it to code that uses `IDistributedCache`. Here's an example of what using `IDistributedCache` looks like:

C#

```
public class SomeService(IDistributedCache cache)
{
    public async Task<SomeInformation> GetSomeInformationAsync
        (string name, int id, CancellationToken token = default)
    {
        var key = $"someinfo:{name}:{id}"; // Unique key for this
combination.
        var bytes = await cache.GetAsync(key, token); // Try to get from
cache.
        SomeInformation info;
        if (bytes is null)
        {
            // Cache miss; get the data from the real source.
            info = await SomeExpensiveOperationAsync(name, id, token);

            // Serialize and cache it.
            bytes = SomeSerializer.Serialize(info);
            await cache.SetAsync(key, bytes, token);
        }
        else
        {
            // Cache hit; deserialize it.
            info = SomeSerializer.Deserialize<SomeInformation>(bytes);
        }
        return info;
    }
```

```
    // This is the work we're trying to cache.
    private async Task<SomeInformation> SomeExpensiveOperationAsync(string
name, int id,
        CancellationToken token = default)
    { /* ... */ }
}
```

That's a lot of work to get right each time, including things like serialization. And in the cache miss scenario, you could end up with multiple concurrent threads, all getting a cache miss, all fetching the underlying data, all serializing it, and all sending that data to the cache.

To simplify and improve this code with `HybridCache`, we first need to add the new library `Microsoft.Extensions.Caching.Hybrid`:

XML

```
<PackageReference Include="Microsoft.Extensions.Caching.Hybrid"
Version="9.0.0" />
```

Register the `HybridCache` service, like you would register an `IDistributedCache` implementation:

C#

```
builder.Services.AddHybridCache(); // Not shown: optional configuration API.
```

Now most caching concerns can be offloaded to `HybridCache`:

C#

```
public class SomeService(HybridCache cache)
{
    public async Task<SomeInformation> GetSomeInformationAsync
        (string name, int id, CancellationToken token = default)
    {
        return await cache.GetOrCreateAsync(
            $"someinfo:{name}:{id}", // Unique key for this combination.
            async cancel => await SomeExpensiveOperationAsync(name, id,
cancel),
            token: token
        );
    }
}
```

We provide a concrete implementation of the `HybridCache` abstract class via dependency injection, but it's intended that developers can provide custom implementations of the API. The `HybridCache` implementation deals with everything related to caching, including concurrent operation handling. The `cancel` token here represents the combined cancellation of *all* concurrent callers—not just the cancellation of the caller we can see (that is, `token`).

High throughput scenarios can be further optimized by using the `TState` pattern, to avoid some overhead from captured variables and per-instance callbacks:

C#

```
public class SomeService(HybridCache cache)
{
    public async Task<SomeInformation> GetSomeInformationAsync(string name,
int id, CancellationToken token = default)
    {
        return await cache.GetOrCreateAsync(
            $"someinfo:{name}:{id}", // unique key for this combination
            (name, id), // all of the state we need for the final call, if
needed
            static async (state, token) =>
                await SomeExpensiveOperationAsync(state.name, state.id,
token),
            token: token
        );
    }
}
```

`HybridCache` uses the configured `IDistributedCache` implementation, if any, for secondary out-of-process caching, for example, using Redis. But even without an `IDistributedCache`, the `HybridCache` service will still provide in-process caching and "stampede" protection.

A note on object reuse

In typical existing code that uses `IDistributedCache`, every retrieval of an object from the cache results in deserialization. This behavior means that each concurrent caller gets a separate instance of the object, which cannot interact with other instances. The result is thread safety, as there's no risk of concurrent modifications to the same object instance.

Because a lot of `HybridCache` usage will be adapted from existing `IDistributedCache` code, `HybridCache` preserves this behavior by default to avoid introducing concurrency bugs. However, a given use case is inherently thread-safe:

- If the types being cached are immutable.
- If the code doesn't modify them.

In such cases, inform `HybridCache` that it's safe to reuse instances by:

- Marking the type as `sealed`. The `sealed` keyword in C# means that the class can't be inherited.
- Applying the `[ImmutableObject(true)]` attribute to it. The `[ImmutableObject(true)]` attribute indicates that the object's state can't be changed after it's created.

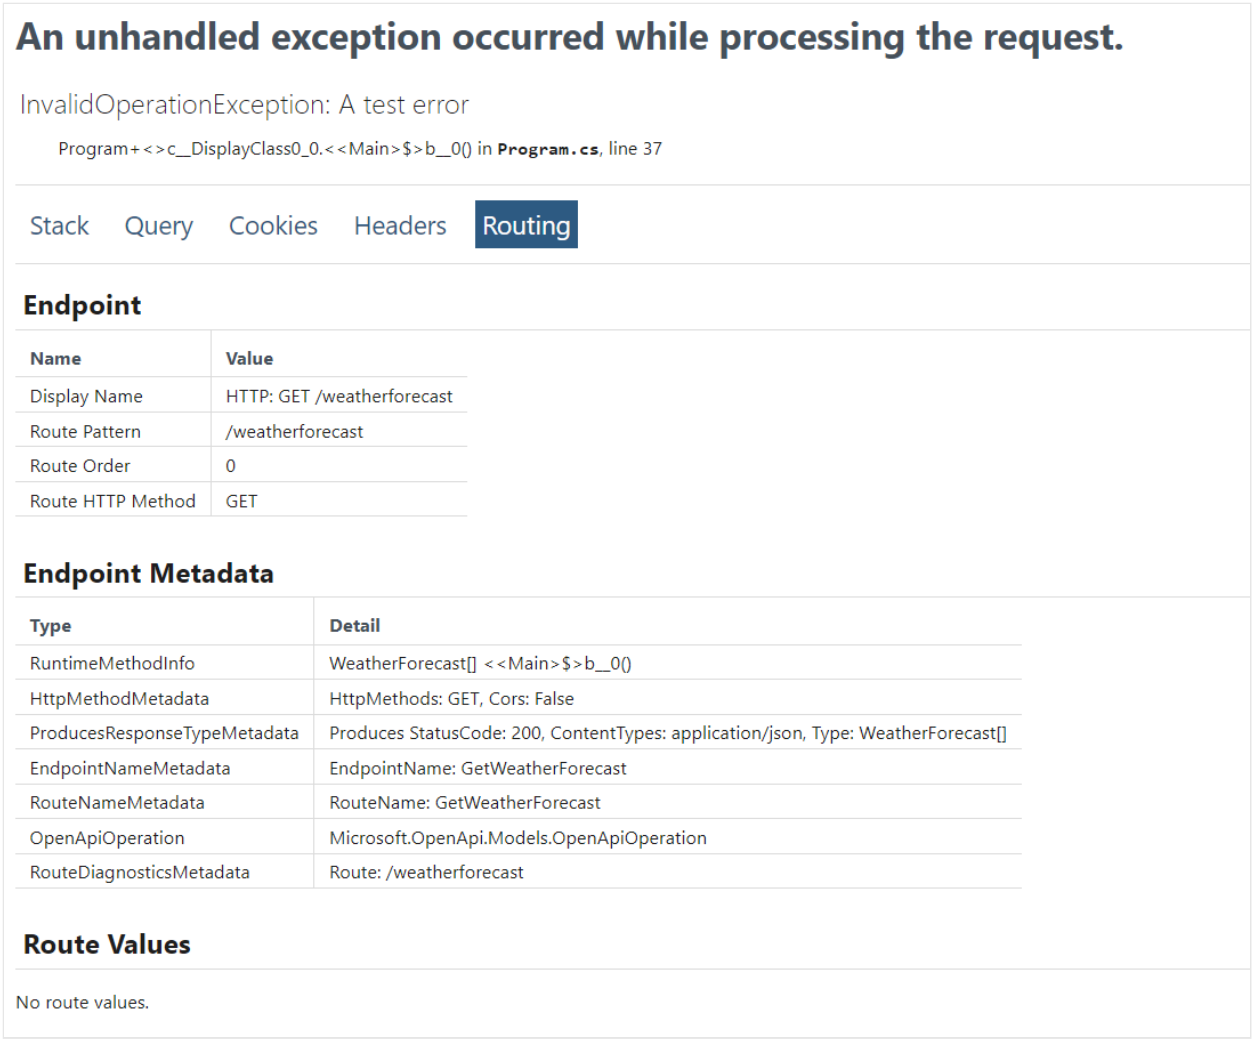
By reusing instances, `HybridCache` can reduce the overhead of CPU and object allocations associated with per-call deserialization. This can lead to performance improvements in scenarios where the cached objects are large or accessed frequently.

Other `HybridCache` features

Like `IDistributedCache`, `HybridCache` supports removal by key with a `RemoveKeyAsync` method.

`HybridCache` also provides optional APIs for `IDistributedCache` implementations, to avoid `byte[]` allocations. This feature is implemented by the preview versions of the `Microsoft.Extensions.Caching.StackExchangeRedis` and `Microsoft.Extensions.Caching.SqlServer` packages.

Serialization is configured as part of registering the service, with support for type-specific and generalized serializers via the `WithSerializer` and `.WithSerializerFactory` methods, chained from the `AddHybridCache` call. By default, the library handles `string` and `byte[]` internally, and uses `System.Text.Json` for everything else, but you can use protobuf, xml, or anything else.

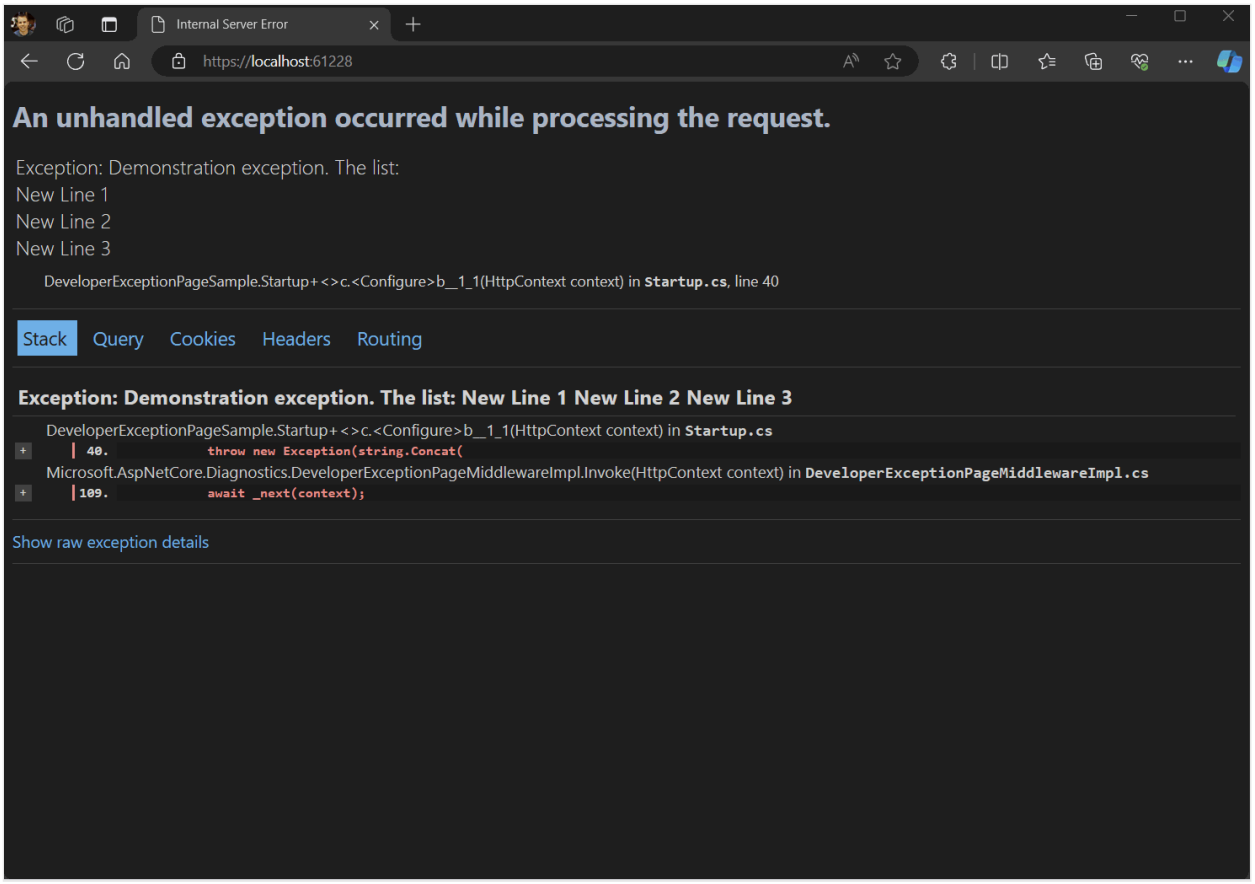


`HybridCache` supports older .NET runtimes, down to .NET Framework 4.7.2 and .NET Standard 2.0.

For more information about `HybridCache`, see HybridCache library in ASP.NET Core

Developer exception page improvements

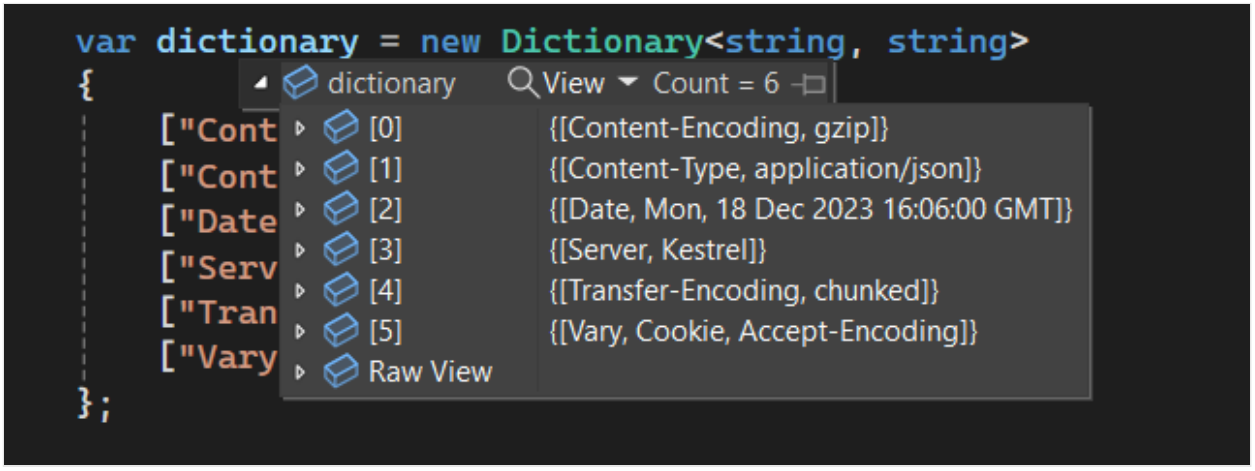
The ASP.NET Core developer exception page is displayed when an app throws an unhandled exception during development. The developer exception page provides detailed information about the exception and request.



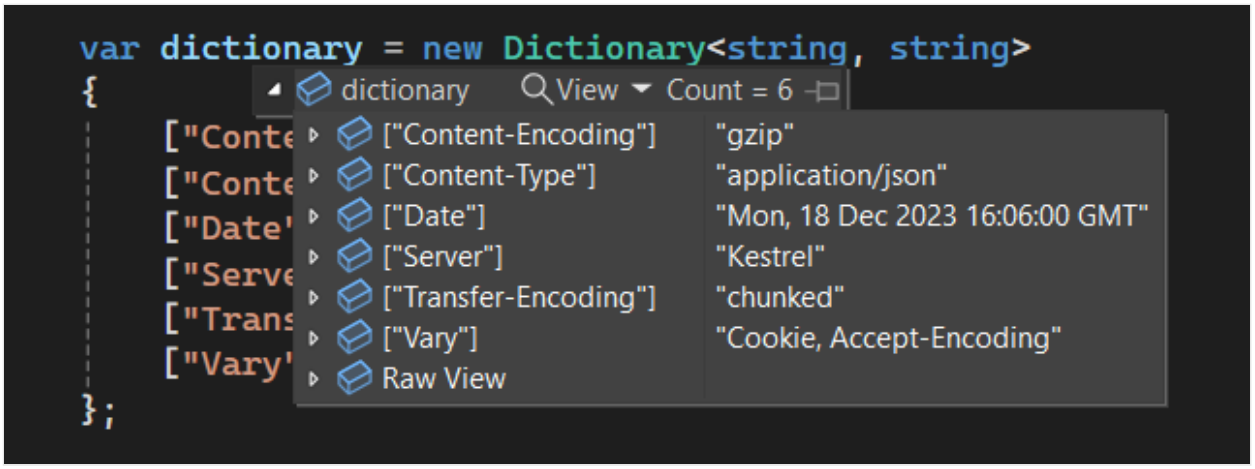
Preview 3 added endpoint metadata to the developer exception page. ASP.NET Core uses endpoint metadata to control endpoint behavior, such as routing, response caching, rate limiting, OpenAPI generation, and more. The following image shows the new metadata information in the `Routing` section of the developer exception page:

While testing the developer exception page, small quality of life improvements were identified. They shipped in Preview 4:

- Better text wrapping. Long cookies, query string values, and method names no longer add horizontal browser scroll bars.
- Bigger text which is found in modern designs.
- More consistent table sizes.



The following animated image shows the new developer exception page:



Dictionary debugging improvements

The debugging display of dictionaries and other key-value collections has an improved layout. The key is displayed in the debugger's key column instead of being concatenated with the value. The following images show the old and new display of a dictionary in the debugger.

Before:

After:

ASP.NET Core has many key-value collections. This improved debugging experience applies to:

- HTTP headers
- Query strings
- Forms
- Cookies
- View data
- Route data
- Features

Fix for 503's during app recycle in IIS

By default there is now a 1 second delay between when IIS is notified of a recycle or shutdown and when ANCM tells the managed server to start shutting down. The delay is configurable via the `ANCM_shutdownDelay` environment variable or by setting the `shutdownDelay` handler setting. Both values are in milliseconds. The delay is mainly to reduce the likelihood of a race where:

- IIS hasn't started queuing requests to go to the new app.
- ANCM starts rejecting new requests that come into the old app.

Slower machines or machines with heavier CPU usage may want to adjust this value to reduce 503 likelihood.

Example of setting `shutdownDelay`:

XML

```
<aspNetCore processPath="dotnet" arguments="myapp.dll"
stdoutLogEnabled="false" stdoutLogFile=".logsstdout">
  <handlerSettings>
    <!-- Milliseconds to delay shutdown by.
    this doesn't mean incoming requests will be delayed by this amount,
```

```
    but the old app instance will start shutting down after this timeout
occurs -->
    <handlerSetting name="shutdownDelay" value="5000" />
  </handlerSettings>
</aspNetCore>
```

The fix is in the globally installed ANCM module that comes from the hosting bundle.

Optimize static web asset delivery

Following production best practices for serving static assets requires a significant amount of work and technical expertise. Without optimizations like compression, caching, and fingerprints:

- The browser has to make additional requests on every page load.
- More bytes than necessary are transferred through the network.
- Sometimes stale versions of files are served to clients.

Creating performant web apps requires optimizing asset delivery to the browser. Possible optimizations include:

- Serve a given asset once until the file changes or the browser clears its cache. Set the ETag header.
- Prevent the browser from using old or stale assets after an app is updated. Set the Last-Modified header.
- Set up proper caching headers.
- Use caching middleware.
- Serve compressed versions of the assets when possible.
- Use a CDN to serve the assets closer to the user.
- Minimize the size of assets served to the browser. This optimization doesn't include minification.

MapStaticAssets is a new feature that optimizes the delivery of static assets in an app. It's designed to work with all UI frameworks, including Blazor, Razor Pages, and MVC. It's typically a drop-in replacement for UseStaticFiles:

diff

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();

var app = builder.Build();

if (!app.Environment.IsDevelopment())
```

```
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();

app.UseRouting();

app.UseAuthorization();

+app.MapStaticAssets();
-app.UseStaticFiles();
app.MapRazorPages();

app.Run();
```

`MapStaticAssets` operates by combining build and publish-time processes to collect information about all the static resources in an app. This information is then utilized by the runtime library to efficiently serve these files to the browser.

`MapStaticAssets` can replace UseStaticFiles in most situations, however, it's optimized for serving the assets that the app has knowledge of at build and publish time. If the app serves assets from other locations, such as disk or embedded resources, `UseStaticFiles` should be used.

`MapStaticAssets` provides the following benefits not found with `UseStaticFiles`:

- Build time compression for all the assets in the app:
  - `gzip` during development and `gzip + brotli` during publish.
  - All assets are compressed with the goal of reducing the size of the assets to the minimum.
- Content based `ETags`: The `Etags` for each resource are the Base64 encoded string of the SHA-256 hash of the content. This ensures that the browser only redownloads a file if its contents have changed.

The following table shows the original and compressed sizes of the CSS and JS files in the default Razor Pages template:

Expand table

File	Original	Compressed	% Reduction
bootstrap.min.css	163	17.5	89.26%
jquery.js	89.6	28	68.75%

File	Original	Compressed	% Reduction
bootstrap.min.js	78.5	20	74.52%
Total	331.1	65.5	80.20%

The following table shows the original and compressed sizes using the Fluent UI Blazor components library:

Expand table

File	Original	Compressed	% Reduction
fluent.js	384	73	80.99%
fluent.css	94	11	88.30%
Total	478	84	82.43%

For a total of 478 KB uncompressed to 84 KB compressed.

The following table shows the original and compressed sizes using the MudBlazor Blazor components library:

Expand table

File	Original	Compressed	Reduction
MudBlazor.min.css	541	37.5	93.07%
MudBlazor.min.js	47.4	9.2	80.59%
Total	588.4	46.7	92.07%

Optimization happens automatically when using `MapStaticAssets`. When a library is added or updated, for example with new JavaScript or CSS, the assets are optimized as part of the build. Optimization is especially beneficial to mobile environments that can have a lower bandwidth or an unreliable connections.

For more information on the new file delivery features, see the following resources:

- Static files in ASP.NET Core
- ASP.NET Core Blazor static files

Enabling dynamic compression on the server vs using `MapStaticAssets`

`MapStaticAssets` has the following advantages over dynamic compression on the server:

- Is simpler because there is no server specific configuration.
- Is more performant because the assets are compressed at build time.
- Allows the developer to spend extra time during the build process to ensure that the assets are the minimum size.

Consider the following table comparing MudBlazor compression with IIS dynamic compression and `MapStaticAssets`:

Expand table

IIS gzip	MapStaticAssets	MapStaticAssets Reduction
≅ 90	37.5	59%

ASP0026: Analyzer to warn when [Authorize] is overridden by [AllowAnonymous] from "farther away"

It seems intuitive that an `[Authorize]` attribute placed "closer" to an MVC action than an `[AllowAnonymous]` attribute would override the `[AllowAnonymous]` attribute and force authorization. However, this is not necessarily the case. What does matter is the relative order of the attributes.

The following code shows examples where a closer `[Authorize]` attribute gets overridden by an `[AllowAnonymous]` attribute that is farther away.

C#

```
[AllowAnonymous]
public class MyController
{
    [Authorize] // Overridden by the [AllowAnonymous] attribute on the class
    public IActionResult Private() => null;
}
```

C#

```
[AllowAnonymous]
public class MyControllerAnon : ControllerBase
{
}

[Authorize] // Overridden by the [AllowAnonymous] attribute on
MyControllerAnon
```

```
public class MyControllerInherited : MyControllerAnon
{
}

public class MyControllerInherited2 : MyControllerAnon
{
    [Authorize] // Overridden by the [AllowAnonymous] attribute on
MyControllerAnon
    public IActionResult Private() => null;
}
```

C#

```
[AllowAnonymous]
[Authorize] // Overridden by the preceding [AllowAnonymous]
public class MyControllerMultiple : ControllerBase
{
}
```

In .NET 9 Preview 6, we've introduced an analyzer that will highlight instances like these where a closer `[Authorize]` attribute gets overridden by an `[AllowAnonymous]` attribute that is farther away from an MVC action. The warning points to the overridden `[Authorize]` attribute with the following message:

```
ASP0026 [Authorize] overridden by [AllowAnonymous] from farther away
```

The correct action to take if you see this warning depends on the intention behind the attributes. The farther away `[AllowAnonymous]` attribute should be removed if it's unintentionally exposing the endpoint to anonymous users. If the `[AllowAnonymous]` attribute was intended to override a closer `[Authorize]` attribute, you can repeat the `[AllowAnonymous]` attribute after the `[Authorize]` attribute to clarify the intent.

C#

```
[AllowAnonymous]
public class MyController
{
    // This produces no warning because the second, "closer"
[AllowAnonymous]
    // clarifies that [Authorize] is intentionally overridden.
    // Specifying AuthenticationSchemes can still be useful
    // for endpoints that allow but don't require authenticated users.
    [Authorize(AuthenticationSchemes = "Cookies")]
    [AllowAnonymous]
```

```
    public IActionResult Privacy() => null;
}
```

Improved Kestrel connection metrics

We've made a significant improvement to Kestrel's connection metrics by including metadata about why a connection failed. The kestrel.connection.duration metric now includes the connection close reason in the `error.type` attribute.

Here is a small sample of the `error.type` values:

- `tls_handshake_failed` - The connection requires TLS, and the TLS handshake failed.
- `connection_reset` - The connection was unexpectedly closed by the client while requests were in progress.
- `request_headers_timeout` - Kestrel closed the connection because it didn't receive request headers in time.
- `max_request_body_size_exceeded` - Kestrel closed the connection because uploaded data exceeded max size.

Previously, diagnosing Kestrel connection issues required a server to record detailed, low-level logging. However, logs can be expensive to generate and store, and it can be difficult to find the right information among the noise.

Metrics are a much cheaper alternative that can be left on in a production environment with minimal impact. Collected metrics can drive dashboards and alerts. Once a problem is identified at a high-level with metrics, further investigation using logging and other tooling can begin.

We expect improved connection metrics to be useful in many scenarios:

- Investigating performance issues caused by short connection lifetimes.
- Observing ongoing external attacks on Kestrel that impact performance and stability.
- Recording attempted external attacks on Kestrel that Kestrel's built-in security hardening prevented.

For more information, see ASP.NET Core metrics.

Customize Kestrel named pipe endpoints

Kestrel's named pipe support has been improved with advanced customization options. The new `CreateNamedPipeServerStream` method on the named pipe options allows pipes to be customized per-endpoint.

An example of where this is useful is a Kestrel app that requires two pipe endpoints with different access security. The `CreateNamedPipeServerStream` option can be used to create pipes with custom security settings, depending on the pipe name.

C#

```
var builder = WebApplication.CreateBuilder();

builder.WebHost.ConfigureKestrel(options =>
{
    options.ListenNamedPipe("pipe1");
    options.ListenNamedPipe("pipe2");
});

builder.WebHost.UseNamedPipes(options =>
{
    options.CreateNamedPipeServerStream = (context) =>
    {
        var pipeSecurity =
CreatePipeSecurity(context.NamedPipeEndpoint.PipeName);

        return
NamedPipeServerStreamAcl.Create(context.NamedPipeEndPoint.PipeName,
PipeDirection.InOut,
            NamedPipeServerStream.MaxAllowedServerInstances,
PipeTransmissionMode.Byte,
            context.PipeOptions, inBufferSize: 0, outBufferSize: 0,
pipeSecurity);
    };
});
```

`ExceptionHandlerMiddleware` option to choose the status code based on the exception type

A new option when configuring the `ExceptionHandlerMiddleware` enables app developers to choose what status code to return when an exception occurs during request handling. The new option changes the status code being set in the `ProblemDetails` response from the `ExceptionHandlerMiddleware`.

C#

```
app.UseExceptionHandler(new ExceptionHandlerOptions
{
```

```
    StatusCodeSelector = ex => ex is TimeoutException
        ? StatusCodes.Status503ServiceUnavailable
        : StatusCodes.Status500InternalServerError,
});
```

Opt-out of HTTP metrics on certain endpoints and requests

.NET 9 introduces the ability to opt-out of HTTP metrics for specific endpoints and requests. Opting out of recording metrics is beneficial for endpoints frequently called by automated systems, such as health checks. Recording metrics for these requests is generally unnecessary.

HTTP requests to an endpoint can be excluded from metrics by adding metadata. Either:

- Add the [DisableHttpMetrics] attribute to the Web API controller, SignalR hub or gRPC service.
- Call DisableHttpMetrics when mapping endpoints in app startup:

C#

```
var builder = WebApplication.CreateBuilder(args);
builder.Services.AddHealthChecks();

var app = builder.Build();
app.MapHealthChecks("/healthz").DisableHttpMetrics();
app.Run();
```

The `MetricsDisabled` property has been added to `IHttpMetricsTagsFeature` for:

- Advanced scenarios where a request doesn't map to an endpoint.
- Dynamically disabling metrics collection for specific HTTP requests.

C#

```
// Middleware that conditionally opts-out HTTP requests.
app.Use(async (context, next) =>
{
    var metricsFeature = context.Features.Get<IHttpMetricsTagsFeature>();
    if (metricsFeature != null &&
        context.Request.Headers.ContainsKey("x-disable-metrics"))
    {
        metricsFeature.MetricsDisabled = true;
    }
```

```
    await next(context);
});
```

Data Protection support for deleting keys

Prior to .NET 9, data protection keys were ***not*** deletable by design, to prevent data loss. Deleting a key renders its protected data irretrievable. Given their small size, the accumulation of these keys generally posed minimal impact. However, to accommodate extremely long-running services, we have introduced the option to delete keys. Generally, only old keys should be deleted. Only delete keys when you can accept the risk of data loss in exchange for storage savings. We recommend data protection keys should ***not*** be deleted.

C#

```
using Microsoft.AspNetCore.DataProtection.KeyManagement;

var services = new ServiceCollection();
services.AddDataProtection();

var serviceProvider = services.BuildServiceProvider();

var keyManager = serviceProvider.GetService<IKeyManager>();

if (keyManager is IDeletableKeyManager deletableKeyManager)
{
    var utcNow = DateTimeOffset.UtcNow;
    var yearAgo = utcNow.AddYears(-1);

    if (!deletableKeyManager.DeleteKeys(key => key.ExpirationDate <
yearAgo))
    {
        Console.WriteLine("Failed to delete keys.");
    }
    else
    {
        Console.WriteLine("Old keys deleted successfully.");
    }
}
else
{
    Console.WriteLine("Key manager does not support deletion.");
}
```

Middleware supports Keyed DI

Middleware now supports Keyed DI in both the constructor and the `Invoke`/`InvokeAsync` method:

C#

```
var builder = WebApplication.CreateBuilder(args);
builder.Services.AddKeyedSingleton<MySingletonClass>("test");
builder.Services.AddKeyedScoped<MyScopedClass>("test2");

var app = builder.Build();
app.UseMiddleware<MyMiddleware>();
app.Run();

internal class MyMiddleware
{
    private readonly RequestDelegate _next;

    public MyMiddleware(RequestDelegate next,
        [FromKeyedServices("test")] MySingletonClass service)
    {
        _next = next;
    }

    public Task Invoke(HttpContext context,
        [FromKeyedServices("test2")]
            MyScopedClass scopedService) => _next(context);
}
```

Trust the ASP.NET Core HTTPS development certificate on Linux

On Ubuntu and Fedora based Linux distros, `dotnet dev-certs https --trust` now configures ASP.NET Core HTTPS development certificate as a trusted certificate for:

- Chromium browsers, for example, Google Chrome, Microsoft Edge, and Chromium.
- Mozilla Firefox and Mozilla derived browsers.
- .NET APIs, for example, HttpClient

Previously, `--trust` only worked on Windows and macOS. Certificate trust is applied per-user.

To establish trust in OpenSSL, the `dev-certs` tool:

- Puts the certificate in `~/.aspnet/dev-certs/trust`
- Runs a simplified version of OpenSSL's c_rehash tool on the directory.
- Asks the user to update the `SSL_CERT_DIR` environment variable.

To establish trust in dotnet, the tool puts the certificate in the `My/Root` certificate store.

To establish trust in NSS databases, if any, the tool searches the home directory for Firefox profiles, `~/.pki/nssdb`, and `~/snap/chromium/current/.pki/nssdb`. For each directory found, the tool adds an entry to the `nssdb`.

Templates updated to latest Bootstrap, jQuery, and jQuery Validation versions

The ASP.NET Core project templates and libraries have been updated to use the latest versions of Bootstrap, jQuery, and jQuery Validation, specifically:

- Bootstrap 5.3.3
- jQuery 3.7.1
- jQuery Validation 1.21.0

What's new in ASP.NET Core 8.0

Article • 11/06/2024

This article highlights the most significant changes in ASP.NET Core 8.0 with links to relevant documentation.

Blazor

Full-stack web UI

With the release of .NET 8, Blazor is a full-stack web UI framework for developing apps that render content at either the component or page level with:

- Static Server rendering (also called *static server-side rendering*, static SSR) to generate static HTML on the server.
- Interactive Server rendering (also called *interactive server-side rendering*, interactive SSR) to generate interactive components with prerendering on the server.
- Interactive WebAssembly rendering (also called *client-side rendering*, CSR, which is always assumed to be interactive) to generate interactive components on the client with prerendering on the server.
- Interactive Auto (automatic) rendering to initially use the server-side ASP.NET Core runtime for content rendering and interactivity. The .NET WebAssembly runtime on the client is used for subsequent rendering and interactivity after the Blazor bundle is downloaded and the WebAssembly runtime activates. Interactive Auto rendering usually provides the fastest app startup experience.

Interactive render modes also prerender content by default.

For more information, see the following articles:

- ASP.NET Core Blazor fundamentals: New sections on rendering and static/interactive concepts appear at the top of the article.
- ASP.NET Core Blazor render modes
- **Migration coverage**: Migrate from ASP.NET Core 7.0 to 8.0

Examples throughout the Blazor documentation have been updated for use in Blazor Web Apps. Blazor Server examples remain in content versioned for .NET 7 or earlier.

New article on class libraries with static server-side rendering (static SSR)

We've added a new article that discusses component library authorship in Razor class libraries (RCLs) with static server-side rendering (static SSR).

For more information, see ASP.NET Core Razor class libraries (RCLs) with static server-side rendering (static SSR).

New article on HTTP caching issues

We've added a new article that discusses some of the common HTTP caching issues that can occur when upgrading Blazor apps across major versions and how to address HTTP caching issues.

For more information, see Avoid HTTP caching issues when upgrading ASP.NET Core Blazor apps.

New Blazor Web App template

We've introduced a new Blazor project template: the *Blazor Web App* template. The new template provides a single starting point for using Blazor components to build any style of web UI. The template combines the strengths of the existing Blazor Server and Blazor WebAssembly hosting models with the new Blazor capabilities added in .NET 8: static server-side rendering (static SSR), streaming rendering, enhanced navigation and form handling, and the ability to add interactivity using either Blazor Server or Blazor WebAssembly on a per-component basis.

As part of unifying the various Blazor hosting models into a single model in .NET 8, we're also consolidating the number of Blazor project templates. We removed the Blazor Server template, and the ASP.NET Core Hosted option has been removed from the Blazor WebAssembly template. Both of these scenarios are represented by options when using the Blazor Web App template.

> **Note**
>
> Existing Blazor Server and Blazor WebAssembly apps remain supported in .NET 8. Optionally, these apps can be updated to use the new full-stack web UI Blazor features.

For more information on the new Blazor Web App template, see the following articles:

- Tooling for ASP.NET Core Blazor
- ASP.NET Core Blazor project structure

New JS initializers for Blazor Web Apps

For Blazor Server, Blazor WebAssembly, and Blazor Hybrid apps:

- `beforeStart` is used for tasks such as customizing the loading process, logging level, and other options.
- `afterStarted` is used for tasks such as registering Blazor event listeners and custom event types.

The preceding legacy JS initializers aren't invoked by default in a Blazor Web App. For Blazor Web Apps, a new set of JS initializers are used: `beforeWebStart`, `afterWebStarted`, `beforeServerStart`, `afterServerStarted`, `beforeWebAssemblyStart`, and `afterWebAssemblyStarted`.

For more information, see ASP.NET Core Blazor startup.

Split of prerendering and integration guidance

For prior releases of .NET, we covered prerendering and integration in a single article. To simplify and focus our coverage, we've split the subjects into the following new articles, which have been updated for .NET 8:

- Prerender ASP.NET Core Razor components
- Integrate ASP.NET Core Razor components into ASP.NET Core apps

Persist component state in a Blazor Web App

You can persist and read component state in a Blazor Web App using the existing PersistentComponentState service. This is useful for persisting component state during prerendering.

Blazor Web Apps automatically persist any registered app-level state created during prerendering, removing the need for the Persist Component State Tag Helper.

Form handling and model binding

Blazor components can now handle submitted form requests, including model binding and validating the request data. Components can implement forms with separate form handlers using the standard HTML `<form>` tag or using the existing `EditForm` component.

Form model binding in Blazor honors the data contract attributes (for example, `[DataMember]` and `[IgnoreDataMember]`) for customizing how the form data is bound to the model.

New antiforgery support is included in .NET 8. A new `AntiforgeryToken` component renders an antiforgery token as a hidden field, and the new `[RequireAntiforgeryToken]` attribute enables antiforgery protection. If an antiforgery check fails, a 400 (Bad Request) response is returned without form processing. The new antiforgery features are enabled by default for forms based on `Editform` and can be applied manually to standard HTML forms.

For more information, see ASP.NET Core Blazor forms overview.

Enhanced navigation and form handling

Static server-side rendering (static SSR) typically performs a full page refresh whenever the user navigates to a new page or submits a form. In .NET 8, Blazor can enhance page navigation and form handling by intercepting the request and performing a fetch request instead. Blazor then handles the rendered response content by patching it into the browser DOM. Enhanced navigation and form handling avoids the need for a full page refresh and preserves more of the page state, so pages load faster and more smoothly. Enhanced navigation is enabled by default when the Blazor script (`blazor.web.js`) is loaded. Enhanced form handling can be optionally enabled for specific forms.

New enhanced navigation API allows you to refresh the current page by calling `NavigationManager.Refresh(bool forceLoad = false)`.

For more information, see the following sections of the Blazor *Routing* article:

- Enhanced navigation and form handling
- Location changes

New article on static rendering with enhanced navigation for JS interop

Some apps depend on JS interop to perform initialization tasks that are specific to each page. When using Blazor's enhanced navigation feature with statically-rendered pages that perform JS interop initialization tasks, page-specific JS may not be executed again as expected each time an enhanced page navigation occurs. A new article explains how to address this scenario in Blazor Web Apps:

ASP.NET Core Blazor JavaScript with static server-side rendering (static SSR)

Streaming rendering

You can now stream content updates on the response stream when using static server-side rendering (static SSR) with Blazor. Streaming rendering can improve the user experience for pages that perform long-running asynchronous tasks in order to fully render by rendering content as soon as it's available.

For example, to render a page you might need to make a long running database query or an API call. Normally, asynchronous tasks executed as part of rendering a page must complete before the rendered response is sent, which can delay loading the page. Streaming rendering initially renders the entire page with placeholder content while asynchronous operations execute. After the asynchronous operations are complete, the updated content is sent to the client on the same response connection and patched by into the DOM. The benefit of this approach is that the main layout of the app renders as quickly as possible and the page is updated as soon as the content is ready.

For more information, see ASP.NET Core Razor component rendering.

Inject keyed services into components

Blazor now supports injecting keyed services using the `[Inject]` attribute. Keys allow for scoping of registration and consumption of services when using dependency injection. Use the new `InjectAttribute.Key` property to specify the key for the service to inject:

C#

```
[Inject(Key = "my-service")]
public IMyService MyService { get; set; }
```

The `@inject` Razor directive doesn't support keyed services for this release, but work is tracked by Update @inject to support keyed services (dotnet/razor #9286) for a future .NET release.

For more information, see ASP.NET Core Blazor dependency injection.

Access `HttpContext` as a cascading parameter

You can now access the current HttpContext as a cascading parameter from a static server component:

C#

```
[CascadingParameter]
public HttpContext? HttpContext { get; set; }
```

Accessing the HttpContext from a static server component might be useful for inspecting and modifying headers or other properties.

For an example that passes HttpContext state, access and refresh tokens, to components, see Server-side ASP.NET Core Blazor additional security scenarios.

Render Razor components outside of ASP.NET Core

You can now render Razor components outside the context of an HTTP request. You can render Razor components as HTML directly to a string or stream independently of the ASP.NET Core hosting environment. This is convenient for scenarios where you want to generate HTML fragments, such as for a generating email or static site content.

For more information, see Render Razor components outside of ASP.NET Core.

Sections support

The new `SectionOutlet` and `SectionContent` components in Blazor add support for specifying outlets for content that can be filled in later. Sections are often used to define placeholders in layouts that are then filled in by specific pages. Sections are referenced either by a unique name or using a unique object ID.

For more information, see ASP.NET Core Blazor sections.

Error page support

Blazor Web Apps can define a custom error page for use with the ASP.NET Core exception handling middleware. The Blazor Web App project template includes a default error page (`Components/Pages/Error.razor`) with similar content to the one used in MVC and Razor Pages apps. When the error page is rendered in response to a request from Exception Handling Middleware, the error page always renders as a static server component, even if interactivity is otherwise enabled.

Error.razor in 8.0 reference source

QuickGrid

The Blazor QuickGrid component is no longer experimental and is now part of the Blazor framework in .NET 8.

QuickGrid is a high performance grid component for displaying data in tabular form. QuickGrid is built to be a simple and convenient way to display your data, while still providing powerful features, such as sorting, filtering, paging, and virtualization.

For more information, see ASP.NET Core Blazor QuickGrid component.

Route to named elements

Blazor now supports using client-side routing to navigate to a specific HTML element on a page using standard URL fragments. If you specify an identifier for an HTML element using the standard `id` attribute, Blazor correctly scrolls to that element when the URL fragment matches the element identifier.

For more information, see ASP.NET Core Blazor routing and navigation.

Root-level cascading values

Root-level cascading values can be registered for the entire component hierarchy. Named cascading values and subscriptions for update notifications are supported.

For more information, see ASP.NET Core Blazor cascading values and parameters.

Virtualize empty content

Use the new `EmptyContent` parameter on the `Virtualize` component to supply content when the component has loaded and either `Items` is empty or `ItemsProviderResult<T>.TotalItemCount` is zero.

For more information, see ASP.NET Core Razor component virtualization.

Close circuits when there are no remaining interactive server components

Interactive server components handle web UI events using a real-time connection with the browser called a circuit. A circuit and its associated state are set up when a root interactive server component is rendered. The circuit is closed when there are no remaining interactive server components on the page, which frees up server resources.

Monitor SignalR circuit activity

You can now monitor inbound circuit activity in server-side apps using the new `CreateInboundActivityHandler` method on `CircuitHandler`. Inbound circuit activity is any activity sent from the browser to the server, such as UI events or JavaScript-to-.NET interop calls.

For more information, see ASP.NET Core Blazor SignalR guidance.

Faster runtime performance with the Jiterpreter

The *Jiterpreter* is a new runtime feature in .NET 8 that enables partial Just-in-Time (JIT) compilation support when running on WebAssembly to achieve improved runtime performance.

For more information, see Host and deploy ASP.NET Core Blazor WebAssembly.

Ahead-of-time (AOT) SIMD and exception handling

Blazor WebAssembly ahead-of-time (AOT) compilation now uses WebAssembly Fixed-width SIMD and WebAssembly Exception handling by default to improve runtime performance.

For more information, see the following articles:

- AOT: Single Instruction, Multiple Data (SIMD)
- AOT: Exception handling

Web-friendly Webcil packaging

Webcil is web-friendly packaging of .NET assemblies that removes content specific to native Windows execution to avoid issues when deploying to environments that block the download or use of `.dll` files. Webcil is enabled by default for Blazor WebAssembly apps.

For more information, see Host and deploy ASP.NET Core Blazor WebAssembly.

> **Note**
>
> Prior to the release of .NET 8, guidance in Deployment layout for ASP.NET Core hosted Blazor WebAssembly apps addresses environments that block clients from downloading and executing DLLs with a multipart bundling approach. In .NET 8 or

later, Blazor uses the Webcil file format to address this problem. Multipart bundling using the experimental NuGet package described by the *WebAssembly deployment layout* article isn't supported for Blazor apps in .NET 8 or later. For more information, see **Enhance Microsoft.AspNetCore.Components.WebAssembly.MultipartBundle package to define a custom bundle format (dotnet/aspnetcore #36978)**. If you desire to continue using the multipart bundle package in .NET 8 or later apps, you can use the guidance in the article to create your own multipart bundling NuGet package, but it won't be supported by Microsoft.

Blazor WebAssembly debugging improvements

When debugging .NET on WebAssembly, the debugger now downloads symbol data from symbol locations that are configured in Visual Studio preferences. This improves the debugging experience for apps that use NuGet packages.

You can now debug Blazor WebAssembly apps using Firefox. Debugging Blazor WebAssembly apps requires configuring the browser for remote debugging and then connecting to the browser using the browser developer tools through the .NET WebAssembly debugging proxy. Debugging Firefox from Visual Studio isn't supported at this time.

For more information, see Debug ASP.NET Core Blazor apps.

Content Security Policy (CSP) compatibility

Blazor WebAssembly no longer requires enabling the `unsafe-eval` script source when specifying a Content Security Policy (CSP).

For more information, see Enforce a Content Security Policy for ASP.NET Core Blazor.

Handle caught exceptions outside of a Razor component's lifecycle

Use `ComponentBase.DispatchExceptionAsync` in a Razor component to process exceptions thrown outside of the component's lifecycle call stack. This permits the component's code to treat exceptions as though they're lifecycle method exceptions. Thereafter, Blazor's error handling mechanisms, such as error boundaries, can process exceptions.

For more information, see Handle errors in ASP.NET Core Blazor apps.

Configure the .NET WebAssembly runtime

The .NET WebAssembly runtime can now be configured for Blazor startup.

For more information, see ASP.NET Core Blazor startup.

Configuration of connection timeouts in `HubConnectionBuilder`

Prior workarounds for configuring hub connection timeouts can be replaced with formal SignalR hub connection builder timeout configuration.

For more information, see the following:

- ASP.NET Core Blazor SignalR guidance
- Host and deploy ASP.NET Core Blazor WebAssembly
- Host and deploy ASP.NET Core server-side Blazor apps

Project templates shed Open Iconic

The Blazor project templates no longer depend on Open Iconic for icons.

Support for dialog cancel and close events

Blazor now supports the cancel and close events on the `dialog` HTML element.

In the following example:

- `OnClose` is called when the `my-dialog` dialog is closed with the **Close** button.
- `OnCancel` is called when the dialog is canceled with the `Esc` key. When an HTML dialog is dismissed with the `Esc` key, both the `cancel` and `close` events are triggered.

razor

```
<div>
    <p>Output: @message</p>

    <button onclick="document.getElementById('my-dialog').showModal()">
        Show modal dialog
    </button>

    <dialog id="my-dialog" @onclose="OnClose" @oncancel="OnCancel">
        <p>Hi there!</p>
```

```
        <form method="dialog">
            <button>Close</button>
        </form>
    </dialog>
</div>

@code {
    private string? message;

    private void OnClose(EventArgs e) => message += "onclose, ";

    private void OnCancel(EventArgs e) => message += "oncancel, ";
}
```

Blazor Identity UI

Blazor supports generating a full Blazor-based Identity UI when you choose the authentication option for *Individual Accounts*. You can either select the option for Individual Accounts in the new project dialog for Blazor Web Apps from Visual Studio or pass the `-au|--auth` option set to `Individual` from the command line when you create a new project.

For more information, see the following resources:

- Secure ASP.NET Core server-side Blazor apps
- What's new with identity in .NET 8 (blog post)

Secure Blazor WebAssembly with ASP.NET Core Identity

The Blazor documentation hosts a new article and sample app to cover securing a standalone Blazor WebAssembly app with ASP.NET Core Identity.

For more information, see the following resources:

- Secure ASP.NET Core Blazor WebAssembly with ASP.NET Core Identity
- What's new with identity in .NET 8 (blog post)

Blazor Server with Yarp routing

Routing and deep linking for Blazor Server with Yarp work correctly in .NET 8.

For more information, see Migrate from ASP.NET Core 7.0 to 8.0.

Multiple Blazor Web Apps per server project

Support for multiple Blazor Web Apps per server project will be considered for .NET 10 (November, 2025).

For more information, see Support for multiple Blazor Web apps per server project (dotnet/aspnetcore #52216).

Blazor Hybrid

The following articles document changes for Blazor Hybrid in .NET 8:

- Troubleshoot ASP.NET Core Blazor Hybrid: A new article explains how to use BlazorWebView logging.
- Build a .NET MAUI Blazor Hybrid app: The project template name **.NET MAUI Blazor** has changed to **.NET MAUI Blazor Hybrid**.
- ASP.NET Core Blazor Hybrid: `BlazorWebView` gains a `TryDispatchAsync` method that calls a specified `Action<ServiceProvider>` asynchronously and passes in the scoped services available in Razor components. This enables code from the native UI to access scoped services such as `NavigationManager`.
- ASP.NET Core Blazor Hybrid routing and navigation: Use the `BlazorWebView.StartPath` property to get or set the path for initial navigation within the Blazor navigation context when the Razor component is finished loading.

`[Parameter]` attribute is no longer required when supplied from the query string

The `[Parameter]` attribute is no longer required when supplying a parameter from the query string:

```diff
- [Parameter]
  [SupplyParameterFromQuery]
```

SignalR

New approach to set the server timeout and Keep-Alive interval

ServerTimeout (default: 30 seconds) and KeepAliveInterval (default: 15 seconds) can be set directly on HubConnectionBuilder.

Prior approach for JavaScript clients

The following example shows the assignment of values that are double the default values in ASP.NET Core 7.0 or earlier:

JavaScript

```
var connection = new signalR.HubConnectionBuilder()
  .withUrl("/chatHub")
  .build();

connection.serverTimeoutInMilliseconds = 60000;
connection.keepAliveIntervalInMilliseconds = 30000;
```

New approach for JavaScript clients

The following example shows the ***new approach*** for assigning values that are double the default values in ASP.NET Core 8.0 or later:

JavaScript

```
var connection = new signalR.HubConnectionBuilder()
  .withUrl("/chatHub")
  .withServerTimeout(60000)
  .withKeepAlive(30000)
  .build();
```

Prior approach for the JavaScript client of a Blazor Server app

The following example shows the assignment of values that are double the default values in ASP.NET Core 7.0 or earlier:

JavaScript

```
Blazor.start({
  configureSignalR: function (builder) {
    let c = builder.build();
    c.serverTimeoutInMilliseconds = 60000;
    c.keepAliveIntervalInMilliseconds = 30000;
    builder.build = () => {
      return c;
    };
```

```
  }
});
```

New approach for the JavaScript client of server-side Blazor app

The following example shows the ***new approach*** for assigning values that are double the default values in ASP.NET Core 8.0 or later for Blazor Web Apps and Blazor Server.

Blazor Web App:

JavaScript

```
Blazor.start({
  circuit: {
    configureSignalR: function (builder) {
      builder.withServerTimeout(60000).withKeepAliveInterval(30000);
    }
  }
});
```

Blazor Server:

JavaScript

```
Blazor.start({
  configureSignalR: function (builder) {
    builder.withServerTimeout(60000).withKeepAliveInterval(30000);
  }
});
```

Prior approach for .NET clients

The following example shows the assignment of values that are double the default values in ASP.NET Core 7.0 or earlier:

C#

```
var builder = new HubConnectionBuilder()
    .WithUrl(Navigation.ToAbsoluteUri("/chathub"))
    .Build();

builder.ServerTimeout = TimeSpan.FromSeconds(60);
builder.KeepAliveInterval = TimeSpan.FromSeconds(30);

builder.On<string, string>("ReceiveMessage", (user, message) => ...
```

```
await builder.StartAsync();
```

New approach for .NET clients

The following example shows the ***new approach*** for assigning values that are double the default values in ASP.NET Core 8.0 or later:

```
C#

var builder = new HubConnectionBuilder()
    .WithUrl(Navigation.ToAbsoluteUri("/chathub"))
    .WithServerTimeout(TimeSpan.FromSeconds(60))
    .WithKeepAliveInterval(TimeSpan.FromSeconds(30))
    .Build();

builder.On<string, string>("ReceiveMessage", (user, message) => ...

await builder.StartAsync();
```

SignalR stateful reconnect

SignalR stateful reconnect reduces the perceived downtime of clients that have a temporary disconnect in their network connection, such as when switching network connections or a short temporary loss in access.

Stateful reconnect achieves this by:

- Temporarily buffering data on the server and client.
- Acknowledging messages received (ACK-ing) by both the server and client.
- Recognizing when a connection is returning and replaying messages that might have been sent while the connection was down.

Stateful reconnect is available in ASP.NET Core 8.0 and later.

Opt in to stateful reconnect at both the server hub endpoint and the client:

- Update the server hub endpoint configuration to enable the `AllowStatefulReconnects` option:

  ```
  C#

  app.MapHub<MyHub>("/hubName", options =>
  {
  ```

```
    options.AllowStatefulReconnects = true;
});
```

Optionally, the maximum buffer size in bytes allowed by the server can be set globally or for a specific hub with the `StatefulReconnectBufferSize` option:

The `StatefulReconnectBufferSize` option set globally:

C#

```
builder.AddSignalR(o => o.StatefulReconnectBufferSize = 1000);
```

The `StatefulReconnectBufferSize` option set for a specific hub:

C#

```
builder.AddSignalR().AddHubOptions<MyHub>(o =>
o.StatefulReconnectBufferSize = 1000);
```

The `StatefulReconnectBufferSize` option is optional with a default of 100,000 bytes.

- Update JavaScript or TypeScript client code to enable the `withStatefulReconnect` option:

JavaScript

```
const builder = new signalR.HubConnectionBuilder()
  .withUrl("/hubname")
  .withStatefulReconnect({ bufferSize: 1000 });  // Optional, defaults
to 100,000
const connection = builder.build();
```

The `bufferSize` option is optional with a default of 100,000 bytes.

- Update .NET client code to enable the `WithStatefulReconnect` option:

C#

```
  var builder = new HubConnectionBuilder()
      .WithUrl("<hub url>")
      .WithStatefulReconnect();
  builder.Services.Configure<HubConnectionOptions>(o =>
o.StatefulReconnectBufferSize = 1000);
  var hubConnection = builder.Build();
```

The `StatefulReconnectBufferSize` option is optional with a default of 100,000 bytes.

For more information, see Configure stateful reconnect.

Minimal APIs

This section describes new features for minimal APIs. See also the section on Native AOT for more information relevant to minimal APIs.

User override culture

Starting in ASP.NET Core 8.0, the RequestLocalizationOptions.CultureInfoUseUserOverride property allows the application to decide whether or not to use nondefault Windows settings for the CultureInfo DateTimeFormat and NumberFormat properties. This has no impact on Linux. This directly corresponds to UseUserOverride.

C#

```
app.UseRequestLocalization(options =>
{
    options.CultureInfoUseUserOverride = false;
});
```

Binding to forms

Explicit binding to form values using the [FromForm] attribute is now supported. Parameters bound to the request with `[FromForm]` include an antiforgery token. The antiforgery token is validated when the request is processed.

Inferred binding to forms using the IFormCollection, IFormFile, and IFormFileCollection types is also supported. OpenAPI metadata is inferred for form parameters to support integration with Swagger UI.

For more information, see:

- Explicit binding from form values.
- Binding to forms with IFormCollection, IFormFile, and IFormFileCollection.
- Form binding in minimal APIs

Binding from forms is now supported for:

- Collections, for example List and Dictionary
- Complex types, for example, `Todo` or `Project`

For more information, see Bind to collections and complex types from forms.

Antiforgery with minimal APIs

This release adds a middleware for validating antiforgery tokens, which are used to mitigate cross-site request forgery attacks. Call AddAntiforgery to register antiforgery services in DI. `WebApplicationBuilder` automatically adds the middleware when the antiforgery services have been registered in the DI container. Antiforgery tokens are used to mitigate cross-site request forgery attacks.

```
C#

var builder = WebApplication.CreateBuilder();

builder.Services.AddAntiforgery();

var app = builder.Build();

app.UseAntiforgery();

app.MapGet("/", () => "Hello World!");

app.Run();
```

The antiforgery middleware:

- Does ***not*** short-circuit the execution of the rest of the request pipeline.
- Sets the IAntiforgeryValidationFeature in the HttpContext.Features of the current request.

The antiforgery token is only validated if:

- The endpoint contains metadata implementing IAntiforgeryMetadata where `RequiresValidation=true`.
- The HTTP method associated with the endpoint is a relevant HTTP method. The relevant methods are all HTTP methods except for TRACE, OPTIONS, HEAD, and GET.
- The request is associated with a valid endpoint.

For more information, see Antiforgery with Minimal APIs.

New `IResettable` interface in `ObjectPool`

Microsoft.Extensions.ObjectPool provides support for pooling object instances in memory. Apps can use an object pool if the values are expensive to allocate or initialize.

In this release, we've made the object pool easier to use by adding the IResettable interface. Reusable types often need to be reset back to a default state between uses. `IResettable` types are automatically reset when returned to an object pool.

For more information, see the ObjectPool sample.

Native AOT

Support for .NET native ahead-of-time (AOT) has been added. Apps that are published using AOT can have substantially better performance: smaller app size, less memory usage, and faster startup time. Native AOT is currently supported by gRPC, minimal API, and worker service apps. For more information, see ASP.NET Core support for Native AOT and Tutorial: Publish an ASP.NET Core app using Native AOT. For information about known issues with ASP.NET Core and Native AOT compatibility, see GitHub issue dotnet/core #8288 .

Libraries and Native AOT

Many of the popular libraries used in ASP.NET Core projects currently have some compatibility issues when used in a project targeting Native AOT, such as:

- Use of reflection to inspect and discover types.
- Conditionally loading libraries at runtime.
- Generating code on the fly to implement functionality.

Libraries using these dynamic features need to be updated in order to work with Native AOT. They can be updated using tools like Roslyn source generators.

Library authors hoping to support Native AOT are encouraged to:

- Read about Native AOT compatibility requirements.
- Prepare the library for trimming.

New project template

The new **ASP.NET Core Web API (Native AOT)** project template (short name `webapiaot`) creates a project with AOT publish enabled. For more information, see The Web API (Native AOT) template.

New `CreateSlimBuilder` method

The CreateSlimBuilder() method used in the Web API (Native AOT) template initializes the WebApplicationBuilder with the minimum ASP.NET Core features necessary to run an app. The `CreateSlimBuilder` method includes the following features that are typically needed for an efficient development experience:

- JSON file configuration for `appsettings.json` and `appsettings.{EnvironmentName}.json`.
- User secrets configuration.
- Console logging.
- Logging configuration.

For more information, see The CreateSlimBuilder method.

New `CreateEmptyBuilder` method

There's another new WebApplicationBuilder factory method for building small apps that only contain necessary features: `WebApplication.CreateEmptyBuilder(WebApplicationOptions options)`. This `WebApplicationBuilder` is created with no built-in behavior. The app it builds contains only the services and middleware that are explicitly configured.

Here's an example of using this API to create a small web application:

C#

```
var builder = WebApplication.CreateEmptyBuilder(new
WebApplicationOptions());
builder.WebHost.UseKestrelCore();

var app = builder.Build();

app.Use(async (context, next) =>
{
    await context.Response.WriteAsync("Hello, World!");
    await next(context);
});

Console.WriteLine("Running...");
app.Run();
```

Publishing this code with Native AOT using .NET 8 Preview 7 on a linux-x64 machine results in a self-contained native executable of about 8.5 MB.

Reduced app size with configurable HTTPS support

We've further reduced Native AOT binary size for apps that don't need HTTPS or HTTP/3 support. Not using HTTPS or HTTP/3 is common for apps that run behind a TLS termination proxy (for example, hosted on Azure). The new `WebApplication.CreateSlimBuilder` method omits this functionality by default. It can be added by calling `builder.WebHost.UseKestrelHttpsConfiguration()` for HTTPS or `builder.WebHost.UseQuic()` for HTTP/3. For more information, see The CreateSlimBuilder method.

JSON serialization of compiler-generated `IAsyncEnumerable<T>` types

New features were added to System.Text.Json to better support Native AOT. These new features add capabilities for the source generation mode of `System.Text.Json`, because reflection isn't supported by AOT.

One of the new features is support for JSON serialization of IAsyncEnumerable<T> implementations implemented by the C# compiler. This support opens up their use in ASP.NET Core projects configured to publish Native AOT.

This API is useful in scenarios where a route handler uses `yield return` to asynchronously return an enumeration. For example, to materialize rows from a database query. For more information, see Unspeakable type support in the .NET 8 Preview 4 announcement.

For information abut other improvements in `System.Text.Json` source generation, see Serialization improvements in .NET 8.

Top-level APIs annotated for trim warnings

The main entry points to subsystems that don't work reliably with Native AOT are now annotated. When these methods are called from an application with Native AOT enabled, a warning is provided. For example, the following code produces a warning at the invocation of `AddControllers` because this API isn't trim-safe and isn't supported by Native AOT.

```
var builder = WebApplication.CreateBuilder();

builder.Services.AddControllers();
var app = builder.Build();

app.Run();
```

IL2026: Using member 'Microsoft.Extensions.DependencyInjection.MvcServiceCollectionExtensions.AddControllers(IServiceCollection)' which has 'RequiresUnreferencedCodeAttribute' can break functionality when trimming application code. MVC does not currently support native AOT. https://aka.ms/aspnet/nativeaot

Request delegate generator

In order to make Minimal APIs compatible with Native AOT, we're introducing the Request Delegate Generator (RDG). The RDG is a source generator that does what the RequestDelegateFactory (RDF) does. That is, it turns the various `MapGet()`, `MapPost()`, and calls like them into RequestDelegate instances associated with the specified routes. But rather than doing it in-memory in an application when it starts, the RDG does it at compile time and generates C# code directly into the project. The RDG:

- Removes the runtime generation of this code.
- Ensures that the types used in APIs are statically analyzable by the Native AOT tool-chain.
- Ensures that required code isn't trimmed away.

We're working to ensure that as many as possible of the Minimal API features are supported by the RDG and thus compatible with Native AOT.

The RDG is enabled automatically in a project when publishing with Native AOT is enabled. RDG can be manually enabled even when not using Native AOT by setting `<EnableRequestDelegateGenerator>true</EnableRequestDelegateGenerator>` in the project file. This can be useful when initially evaluating a project's readiness for Native AOT, or to reduce the startup time of an app.

Improved performance using Interceptors

The Request Delegate Generator uses the new C# 12 interceptors compiler feature to support intercepting calls to minimal API Map methods with statically generated

variants at runtime. The use of interceptors results in increased startup performance for apps compiled with `PublishAot`.

Logging and exception handling in compile-time generated minimal APIs

Minimal APIs generated at run time support automatically logging (or throwing exceptions in Development environments) when parameter binding fails. .NET 8 introduces the same support for APIs generated at compile time via the Request Delegate Generator (RDG). For more information, see Logging and exception handling in compile-time generated minimal APIs.

AOT and System.Text.Json

Minimal APIs are optimized for receiving and returning JSON payloads using `System.Text.Json`, so the compatibility requirements for JSON and Native AOT apply too. Native AOT compatibility requires the use of the `System.Text.Json` source generator. All types accepted as parameters to or returned from request delegates in Minimal APIs must be configured on a `JsonSerializerContext` that is registered via ASP.NET Core's dependency injection, for example:

C#

```
// Register the JSON serializer context with DI
builder.Services.ConfigureHttpJsonOptions(options =>
{
    options.SerializerOptions.TypeInfoResolverChain.Insert(0,
AppJsonSerializerContext.Default);
});

...

// Add types used in the minimal API app to source generated JSON serializer
content
[JsonSerializable(typeof(Todo[]))]
internal partial class AppJsonSerializerContext : JsonSerializerContext
{

}
```

For more information about the TypeInfoResolverChain API, see the following resources:

- JsonSerializerOptions.TypeInfoResolverChain
- Chain source generators

- Changes to support source generation

Libraries and Native AOT

Many of the common libraries available for ASP.NET Core projects today have some compatibility issues if used in a project targeting Native AOT. Popular libraries often rely on the dynamic capabilities of .NET reflection to inspect and discover types, conditionally load libraries at runtime, and generate code on the fly to implement their functionality. These libraries need to be updated in order to work with Native AOT by using tools like Roslyn source generators.

Library authors wishing to learn more about preparing their libraries for Native AOT are encouraged to start by preparing their library for trimming and learning more about the Native AOT compatibility requirements.

Kestrel and HTTP.sys servers

There are several new features for Kestrel and HTTP.sys.

Support for named pipes in Kestrel

Named pipes is a popular technology for building inter-process communication (IPC) between Windows apps. You can now build an IPC server using .NET, Kestrel, and named pipes.

C#

```
var builder = WebApplication.CreateBuilder(args);
builder.WebHost.ConfigureKestrel(serverOptions =>
{
    serverOptions.ListenNamedPipe("MyPipeName");
});
```

For more information about this feature and how to use .NET and gRPC to create an IPC server and client, see Inter-process communication with gRPC.

Performance improvements to named pipes transport

We've improved named pipe connection performance. Kestrel's named pipe transport now accepts connections in parallel, and reuses NamedPipeServerStream instances.

Time to create 100,000 connections:

- Before : 5.916 seconds
- After : 2.374 seconds

HTTP/2 over TLS (HTTPS) support on macOS in Kestrel

.NET 8 adds support for Application-Layer Protocol Negotiation (ALPN) to macOS. ALPN is a TLS feature used to negotiate which HTTP protocol a connection will use. For example, ALPN allows browsers and other HTTP clients to request an HTTP/2 connection. This feature is especially useful for gRPC apps, which require HTTP/2. For more information, see Use HTTP/2 with the ASP.NET Core Kestrel web server.

Certificate file watching in Kestrel

TLS certificates configured by path are now monitored for changes when `reloadOnChange` is passed to KestrelServerOptions.Configure(). A change to the certificate file is treated the same way as a change to the configured path (that is, endpoints are reloaded).

Note that file deletions are specifically not tracked since they arise transiently and would crash the server if non-transient.

Warning when specified HTTP protocols won't be used

If TLS is disabled and HTTP/1.x is available, HTTP/2 and HTTP/3 will be disabled, even if they've been specified. This can cause some nasty surprises, so we've added warning output to let you know when it happens.

`HTTP_PORTS` and `HTTPS_PORTS` config keys

Applications and containers are often only given a port to listen on, like 80, without additional constraints like host or path. `HTTP_PORTS` and `HTTPS_PORTS` are new config keys that allow specifying the listening ports for the Kestrel and HTTP.sys servers. These can be defined with the `DOTNET_` or `ASPNETCORE_` environment variable prefixes, or specified directly through any other config input like appsettings.json. Each is a semicolon delimited list of port values. For example:

cli

```
ASPNETCORE_HTTP_PORTS=80;8080
ASPNETCORE_HTTPS_PORTS=443;8081
```

This is shorthand for the following, which specifies the scheme (HTTP or HTTPS) and any host or IP:

```
cli
```

```
ASPNETCORE_URLS=http://*:80/;http://*:8080/;https://*:443/;https://*:8081/
```

For more information, see Configure endpoints for the ASP.NET Core Kestrel web server and HTTP.sys web server implementation in ASP.NET Core.

SNI host name in ITlsHandshakeFeature

The Server Name Indication (SNI) host name is now exposed in the HostName property of the ITlsHandshakeFeature interface.

SNI is part of the TLS handshake process. It allows clients to specify the host name they're attempting to connect to when the server hosts multiple virtual hosts or domains. To present the correct security certificate during the handshake process, the server needs to know the host name selected for each request.

Normally the host name is only handled within the TLS stack and is used to select the matching certificate. But by exposing it, other components in an app can use that information for purposes such as diagnostics, rate limiting, routing, and billing.

Exposing the host name is useful for large-scale services managing thousands of SNI bindings. This feature can significantly improve debugging efficiency during customer escalations. The increased transparency allows for faster problem resolution and enhanced service reliability.

For more information, see ITlsHandshakeFeature.HostName.

IHttpSysRequestTimingFeature

IHttpSysRequestTimingFeature provides detailed timing information for requests when using the HTTP.sys server and In-process hosting with IIS:

- Timestamps are obtained using QueryPerformanceCounter.
- The timestamp frequency can be obtained via QueryPerformanceFrequency.
- The index of the timing can be cast to HttpSysRequestTimingType to know what the timing represents.
- The value might be 0 if the timing isn't available for the current request.

IHttpSysRequestTimingFeature.TryGetTimestamp retrieves the timestamp for the provided timing type:

C#

```
using Microsoft.AspNetCore.Http.Features;
using Microsoft.AspNetCore.Server.HttpSys;
var builder = WebApplication.CreateBuilder(args);

builder.WebHost.UseHttpSys();

var app = builder.Build();

app.Use((context, next) =>
{
    var feature =
context.Features.GetRequiredFeature<IHttpSysRequestTimingFeature>();

    var loggerFactory =
context.RequestServices.GetRequiredService<ILoggerFactory>();
    var logger = loggerFactory.CreateLogger("Sample");

    var timingType = HttpSysRequestTimingType.RequestRoutingEnd;

    if (feature.TryGetTimestamp(timingType, out var timestamp))
    {
        logger.LogInformation("Timestamp {timingType}: {timestamp}",
                                            timingType, timestamp);
    }
    else
    {
        logger.LogInformation("Timestamp {timingType}: not available for the
"
                                             + "current request",
timingType);
    }

    return next(context);
});

app.MapGet("/", () => Results.Ok());

app.Run();
```

For more information, see Get detailed timing information with IHttpSysRequestTimingFeature and Timing information and In-process hosting with IIS.

HTTP.sys: opt-in support for kernel-mode response buffering

In some scenarios, high volumes of small writes with high latency can cause significant performance impact to `HTTP.sys`. This impact is due to the lack of a Pipe buffer in the `HTTP.sys` implementation. To improve performance in these scenarios, support for response buffering has been added to `HTTP.sys`. Enable buffering by setting HttpSysOptions.EnableKernelResponseBuffering to `true`.

Response buffering should be enabled by an app that does synchronous I/O, or asynchronous I/O with no more than one outstanding write at a time. In these scenarios, response buffering can significantly improve throughput over high-latency connections.

Apps that use asynchronous I/O and that can have more than one write outstanding at a time should ***not*** use this flag. Enabling this flag can result in higher CPU and memory usage by HTTP.Sys.

Authentication and authorization

ASP.NET Core 8 adds new features to authentication and authorization.

Identity API endpoints

MapIdentityApi<TUser> is a new extension method that adds two API endpoints (`/register` and `/login`). The main goal of the `MapIdentityApi` is to make it easy for developers to use ASP.NET Core Identity for authentication in JavaScript-based single page apps (SPA) or Blazor apps. Instead of using the default UI provided by ASP.NET Core Identity, which is based on Razor Pages, MapIdentityApi adds JSON API endpoints that are more suitable for SPA apps and nonbrowser apps. For more information, see Identity API endpoints.

IAuthorizationRequirementData

Prior to ASP.NET Core 8, adding a parameterized authorization policy to an endpoint required implementing an:

- `AuthorizeAttribute` for each policy.
- `AuthorizationPolicyProvider` to process a custom policy from a string-based contract.
- `AuthorizationRequirement` for the policy.
- `AuthorizationHandler` for each requirement.

For example, consider the following sample written for ASP.NET Core 7.0:

```
```

C#

```
using AuthRequirementsData.Authorization;
using Microsoft.AspNetCore.Authorization;

var builder = WebApplication.CreateBuilder();

builder.Services.AddAuthentication().AddJwtBearer();
builder.Services.AddAuthorization();
builder.Services.AddControllers();
builder.Services.AddSingleton<IAuthorizationPolicyProvider,
MinimumAgePolicyProvider>();
builder.Services.AddSingleton<IAuthorizationHandler,
MinimumAgeAuthorizationHandler>();

var app = builder.Build();

app.MapControllers();

app.Run();
```

C#

```
using Microsoft.AspNetCore.Mvc;

namespace AuthRequirementsData.Controllers;

[ApiController]
[Route("api/[controller]")]
public class GreetingsController : Controller
{
    [MinimumAgeAuthorize(16)]
    [HttpGet("hello")]
    public string Hello() => $"Hello {(HttpContext.User.Identity?.Name ??
"world")}!";
}
```

C#

```
using Microsoft.AspNetCore.Authorization;
using System.Globalization;
using System.Security.Claims;

namespace AuthRequirementsData.Authorization;

class MinimumAgeAuthorizationHandler :
AuthorizationHandler<MinimumAgeRequirement>
{
    private readonly ILogger<MinimumAgeAuthorizationHandler> _logger;

    public
MinimumAgeAuthorizationHandler(ILogger<MinimumAgeAuthorizationHandler>
```

```
logger)
    {
        _logger = logger;
    }

    // Check whether a given MinimumAgeRequirement is satisfied or not for a
particular
    // context.
    protected override Task
HandleRequirementAsync(AuthorizationHandlerContext context,
                                                MinimumAgeRequirement
requirement)
    {
        // Log as a warning so that it's very clear in sample output which
authorization
        // policies(and requirements/handlers) are in use.
        _logger.LogWarning("Evaluating authorization requirement for age >=
{age}",

requirement.Age);

        // Check the user's age
        var dateOfBirthClaim = context.User.FindFirst(c => c.Type ==

ClaimTypes.DateOfBirth);
        if (dateOfBirthClaim != null)
        {
            // If the user has a date of birth claim, check their age
            var dateOfBirth = Convert.ToDateTime(dateOfBirthClaim.Value,
CultureInfo.InvariantCulture);
            var age = DateTime.Now.Year - dateOfBirth.Year;
            if (dateOfBirth > DateTime.Now.AddYears(-age))
            {
                // Adjust age if the user hasn't had a birthday yet this
year.
                age--;
            }

            // If the user meets the age criterion, mark the authorization
requirement
            // succeeded.
            if (age >= requirement.Age)
            {
                _logger.LogInformation("Minimum age authorization
requirement {age} satisfied",
                                       requirement.Age);
                context.Succeed(requirement);
            }
            else
            {
                _logger.LogInformation("Current user's DateOfBirth claim
({dateOfBirth})" +
                    " does not satisfy the minimum age authorization
requirement {age}",
                    dateOfBirthClaim.Value,
```

```
                    requirement.Age);
            }
        }
        else
        {
            _logger.LogInformation("No DateOfBirth claim present");
        }

        return Task.CompletedTask;
    }
}
```

The complete sample is here in the AspNetCore.Docs.Samples repository.

ASP.NET Core 8 introduces the IAuthorizationRequirementData interface. The `IAuthorizationRequirementData` interface allows the attribute definition to specify the requirements associated with the authorization policy. Using `IAuthorizationRequirementData`, the preceding custom authorization policy code can be written with fewer lines of code. The updated `Program.cs` file:

diff

```
  using AuthRequirementsData.Authorization;
  using Microsoft.AspNetCore.Authorization;

  var builder = WebApplication.CreateBuilder();

  builder.Services.AddAuthentication().AddJwtBearer();
  builder.Services.AddAuthorization();
  builder.Services.AddControllers();
- builder.Services.AddSingleton<IAuthorizationPolicyProvider,
MinimumAgePolicyProvider>();
  builder.Services.AddSingleton<IAuthorizationHandler,
MinimumAgeAuthorizationHandler>();

  var app = builder.Build();

  app.MapControllers();

  app.Run();
```

The updated `MinimumAgeAuthorizationHandler`:

diff

```
using Microsoft.AspNetCore.Authorization;
using System.Globalization;
using System.Security.Claims;

namespace AuthRequirementsData.Authorization;
```

```
- class MinimumAgeAuthorizationHandler :
AuthorizationHandler<MinimumAgeRequirement>
+ class MinimumAgeAuthorizationHandler :
AuthorizationHandler<MinimumAgeAuthorizeAttribute>
{
    private readonly ILogger<MinimumAgeAuthorizationHandler> _logger;

    public
MinimumAgeAuthorizationHandler(ILogger<MinimumAgeAuthorizationHandler>
logger)
    {
        _logger = logger;
    }

    // Check whether a given MinimumAgeRequirement is satisfied or not for a
particular
    // context
    protected override Task
HandleRequirementAsync(AuthorizationHandlerContext context,
-                                           MinimumAgeRequirement
requirement)
+                                           MinimumAgeAuthorizeAttribute
requirement)
    {
        // Remaining code omitted for brevity.
```

The complete updated sample can be found here.

See Custom authorization policies with IAuthorizationRequirementData for a detailed examination of the new sample.

Securing Swagger UI endpoints

Swagger UI endpoints can now be secured in production environments by calling MapSwagger().RequireAuthorization. For more information, see Securing Swagger UI endpoints

Miscellaneous

The following sections describe miscellaneous new features in ASP.NET Core 8.

Keyed services support in Dependency Injection

Keyed services refers to a mechanism for registering and retrieving Dependency Injection (DI) services using keys. A service is associated with a key by calling AddKeyedSingleton (or `AddKeyedScoped` or `AddKeyedTransient`) to register it. Access a registered service by

specifying the key with the [FromKeyedServices] attribute. The following code shows how to use keyed services:

C#

```
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.SignalR;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddKeyedSingleton<ICache, BigCache>("big");
builder.Services.AddKeyedSingleton<ICache, SmallCache>("small");
builder.Services.AddControllers();

var app = builder.Build();

app.MapGet("/big", ([FromKeyedServices("big")] ICache bigCache) =>
bigCache.Get("date"));
app.MapGet("/small", ([FromKeyedServices("small")] ICache smallCache) =>

smallCache.Get("date"));

app.MapControllers();

app.Run();

public interface ICache
{
    object Get(string key);
}
public class BigCache : ICache
{
    public object Get(string key) => $"Resolving {key} from big cache.";
}

public class SmallCache : ICache
{
    public object Get(string key) => $"Resolving {key} from small cache.";
}

[ApiController]
[Route("/cache")]
public class CustomServicesApiController : Controller
{
    [HttpGet("big-cache")]
    public ActionResult<object> GetOk([FromKeyedServices("big")] ICache
cache)
    {
        return cache.Get("data-mvc");
    }
}

public class MyHub : Hub
{
```

```
    public void Method([FromKeyedServices("small")] ICache cache)
    {
        Console.WriteLine(cache.Get("signalr"));
    }
}
```

Visual Studio project templates for SPA apps with ASP.NET Core backend

Visual Studio project templates are now the recommended way to create single-page apps (SPAs) that have an ASP.NET Core backend. Templates are provided that create apps based on the JavaScript frameworks Angular, React, and Vue. These templates:

- Create a Visual Studio solution with a frontend project and a backend project.
- Use the Visual Studio project type for JavaScript and TypeScript (*.esproj*) for the frontend.
- Use an ASP.NET Core project for the backend.

For more information about the Visual Studio templates and how to access the legacy templates, see Overview of Single Page Apps (SPAs) in ASP.NET Core

Support for generic attributes

Attributes that previously required a Type parameter are now available in cleaner generic variants. This is made possible by support for generic attributes in C# 11. For example, the syntax for annotating the response type of an action can be modified as follows:

diff

```
[ApiController]
[Route("api/[controller]")]
public class TodosController : Controller
{
  [HttpGet("/")]
- [ProducesResponseType(typeof(Todo), StatusCodes.Status200OK)]
+ [ProducesResponseType<Todo>(StatusCodes.Status200OK)]
  public Todo Get() => new Todo(1, "Write a sample", DateTime.Now, false);
}
```

Generic variants are supported for the following attributes:

- `[ProducesResponseType<T>]`

- `[Produces<T>]`
- `[MiddlewareFilter<T>]`
- `[ModelBinder<T>]`
- `[ModelMetadataType<T>]`
- `[ServiceFilter<T>]`
- `[TypeFilter<T>]`

Code analysis in ASP.NET Core apps

The new analyzers shown in the following table are available in ASP.NET Core 8.0.

Expand table

Diagnostic ID	Breaking or nonbreaking	Description
ASP0016	Nonbreaking	Don't return a value from RequestDelegate
ASP0019	Nonbreaking	Suggest using IHeaderDictionary.Append or the indexer
ASP0020	Nonbreaking	Complex types referenced by route parameters must be parsable
ASP0021	Nonbreaking	The return type of the BindAsync method must be `ValueTask<T>`
ASP0022	Nonbreaking	Route conflict detected between route handlers
ASP0023	Nonbreaking	MVC: Route conflict detected between route handlers
ASP0024	Nonbreaking	Route handler has multiple parameters with the `[FromBody]` attribute
ASP0025	Nonbreaking	Use AddAuthorizationBuilder

Route tooling

ASP.NET Core is built on routing. Minimal APIs, Web APIs, Razor Pages, and Blazor all use routes to customize how HTTP requests map to code.

In .NET 8 we've invested in a suite of new features to make routing easier to learn and use. These new features include:

- Route syntax highlighting
- Autocomplete of parameter and route names

- Autocomplete of route constraints
- Route analyzers and fixers
  - Route syntax analyzer
  - Mismatched parameter optionality analyzer and fixer
  - Ambiguous Minimal API and Web API route analyzer
- Support for Minimal APIs, Web APIs, and Blazor

For more information, see Route tooling in .NET 8.

ASP.NET Core metrics

Metrics are measurements reported over time and are most often used to monitor the health of an app and to generate alerts. For example, a counter that reports failed HTTP requests could be displayed in dashboards or generate alerts when failures pass a threshold.

This preview adds new metrics throughout ASP.NET Core using System.Diagnostics.Metrics. `Metrics` is a modern API for reporting and collecting information about apps.

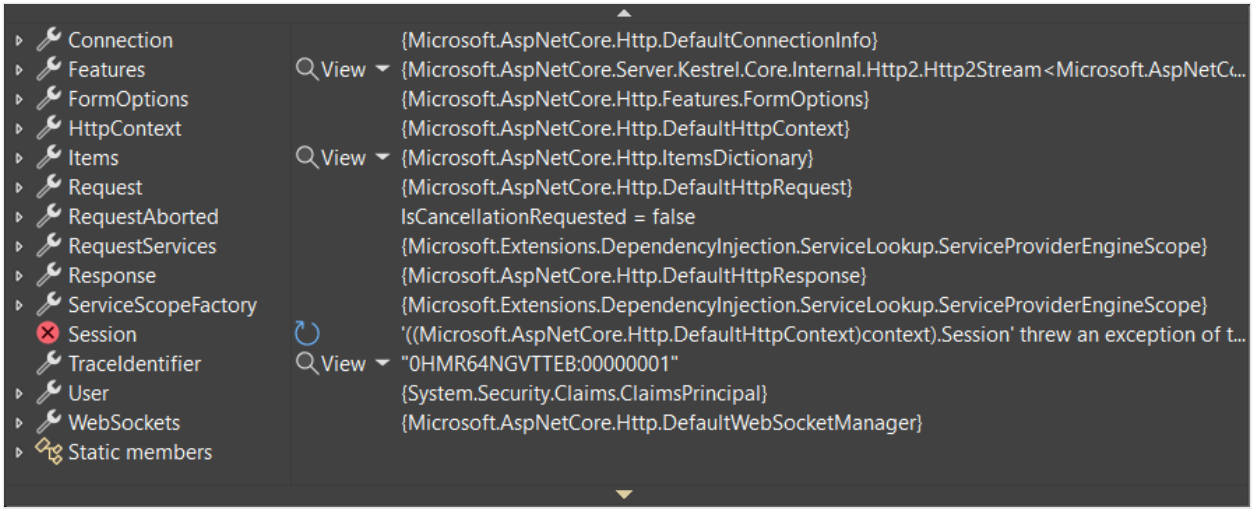
Metrics offers many improvements compared to existing event counters:

- New kinds of measurements with counters, gauges and histograms.
- Powerful reporting with multi-dimensional values.
- Integration into the wider cloud native ecosystem by aligning with OpenTelemetry standards.

Metrics have been added for ASP.NET Core hosting, Kestrel, and SignalR. For more information, see System.Diagnostics.Metrics.

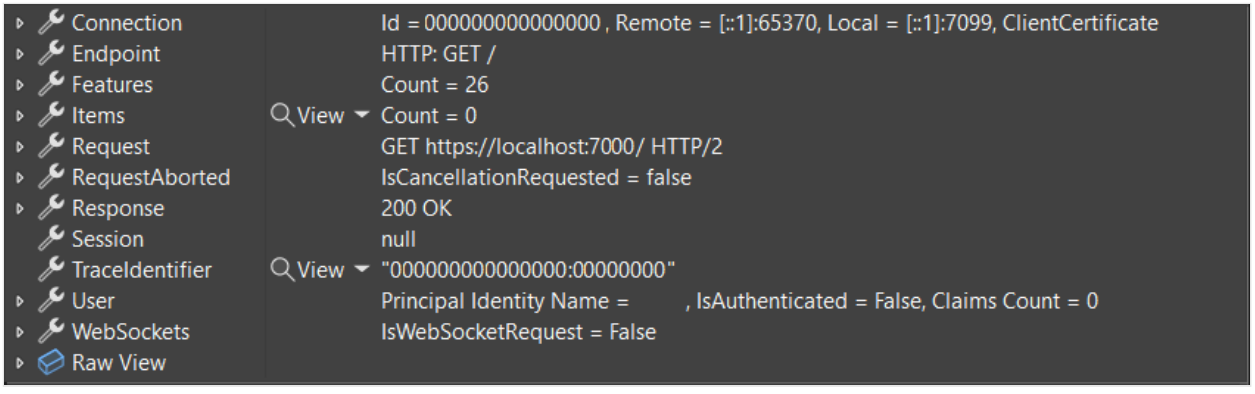
IExceptionHandler

IExceptionHandler is a new interface that gives the developer a callback for handling known exceptions in a central location.



`IExceptionHandler` implementations are registered by calling IServiceCollection.AddExceptionHandler<T>. Multiple implementations can be added, and they're called in the order registered. If an exception handler handles a request, it can return `true` to stop processing. If an exception isn't handled by any exception handler, then control falls back to the default behavior and options from the middleware.

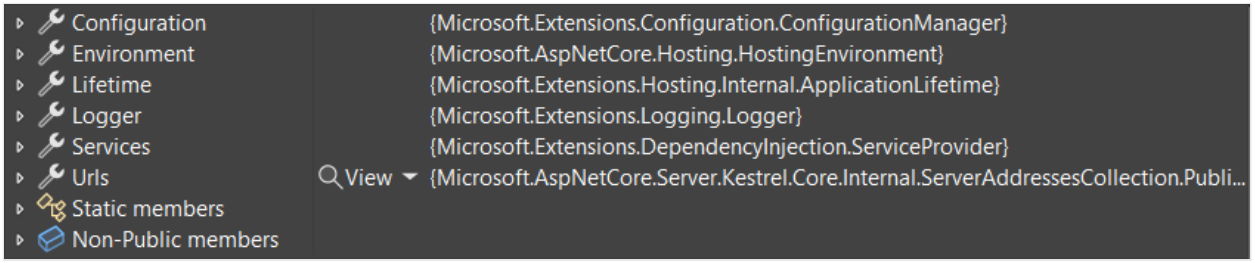
For more information, see IExceptionHandler.



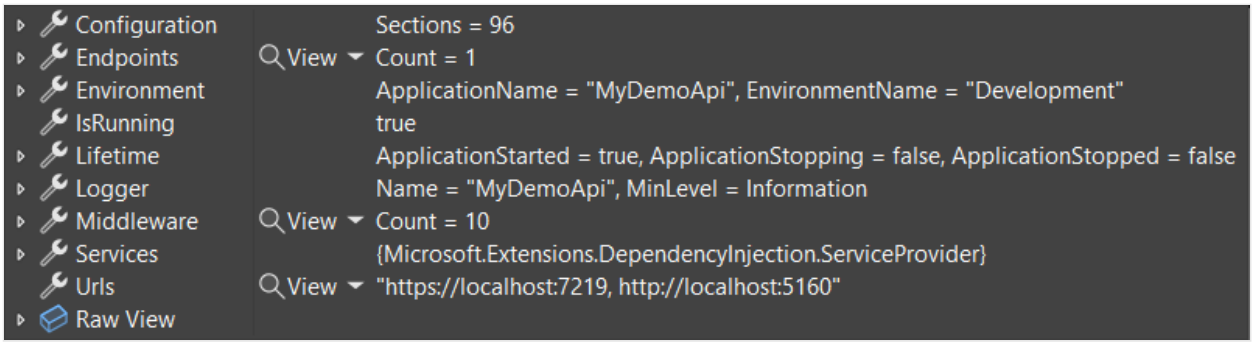
Improved debugging experience

Debug customization attributes have been added to types like `HttpContext`, `HttpRequest`, `HttpResponse`, `ClaimsPrincipal`, and `WebApplication`. The enhanced debugger displays for these types make finding important information easier in an IDE's debugger. The following screenshots show the difference that these attributes make in the debugger's display of `HttpContext`.

.NET 7:



.NET 8:



The debugger display for `WebApplication` highlights important information such as configured endpoints, middleware, and `IConfiguration` values.

.NET 7:

.NET 8:

For more information about debugging improvements in .NET 8, see:

- Debugging Enhancements in .NET 8
- GitHub issue dotnet/aspnetcore 48205

`IPNetwork.Parse` and `TryParse`

The new Parse and TryParse methods on IPNetwork add support for creating an `IPNetwork` by using an input string in CIDR notation or "slash notation".

Here are IPv4 examples:

C#

```
// Using Parse
var network = IPNetwork.Parse("192.168.0.1/32");
```

C#

```
// Using TryParse
bool success = IPNetwork.TryParse("192.168.0.1/32", out var network);
```

C#

```
// Constructor equivalent
var network = new IPNetwork(IPAddress.Parse("192.168.0.1"), 32);
```

And here are examples for IPv6:

C#

```
// Using Parse
var network = IPNetwork.Parse("2001:db8:3c4d::1/128");
```

C#

```
// Using TryParse
bool success = IPNetwork.TryParse("2001:db8:3c4d::1/128", out var network);
```

C#

```
// Constructor equivalent
var network = new IPNetwork(IPAddress.Parse("2001:db8:3c4d::1"), 128);
```

Redis-based output caching

ASP.NET Core 8 adds support for using Redis as a distributed cache for output caching. Output caching is a feature that enables an app to cache the output of a minimal API endpoint, controller action, or Razor Page. For more information, see Output caching.

Short-circuit middleware after routing

When routing matches an endpoint, it typically lets the rest of the middleware pipeline run before invoking the endpoint logic. Services can reduce resource usage by filtering out known requests early in the pipeline. Use the ShortCircuit extension method to cause routing to invoke the endpoint logic immediately and then end the request. For example, a given route might not need to go through authentication or CORS middleware. The following example short-circuits requests that match the `/short-circuit` route:

C#

```
app.MapGet("/short-circuit", () => "Short circuiting!").ShortCircuit();
```

Use the MapShortCircuit method to set up short-circuiting for multiple routes at once, by passing to it a params array of URL prefixes. For example, browsers and bots often probe servers for well known paths like `robots.txt` and `favicon.ico`. If the app doesn't have those files, one line of code can configure both routes:

C#

```
app.MapShortCircuit(404, "robots.txt", "favicon.ico");
```

For more information, see Short-circuit middleware after routing.

HTTP logging middleware extensibility

The HTTP logging middleware has several new capabilities:

- HttpLoggingFields.Duration: When enabled, the middleware emits a new log at the end of the request and response that measures the total time taken for processing. This new field has been added to the HttpLoggingFields.All set.
- HttpLoggingOptions.CombineLogs: When enabled, the middleware consolidates all of its enabled logs for a request and response into one log at the end. A single log message includes the request, request body, response, response body, and duration.
- IHttpLoggingInterceptor: A new interface for a service that can be implemented and registered (using AddHttpLoggingInterceptor) to receive per-request and per-response callbacks for customizing what details get logged. Any endpoint-specific log settings are applied first and can then be overridden in these callbacks. An implementation can:
  - Inspect a request and response.
  - Enable or disable any HttpLoggingFields.
  - Adjust how much of the request or response body is logged.
  - Add custom fields to the logs.

For more information, see HTTP logging in .NET Core and ASP.NET Core.

New APIs in ProblemDetails to support more resilient integrations

In .NET 7, the ProblemDetails service was introduced to improve the experience for generating error responses that comply with the ProblemDetails specification. In .NET 8, a new API was added to make it easier to implement fallback behavior if IProblemDetailsService isn't able to generate ProblemDetails. The following example illustrates use of the new TryWriteAsync API:

C#

```
var builder = WebApplication.CreateBuilder(args);
builder.Services.AddProblemDetails();

var app = builder.Build();

app.UseExceptionHandler(exceptionHandlerApp =>
{
    exceptionHandlerApp.Run(async httpContext =>
    {
        var pds =
```

```
httpContext.RequestServices.GetService<IProblemDetailsService>();
        if (pds == null
            || !await pds.TryWriteAsync(new() { HttpContext = httpContext
}))
        {
            // Fallback behavior
            await httpContext.Response.WriteAsync("Fallback: An error
occurred.");
        }
    });
});

app.MapGet("/exception", () =>
{
    throw new InvalidOperationException("Sample Exception");
});

app.MapGet("/", () => "Test by calling /exception");

app.Run();
```

For more information, see IProblemDetailsService fallback

What's new in ASP.NET Core 7.0

Article • 09/27/2024

This article highlights the most significant changes in ASP.NET Core 7.0 with links to relevant documentation.

Rate limiting middleware in ASP.NET Core

The `Microsoft.AspNetCore.RateLimiting` middleware provides rate limiting middleware. Apps configure rate limiting policies and then attach the policies to endpoints. For more information, see Rate limiting middleware in ASP.NET Core.

Authentication uses single scheme as DefaultScheme

As part of the work to simplify authentication, when there's only a single authentication scheme registered, it's automatically used as the DefaultScheme and doesn't need to be specified. For more information, see DefaultScheme.

MVC and Razor pages

Support for nullable models in MVC views and Razor Pages

Nullable page or view models are supported to improve the experience when using null state checking with ASP.NET Core apps:

```
C#

@model Product?
```

Bind with `IParsable<T>.TryParse` in MVC and API Controllers

The IParsable<TSelf>.TryParse API supports binding controller action parameter values. For more information, see Bind with IParsable<T>.TryParse.

Customize the cookie consent value

In ASP.NET Core versions earlier than 7, the cookie consent validation uses the cookie value `yes` to indicate consent. Now you can specify the value that represents consent. For example, you could use `true` instead of `yes`:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();
builder.Services.Configure<CookiePolicyOptions>(options =>
{
    options.CheckConsentNeeded = context => true;
    options.MinimumSameSitePolicy = SameSiteMode.None;
    options.ConsentCookieValue = "true";
});

var app = builder.Build();
```

For more information, see Customize the cookie consent value.

API controllers

Parameter binding with DI in API controllers

Parameter binding for API controller actions binds parameters through dependency injection when the type is configured as a service. This means it's no longer required to explicitly apply the [FromServices] attribute to a parameter. In the following code, both actions return the time:

C#

```
[Route("[controller]")]
[ApiController]
public class MyController : ControllerBase
{
    public ActionResult GetWithAttribute([FromServices] IDateTime dateTime)
                                                        => Ok(dateTime.Now);

    [Route("noAttribute")]
    public ActionResult Get(IDateTime dateTime) => Ok(dateTime.Now);
}
```

In rare cases, automatic DI can break apps that have a type in DI that is also accepted in an API controllers action method. It's not common to have a type in DI and as an argument in an API controller action. To disable automatic binding of parameters, set DisableImplicitFromServicesParameters

C#

```
using Microsoft.AspNetCore.Mvc;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddControllers();
builder.Services.AddSingleton<IDateTime, SystemDateTime>();

builder.Services.Configure<ApiBehaviorOptions>(options =>
{
    options.DisableImplicitFromServicesParameters = true;
});

var app = builder.Build();

app.MapControllers();

app.Run();
```

In ASP.NET Core 7.0, types in DI are checked at app startup with IServiceProviderIsService to determine if an argument in an API controller action comes from DI or from the other sources.

The new mechanism to infer binding source of API Controller action parameters uses the following rules:

1. A previously specified BindingInfo.BindingSource is never overwritten.
2. A complex type parameter, registered in the DI container, is assigned BindingSource.Services.
3. A complex type parameter, not registered in the DI container, is assigned BindingSource.Body.
4. A parameter with a name that appears as a route value in ***any*** route template is assigned BindingSource.Path.
5. All other parameters are BindingSource.Query.

JSON property names in validation errors

By default, when a validation error occurs, model validation produces a ModelStateDictionary with the property name as the error key. Some apps, such as single page apps, benefit from using JSON property names for validation errors

generated from Web APIs. The following code configures validation to use the SystemTextJsonValidationMetadataProvider to use JSON property names:

C#

```
using Microsoft.AspNetCore.Mvc.ModelBinding.Metadata;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddControllers(options =>
{
    options.ModelMetadataDetailsProviders.Add(new
SystemTextJsonValidationMetadataProvider());
});

var app = builder.Build();

app.UseHttpsRedirection();

app.UseAuthorization();

app.MapControllers();

app.Run();
```

The following code configures validation to use the NewtonsoftJsonValidationMetadataProvider to use JSON property name when using Json.NET:

C#

```
using Microsoft.AspNetCore.Mvc.NewtonsoftJson;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddControllers(options =>
{
    options.ModelMetadataDetailsProviders.Add(new
NewtonsoftJsonValidationMetadataProvider());
}).AddNewtonsoftJson();

var app = builder.Build();

app.UseHttpsRedirection();

app.UseAuthorization();

app.MapControllers();

app.Run();
```

For more information, see Use JSON property names in validation errors

Minimal APIs

Filters in Minimal API apps

Minimal API filters allow developers to implement business logic that supports:

- Running code before and after the route handler.
- Inspecting and modifying parameters provided during a route handler invocation.
- Intercepting the response behavior of a route handler.

Filters can be helpful in the following scenarios:

- Validating the request parameters and body that are sent to an endpoint.
- Logging information about the request and response.
- Validating that a request is targeting a supported API version.

For more information, see Filters in Minimal API apps

Bind arrays and string values from headers and query strings

In ASP.NET 7, binding query strings to an array of primitive types, string arrays, and StringValues is supported:

C#

```
// Bind query string values to a primitive type array.
// GET  /tags?q=1&q=2&q=3
app.MapGet("/tags", (int[] q) =>
                      $"tag1: {q[0]} , tag2: {q[1]}, tag3: {q[2]}");

// Bind to a string array.
// GET /tags2?names=john&names=jack&names=jane
app.MapGet("/tags2", (string[] names) =>
            $"tag1: {names[0]} , tag2: {names[1]}, tag3: {names[2]}");

// Bind to StringValues.
// GET /tags3?names=john&names=jack&names=jane
app.MapGet("/tags3", (StringValues names) =>
            $"tag1: {names[0]} , tag2: {names[1]}, tag3: {names[2]}");
```

Binding query strings or header values to an array of complex types is supported when the type has `TryParse` implemented. For more information, see Bind arrays and string

values from headers and query strings.

For more information, see Add endpoint summary or description.

Bind the request body as a `Stream` or `PipeReader`

The request body can bind as a Stream or PipeReader to efficiently support scenarios where the user has to process data and:

- Store the data to blob storage or enqueue the data to a queue provider.
- Process the stored data with a worker process or cloud function.

For example, the data might be enqueued to Azure Queue storage or stored in Azure Blob storage.

For more information, see Bind the request body as a Stream or PipeReader

New Results.Stream overloads

We introduced new Results.Stream overloads to accommodate scenarios that need access to the underlying HTTP response stream without buffering. These overloads also improve cases where an API streams data to the HTTP response stream, like from Azure Blob Storage. The following example uses ImageSharp to return a reduced size of the specified image:

C#

```
using SixLabors.ImageSharp;
using SixLabors.ImageSharp.Formats.Jpeg;
using SixLabors.ImageSharp.Processing;

var builder = WebApplication.CreateBuilder(args);

var app = builder.Build();

app.MapGet("/process-image/{strImage}", (string strImage, HttpContext http,
CancellationToken token) =>
{
    http.Response.Headers.CacheControl = $"public,max-age=
{TimeSpan.FromHours(24).TotalSeconds}";
    return Results.Stream(stream => ResizeImageAsync(strImage, stream,
token), "image/jpeg");
});

async Task ResizeImageAsync(string strImage, Stream stream,
CancellationToken token)
{
    var strPath = $"wwwroot/img/{strImage}";
```

```
    using var image = await Image.LoadAsync(strPath, token);
    int width = image.Width / 2;
    int height = image.Height / 2;
    image.Mutate(x =>x.Resize(width, height));
    await image.SaveAsync(stream, JpegFormat.Instance, cancellationToken:
token);
}
```

For more information, see Stream examples

Typed results for minimal APIs

In .NET 6, the IResult interface was introduced to represent values returned from minimal APIs that don't utilize the implicit support for JSON serializing the returned object to the HTTP response. The static Results class is used to create varying `IResult` objects that represent different types of responses. For example, setting the response status code or redirecting to another URL. The `IResult` implementing framework types returned from these methods were internal however, making it difficult to verify the specific `IResult` type being returned from methods in a unit test.

In .NET 7 the types implementing `IResult` are public, allowing for type assertions when testing. For example:

C#

```
[TestClass()]
public class WeatherApiTests
{
    [TestMethod()]
    public void MapWeatherApiTest()
    {
        var result = WeatherApi.GetAllWeathers();
        Assert.IsInstanceOfType(result, typeof(Ok<WeatherForecast[]>));
    }
}
```

Improved unit testability for minimal route handlers

IResult implementation types are now publicly available in the Microsoft.AspNetCore.Http.HttpResults namespace. The `IResult` implementation types can be used to unit test minimal route handlers when using named methods instead of lambdas.

The following code uses the Ok<TValue> class:

C#

```
[Fact]
public async Task GetTodoReturnsTodoFromDatabase()
{
    // Arrange
    await using var context = new MockDb().CreateDbContext();

    context.Todos.Add(new Todo
    {
        Id = 1,
        Title = "Test title",
        Description = "Test description",
        IsDone = false
    });

    await context.SaveChangesAsync();

    // Act
    var result = await TodoEndpointsV1.GetTodo(1, context);

    //Assert
    Assert.IsType<Results<Ok<Todo>, NotFound>>(result);

    var okResult = (Ok<Todo>)result.Result;

    Assert.NotNull(okResult.Value);
    Assert.Equal(1, okResult.Value.Id);
}
```

For more information, see IResult implementation types.

New HttpResult interfaces

The following interfaces in the Microsoft.AspNetCore.Http namespace provide a way to detect the `IResult` type at runtime, which is a common pattern in filter implementations:

- IContentTypeHttpResult
- IFileHttpResult
- INestedHttpResult
- IStatusCodeHttpResult
- IValueHttpResult
- IValueHttpResult<TValue>

For more information, see IHttpResult interfaces.

OpenAPI improvements for minimal APIs

`Microsoft.AspNetCore.OpenApi` NuGet package

The Microsoft.AspNetCore.OpenApi package allows interactions with OpenAPI specifications for endpoints. The package acts as a link between the OpenAPI models that are defined in the `Microsoft.AspNetCore.OpenApi` package and the endpoints that are defined in Minimal APIs. The package provides an API that examines an endpoint's parameters, responses, and metadata to construct an OpenAPI annotation type that is used to describe an endpoint.

C#

```
app.MapPost("/todoitems/{id}", async (int id, Todo todo, TodoDb db) =>
{
    todo.Id = id;
    db.Todos.Add(todo);
    await db.SaveChangesAsync();

    return Results.Created($"/todoitems/{todo.Id}", todo);
})
.WithOpenApi();
```

Call `WithOpenApi` with parameters

The WithOpenApi method accepts a function that can be used to modify the OpenAPI annotation. For example, in the following code, a description is added to the first parameter of the endpoint:

C#

```
app.MapPost("/todo2/{id}", async (int id, Todo todo, TodoDb db) =>
{
    todo.Id = id;
    db.Todos.Add(todo);
    await db.SaveChangesAsync();

    return Results.Created($"/todoitems/{todo.Id}", todo);
})
.WithOpenApi(generatedOperation =>
{
    var parameter = generatedOperation.Parameters[0];
    parameter.Description = "The ID associated with the created Todo";
    return generatedOperation;
});
```

Provide endpoint descriptions and summaries

Minimal APIs now support annotating operations with descriptions and summaries for OpenAPI spec generation. You can call extension methods WithDescription and WithSummary or use attributes [EndpointDescription] and [EndpointSummary]).

For more information, see OpenAPI in minimal API apps

File uploads using IFormFile and IFormFileCollection

Minimal APIs now support file upload with `IFormFile` and `IFormFileCollection`. The following code uses IFormFile and IFormFileCollection to upload file:

C#

```
var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

app.MapGet("/", () => "Hello World!");

app.MapPost("/upload", async (IFormFile file) =>
{
    var tempFile = Path.GetTempFileName();
    app.Logger.LogInformation(tempFile);
    using var stream = File.OpenWrite(tempFile);
    await file.CopyToAsync(stream);
});

app.MapPost("/upload_many", async (IFormFileCollection myFiles) =>
{
    foreach (var file in myFiles)
    {
        var tempFile = Path.GetTempFileName();
        app.Logger.LogInformation(tempFile);
        using var stream = File.OpenWrite(tempFile);
        await file.CopyToAsync(stream);
    }
});

app.Run();
```

Authenticated file upload requests are supported using an Authorization header, a client certificate, or a cookie header.

There is no built-in support for antiforgery. However, it can be implemented using the IAntiforgery service.

`[AsParameters]` attribute enables parameter binding for argument lists

The [AsParameters] attribute enables parameter binding for argument lists. For more information, see Parameter binding for argument lists with [AsParameters].

Minimal APIs and API controllers

New problem details service

The problem details service implements the IProblemDetailsService interface, which supports creating Problem Details for HTTP APIs.

For more information, see Problem details service.

Route groups

The MapGroup extension method helps organize groups of endpoints with a common prefix. It reduces repetitive code and allows for customizing entire groups of endpoints with a single call to methods like RequireAuthorization and WithMetadata which add endpoint metadata.

For example, the following code creates two similar groups of endpoints:

C#

```
app.MapGroup("/public/todos")
    .MapTodosApi()
    .WithTags("Public");

app.MapGroup("/private/todos")
    .MapTodosApi()
    .WithTags("Private")
    .AddEndpointFilterFactory(QueryPrivateTodos)
    .RequireAuthorization();

EndpointFilterDelegate QueryPrivateTodos(EndpointFilterFactoryContext
factoryContext, EndpointFilterDelegate next)
{
    var dbContextIndex = -1;

    foreach (var argument in factoryContext.MethodInfo.GetParameters())
    {
        if (argument.ParameterType == typeof(TodoDb))
        {
            dbContextIndex = argument.Position;
            break;
        }
    }
```

```
    // Skip filter if the method doesn't have a TodoDb parameter.
    if (dbContextIndex < 0)
    {
        return next;
    }

    return async invocationContext =>
    {
        var dbContext = invocationContext.GetArgument<TodoDb>
(dbContextIndex);
        dbContext.IsPrivate = true;

        try
        {
            return await next(invocationContext);
        }
        finally
        {
            // This should only be relevant if you're pooling or otherwise
reusing the DbContext instance.
            dbContext.IsPrivate = false;
        }
    };
}
```

C#

```
public static RouteGroupBuilder MapTodosApi(this RouteGroupBuilder group)
{
    group.MapGet("/", GetAllTodos);
    group.MapGet("/{id}", GetTodo);
    group.MapPost("/", CreateTodo);
    group.MapPut("/{id}", UpdateTodo);
    group.MapDelete("/{id}", DeleteTodo);

    return group;
}
```

In this scenario, you can use a relative address for the `Location` header in the `201 Created` result:

C#

```
public static async Task<Created<Todo>> CreateTodo(Todo todo, TodoDb
database)
{
    await database.AddAsync(todo);
    await database.SaveChangesAsync();
```

```
    return TypedResults.Created($"{todo.Id}", todo);
}
```

The first group of endpoints will only match requests prefixed with `/public/todos` and are accessible without any authentication. The second group of endpoints will only match requests prefixed with `/private/todos` and require authentication.

The `QueryPrivateTodos` endpoint filter factory is a local function that modifies the route handler's `TodoDb` parameters to allow to access and store private todo data.

Route groups also support nested groups and complex prefix patterns with route parameters and constraints. In the following example, and route handler mapped to the `user` group can capture the `{org}` and `{group}` route parameters defined in the outer group prefixes.

The prefix can also be empty. This can be useful for adding endpoint metadata or filters to a group of endpoints without changing the route pattern.

C#

```
var all = app.MapGroup("").WithOpenApi();
var org = all.MapGroup("{org}");
var user = org.MapGroup("{user}");
user.MapGet("", (string org, string user) => $"{org}/{user}");
```

Adding filters or metadata to a group behaves the same way as adding them individually to each endpoint before adding any extra filters or metadata that may have been added to an inner group or specific endpoint.

C#

```
var outer = app.MapGroup("/outer");
var inner = outer.MapGroup("/inner");

inner.AddEndpointFilter((context, next) =>
{
    app.Logger.LogInformation("/inner group filter");
    return next(context);
});

outer.AddEndpointFilter((context, next) =>
{
    app.Logger.LogInformation("/outer group filter");
    return next(context);
});

inner.MapGet("/", () => "Hi!").AddEndpointFilter((context, next) =>
```

```
{
    app.Logger.LogInformation("MapGet filter");
    return next(context);
});
```

In the above example, the outer filter will log the incoming request before the inner filter even though it was added second. Because the filters were applied to different groups, the order they were added relative to each other does not matter. The order filters are added does matter if applied to the same group or specific endpoint.

A request to `/outer/inner/` will log the following:

.NET CLI

```
/outer group filter
/inner group filter
MapGet filter
```

gRPC

JSON transcoding

gRPC JSON transcoding is an extension for ASP.NET Core that creates RESTful JSON APIs for gRPC services. gRPC JSON transcoding allows:

- Apps to call gRPC services with familiar HTTP concepts.
- ASP.NET Core gRPC apps to support both gRPC and RESTful JSON APIs without replicating functionality.
- Experimental support for generating OpenAPI from transcoded RESTful APIs by integrating with Swashbuckle.

For more information, see gRPC JSON transcoding in ASP.NET Core gRPC apps and Use OpenAPI with gRPC JSON transcoding ASP.NET Core apps.

gRPC health checks in ASP.NET Core

The gRPC health checking protocol is a standard for reporting the health of gRPC server apps. An app exposes health checks as a gRPC service. They are typically used with an external monitoring service to check the status of an app.

gRPC ASP.NET Core has added built-in support for gRPC health checks with the Grpc.AspNetCore.HealthChecks package. Results from .NET health checks are

reported to callers.

For more information, see gRPC health checks in ASP.NET Core.

Improved call credentials support

Call credentials are the recommended way to configure a gRPC client to send an auth token to the server. gRPC clients support two new features to make call credentials easier to use:

- Support for call credentials with plaintext connections. Previously, a gRPC call only sent call credentials if the connection was secured with TLS. A new setting on `GrpcChannelOptions`, called `UnsafeUseInsecureChannelCallCredentials`, allows this behavior to be customized. There are security implications to not securing a connection with TLS.
- A new method called `AddCallCredentials` is available with the gRPC client factory. `AddCallCredentials` is a quick way to configure call credentials for a gRPC client and integrates well with dependency injection (DI).

The following code configures the gRPC client factory to send `Authorization` metadata:

C#

```
builder.Services
    .AddGrpcClient<Greeter.GreeterClient>(o =>
    {
       o.Address = new Uri("https://localhost:5001");
    })
    .AddCallCredentials((context, metadata) =>
    {
       if (!string.IsNullOrEmpty(_token))
       {
          metadata.Add("Authorization", $"Bearer {_token}");
       }
       return Task.CompletedTask;
    });
```

For more information, see Configure a bearer token with the gRPC client factory.

SignalR

Client results

The server now supports requesting a result from a client. This requires the server to use `ISingleClientProxy.InvokeAsync` and the client to return a result from its `.On` handler. Strongly-typed hubs can also return values from interface methods.

For more information, see Client results

Dependency injection for SignalR hub methods

SignalR hub methods now support injecting services through dependency injection (DI).

Hub constructors can accept services from DI as parameters, which can be stored in properties on the class for use in a hub method. For more information, see Inject services into a hub

Blazor

Handle location changing events and navigation state

In .NET 7, Blazor supports location changing events and maintaining navigation state. This allows you to warn users about unsaved work or to perform related actions when the user performs a page navigation.

For more information, see the following sections of the *Routing and navigation* article:

- Navigation options
- Handle/prevent location changes

Empty Blazor project templates

Blazor has two new project templates for starting from a blank slate. The new **Blazor Server App Empty** and **Blazor WebAssembly App Empty** project templates are just like their non-empty counterparts but without example code. These empty templates only include a basic home page, and we've removed Bootstrap so that you can start with a different CSS framework.

For more information, see the following articles:

- Tooling for ASP.NET Core Blazor
- ASP.NET Core Blazor project structure

Blazor custom elements

The Microsoft.AspNetCore.Components.CustomElements package enables building standards based custom DOM elements using Blazor.

For more information, see ASP.NET Core Razor components.

Bind modifiers (`@bind:after`, `@bind:get`, `@bind:set`)

> **Important**
>
> The `@bind:after`/`@bind:get`/`@bind:set` features are receiving further updates at this time. To take advantage of the latest updates, confirm that you've installed the latest SDK.
>
> Using an event callback parameter (`[Parameter] public EventCallback<string> ValueChanged { get; set; }`) isn't supported. Instead, pass an Action-returning or Task-returning method to `@bind:set`/`@bind:after`.
>
> For more information, see the following resources:
>
> - Blazor @bind:after not working on .NET 7 RTM release (dotnet/aspnetcore #44957)
> - BindGetSetAfter701 sample app (javiercn/BindGetSetAfter701 GitHub repository)

In .NET 7, you can run asynchronous logic after a binding event has completed using the new `@bind:after` modifier. In the following example, the `PerformSearch` asynchronous method runs automatically after any changes to the search text are detected:

razor

```
<input @bind="searchText" @bind:after="PerformSearch" />

@code {
    private string searchText;

    private async Task PerformSearch()
    {
        ...
    }
}
```

In .NET 7, it's also easier to set up binding for component parameters. Components can support two-way data binding by defining a pair of parameters:

- `@bind:get`: Specifies the value to bind.
- `@bind:set`: Specifies a callback for when the value changes.

The `@bind:get` and `@bind:set` modifiers are always used together.

Examples:

razor

```
@* Elements *@

<input type="text" @bind="text" @bind:after="() => { }" />

<input type="text" @bind:get="text" @bind:set="(value) => { }" />

<input type="text" @bind="text" @bind:after="AfterAsync" />

<input type="text" @bind:get="text" @bind:set="SetAsync" />

<input type="text" @bind="text" @bind:after="() => { }" />

<input type="text" @bind:get="text" @bind:set="(value) => { }" />

<input type="text" @bind="text" @bind:after="AfterAsync" />

<input type="text" @bind:get="text" @bind:set="SetAsync" />

@* Components *@

<InputText @bind-Value="text" @bind-Value:after="() => { }" />

<InputText @bind-Value:get="text" @bind-Value:set="(value) => { }" />

<InputText @bind-Value="text" @bind-Value:after="AfterAsync" />

<InputText @bind-Value:get="text" @bind-Value:set="SetAsync" />

<InputText @bind-Value="text" @bind-Value:after="() => { }" />

<InputText @bind-Value:get="text" @bind-Value:set="(value) => { }" />

<InputText @bind-Value="text" @bind-Value:after="AfterAsync" />

<InputText @bind-Value:get="text" @bind-Value:set="SetAsync" />

@code {
    private string text = "";

    private void After(){}
    private void Set() {}
    private Task AfterAsync() { return Task.CompletedTask; }
```

```
    private Task SetAsync(string value) { return Task.CompletedTask; }
}
```

For more information on the `InputText` component, see ASP.NET Core Blazor input components.

Hot Reload improvements

In .NET 7, Hot Reload support includes the following:

- Components reset their parameters to their default values when a value is removed.
- Blazor WebAssembly:
  - Add new types.
  - Add nested classes.
  - Add static and instance methods to existing types.
  - Add static fields and methods to existing types.
  - Add static lambdas to existing methods.
  - Add lambdas that capture `this` to existing methods that already captured `this` previously.

Dynamic authentication requests with MSAL in Blazor WebAssembly

New in .NET 7, Blazor WebAssembly supports creating dynamic authentication requests at runtime with custom parameters to handle advanced authentication scenarios.

For more information, see the following articles:

- Secure ASP.NET Core Blazor WebAssembly
- ASP.NET Core Blazor WebAssembly additional security scenarios

Blazor WebAssembly debugging improvements

Blazor WebAssembly debugging has the following improvements:

- Support for the **Just My Code** setting to show or hide type members that aren't from user code.
- Support for inspecting multidimensional arrays.
- **Call Stack** now shows the correct name for asynchronous methods.
- Improved expression evaluation.
- Correct handling of the `new` keyword on derived members.

- Support for debugger-related attributes in `System.Diagnostics`.

`System.Security.Cryptography` support on WebAssembly

.NET 6 supported the SHA family of hashing algorithms when running on WebAssembly. .NET 7 enables more cryptographic algorithms by taking advantage of SubtleCrypto, when possible, and falling back to a .NET implementation when SubtleCrypto can't be used. The following algorithms are supported on WebAssembly in .NET 7:

- SHA1
- SHA256
- SHA384
- SHA512
- HMACSHA1
- HMACSHA256
- HMACSHA384
- HMACSHA512
- AES-CBC
- PBKDF2
- HKDF

For more information, see Developers targeting browser-wasm can use Web Crypto APIs (dotnet/runtime #40074).

Inject services into custom validation attributes

You can now inject services into custom validation attributes. Blazor sets up the `ValidationContext` so that it can be used as a service provider.

For more information, see ASP.NET Core Blazor forms validation.

`Input*` components outside of an `EditContext`/`EditForm`

The built-in input components are now supported outside of a form in Razor component markup.

For more information, see ASP.NET Core Blazor input components.

Project template changes

When .NET 6 was released last year, the HTML markup of the `_Host` page (`Pages/_Host.chstml`) was split between the `_Host` page and a new `_Layout` page (`Pages/_Layout.chstml`) in the .NET 6 Blazor Server project template.

In .NET 7, the HTML markup has been recombined with the `_Host` page in project templates.

Several additional changes were made to the Blazor project templates. It isn't feasible to list every change to the templates in the documentation. To migrate an app to .NET 7 in order to adopt all of the changes, see Migrate from ASP.NET Core 6.0 to 7.0.

Experimental `QuickGrid` component

The new `QuickGrid` component provides a convenient data grid component for most common requirements and as a reference architecture and performance baseline for anyone building Blazor data grid components.

For more information, see ASP.NET Core Blazor QuickGrid component.

Live demo: QuickGrid for Blazor sample app

Virtualization enhancements

Virtualization enhancements in .NET 7:

- The `Virtualize` component supports using the document itself as the scroll root, as an alternative to having some other element with `overflow-y: scroll` applied.
- If the `Virtualize` component is placed inside an element that requires a specific child tag name, `SpacerElement` allows you to obtain or set the virtualization spacer tag name.

For more information, see the following sections of the *Virtualization* article:

- Root-level virtualization
- Control the spacer element tag name

`MouseEventArgs` updates

`MovementX` and `MovementY` have been added to `MouseEventArgs`.

For more information, see ASP.NET Core Blazor event handling.

New Blazor loading page

The Blazor WebAssembly project template has a new loading UI that shows the progress of loading the app.

For more information, see ASP.NET Core Blazor startup.

Improved diagnostics for authentication in Blazor WebAssembly

To help diagnose authentication issues in Blazor WebAssembly apps, detailed logging is available.

For more information, see ASP.NET Core Blazor logging.

JavaScript interop on WebAssembly

JavaScript `[JSImport]`/`[JSExport]` interop API is a new low-level mechanism for using .NET in Blazor WebAssembly and JavaScript-based apps. With this new JavaScript interop capability, you can invoke .NET code from JavaScript using the .NET WebAssembly runtime and call into JavaScript functionality from .NET without any dependency on the Blazor UI component model.

For more information:

- JavaScript JSImport/JSExport interop with ASP.NET Core Blazor: Pertains only to Blazor WebAssembly apps.
- JavaScript `[JSImport]`/`[JSExport]` interop in .NET WebAssembly: Pertains only to JavaScript apps that don't depend on the Blazor UI component model.

Conditional registration of the authentication state provider

Prior to the release of .NET 7, `AuthenticationStateProvider` was registered in the service container with `AddScoped`. This made it difficult to debug apps, as it forced a specific order of service registrations when providing a custom implementation. Due to internal framework changes over time, it's no longer necessary to register `AuthenticationStateProvider` with `AddScoped`.

In developer code, make the following change to the authentication state provider service registration:

```diff
- builder.Services.AddScoped<AuthenticationStateProvider,
ExternalAuthStateProvider>();
+ builder.Services.TryAddScoped<AuthenticationStateProvider,
ExternalAuthStateProvider>();
```

In the preceding example, `ExternalAuthStateProvider` is the developer's service implementation.

Improvements to the .NET WebAssembly build tools

New features in the `wasm-tools` workload for .NET 7 that help improve performance and handle exceptions:

- WebAssembly Single Instruction, Multiple Data (SIMD) support (only with AOT, not supported by Apple Safari)
- WebAssembly exception handling support

For more information, see ASP.NET Core Blazor WebAssembly build tools and ahead-of-time (AOT) compilation.

Blazor Hybrid

External URLs

An option has been added that permits opening external webpages in the browser.

For more information, see ASP.NET Core Blazor Hybrid routing and navigation.

Security

New guidance is available for Blazor Hybrid security scenarios. For more information, see the following articles:

- ASP.NET Core Blazor Hybrid authentication and authorization
- ASP.NET Core Blazor Hybrid security considerations

Performance

Output caching middleware

Output caching is a new middleware that stores responses from a web app and serves them from a cache rather than computing them every time. Output caching differs from response caching in the following ways:

- The caching behavior is configurable on the server.
- Cache entries can be programmatically invalidated.
- Resource locking mitigates the risk of cache stampede and thundering herd.
- Cache revalidation means the server can return a `304 Not Modified` HTTP status code instead of a cached response body.
- The cache storage medium is extensible.

For more information, see Overview of caching and Output caching middleware.

HTTP/3 improvements

This release:

- Makes HTTP/3 fully supported by ASP.NET Core, it's no longer experimental.
- Improves Kestrel's support for HTTP/3. The two main areas of improvement are feature parity with HTTP/1.1 and HTTP/2, and performance.
- Provides full support for UseHttps(ListenOptions, X509Certificate2) with HTTP/3. Kestrel offers advanced options for configuring connection certificates, such as hooking into Server Name Indication (SNI).
- Adds support for HTTP/3 on HTTP.sys and IIS.

The following example shows how to use an SNI callback to resolve TLS options:

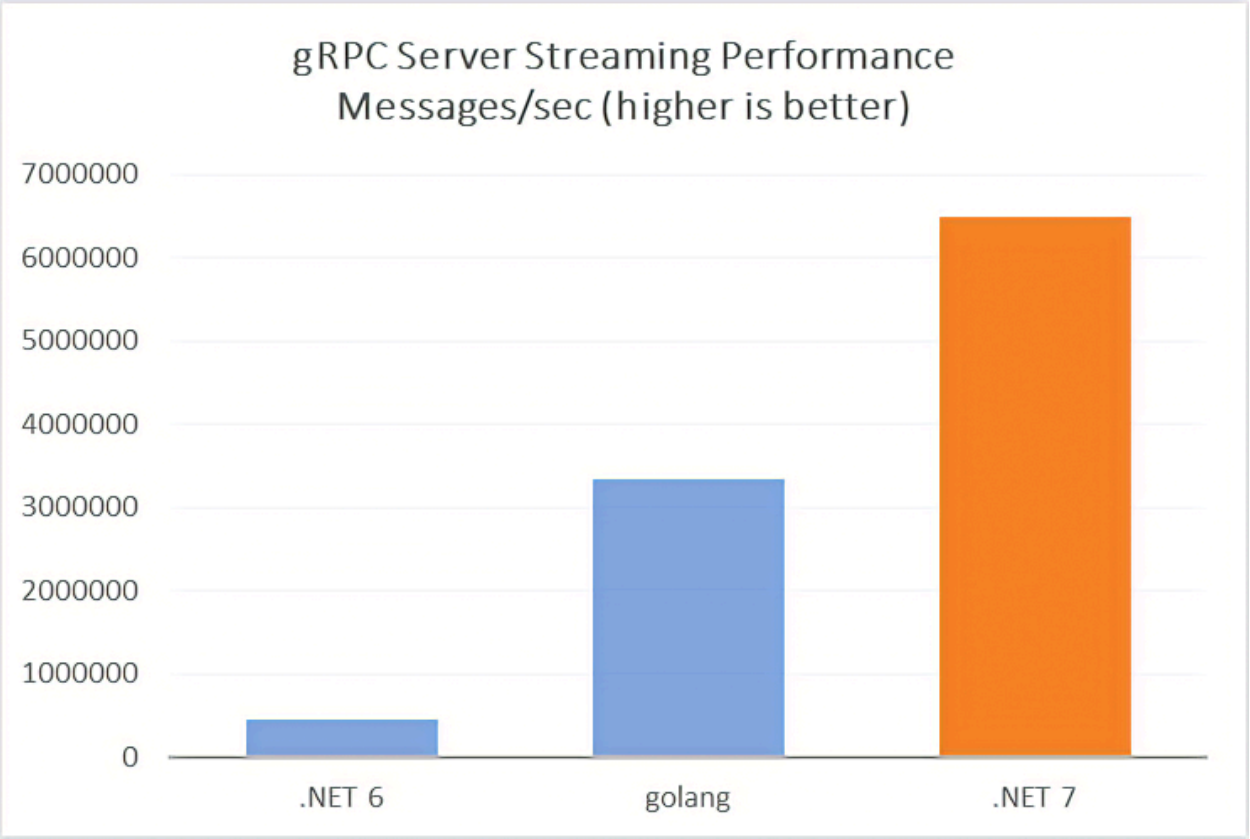
C#

```
using Microsoft.AspNetCore.Server.Kestrel.Core;
using Microsoft.AspNetCore.Server.Kestrel.Https;
using System.Net.Security;
using System.Security.Cryptography.X509Certificates;

var builder = WebApplication.CreateBuilder(args);
builder.WebHost.ConfigureKestrel(options =>
{
    options.ListenAnyIP(8080, listenOptions =>
    {
        listenOptions.Protocols = HttpProtocols.Http1AndHttp2AndHttp3;
        listenOptions.UseHttps(new TlsHandshakeCallbackOptions
        {
            OnConnection = context =>
            {
                var options = new SslServerAuthenticationOptions
                {
                    ServerCertificate =
```

```
MyResolveCertForHost(context.ClientHelloInfo.ServerName)
                };
                return new ValueTask<SslServerAuthenticationOptions>
(options);
            },
        });
    });
});
```

Significant work was done in .NET 7 to reduce HTTP/3 allocations. You can see some of those improvements in the following GitHub PR's:



- HTTP/3: Avoid per-request cancellation token allocations
- HTTP/3: Avoid ConnectionAbortedException allocations
- HTTP/3: ValueTask pooling

HTTP/2 Performance improvements

.NET 7 introduces a significant re-architecture of how Kestrel processes HTTP/2 requests. ASP.NET Core apps with busy HTTP/2 connections will experience reduced CPU usage and higher throughput.

Previously, the HTTP/2 multiplexing implementation relied on a lock controlling which request can write to the underlying TCP connection. A thread-safe queue replaces the write lock. Now, rather than fighting over which thread gets to use the write lock, requests now queue up and a dedicated consumer processes them. Previously wasted CPU resources are available to the rest of the app.

One place where these improvements can be noticed is in gRPC, a popular RPC framework that uses HTTP/2. Kestrel + gRPC benchmarks show a dramatic improvement:

Changes were made in the HTTP/2 frame writing code that improves performance when there are multiple streams trying to write data on a single HTTP/2 connection. We now dispatch TLS work to the thread pool and more quickly release a write lock that other streams can acquire to write their data. The reduction in wait times can yield significant performance improvements in cases where there is contention for this write lock. A gRPC benchmark with 70 streams on a single connection (with TLS) showed a ~15% improvement in requests per second (RPS) with this change.

Http/2 WebSockets support

.NET 7 introduces WebSockets over HTTP/2 support for Kestrel, the SignalR JavaScript client, and SignalR with Blazor WebAssembly.

Using WebSockets over HTTP/2 takes advantage of new features such as:

- Header compression.
- Multiplexing, which reduces the time and resources needed when making multiple requests to the server.

These supported features are available in Kestrel on all HTTP/2 enabled platforms. The version negotiation is automatic in browsers and Kestrel, so no new APIs are needed.

For more information, see Http/2 WebSockets support.

Kestrel performance improvements on high core machines

Kestrel uses ConcurrentQueue<T> for many purposes. One purpose is scheduling I/O operations in Kestrel's default Socket transport. Partitioning the `ConcurrentQueue` based on the associated socket reduces contention and increases throughput on machines with many CPU cores.

Profiling on high core machines on .NET 6 showed significant contention in one of Kestrel's other `ConcurrentQueue` instances, the `PinnedMemoryPool` that Kestrel uses to cache byte buffers.

In .NET 7, Kestrel's memory pool is partitioned the same way as its I/O queue, which leads to much lower contention and higher throughput on high core machines. On the 80 core ARM64 VMs, we're seeing over 500% improvement in responses per second (RPS) in the TechEmpower plaintext benchmark. On 48 Core AMD VMs, the improvement is nearly 100% in our HTTPS JSON benchmark.

`ServerReady` event to measure startup time

Apps using EventSource can measure the startup time to understand and optimize startup performance. The new ServerReady event in Microsoft.AspNetCore.Hosting represents the point where the server is ready to respond to requests.

Server

New ServerReady event for measuring startup time

The ServerReady event has been added to measure startup time of ASP.NET Core apps.

IIS

Shadow copying in IIS

Shadow copying app assemblies to the ASP.NET Core Module (ANCM) for IIS can provide a better end user experience than stopping the app by deploying an app offline file.

For more information, see Shadow copying in IIS.

Miscellaneous

Kestrel full certificate chain improvements

HttpsConnectionAdapterOptions has a new ServerCertificateChain property of type X509Certificate2Collection, which makes it easier to validate certificate chains by allowing a full chain including intermediate certificates to be specified. See dotnet/aspnetcore#21513 for more details.

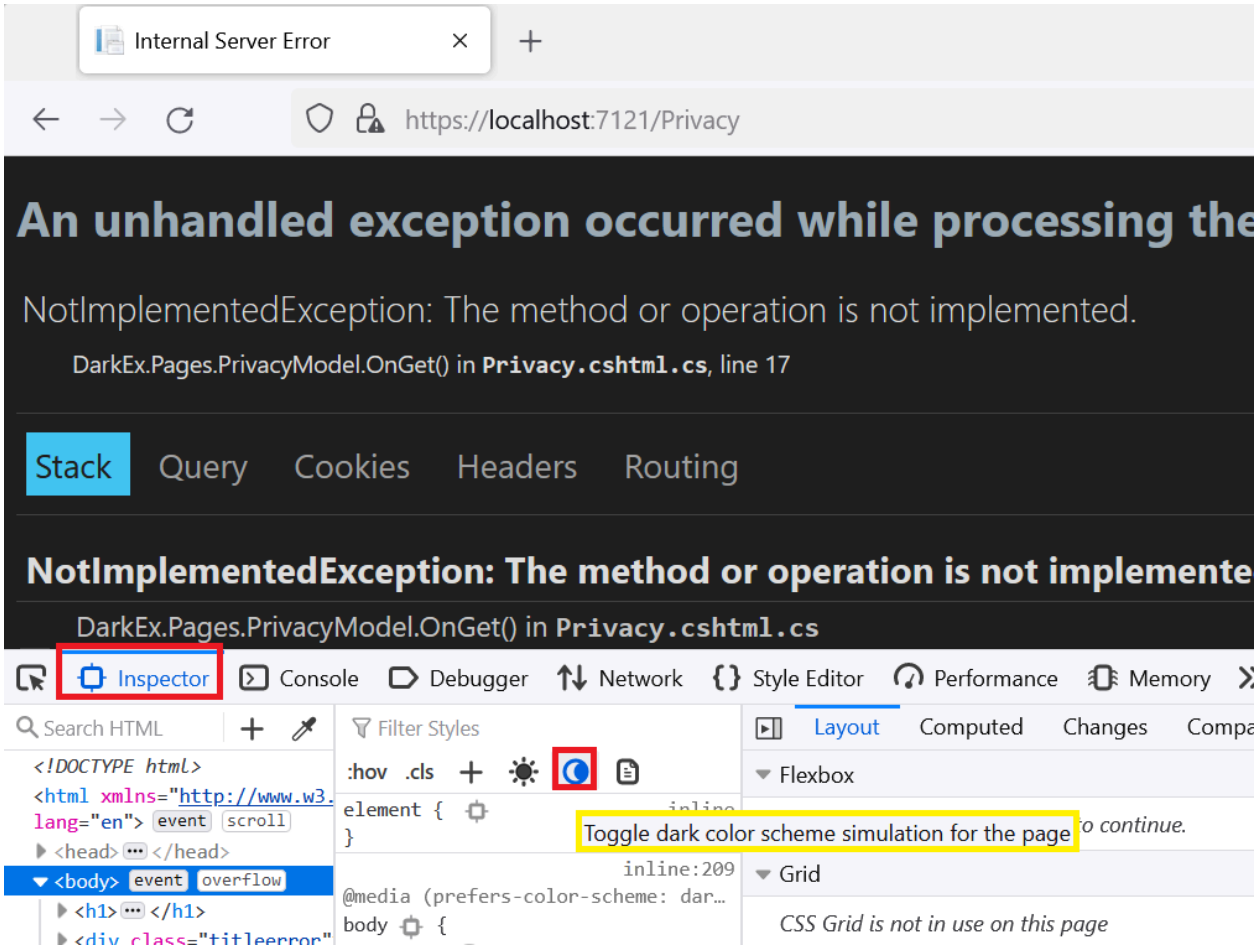
dotnet watch

Improved console output for dotnet watch

The console output from dotnet watch has been improved to better align with the logging of ASP.NET Core and to stand out with 😮emojis😍.

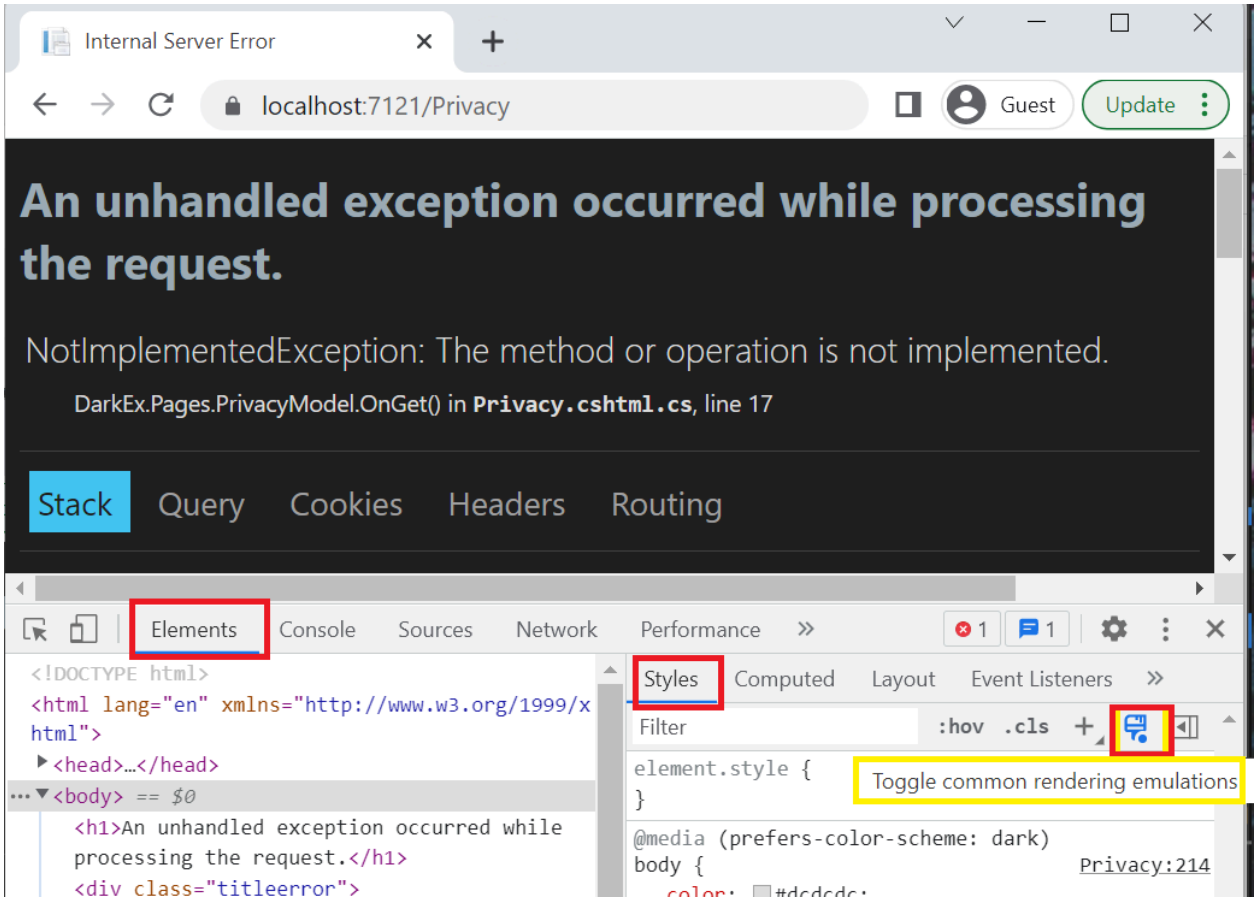
Here's an example of what the new output looks like:

```
dotnet watch 🔥 Hot reload enabled. For a list of supported edits, see https://aka.ms/dotnet/hot-reload.
  💡 Press "Ctrl + R" to restart.
dotnet watch 🔧 Building...
  Determining projects to restore...
  All projects are up-to-date for restore.
  WebApplication18 -> C:\tmp\WebApplication18\bin\Debug\net6.0\WebApplication18.dll
dotnet watch 🚀 Started
dotnet watch ⌚ Files changed: .\Pages\Index.cshtml, .\Pages\Index.cshtml.cs
dotnet watch 🔥 Hot reload of changes succeeded.
```



For more information, see this GitHub pull request.

Configure dotnet watch to always restart for rude edits



Rude edits are edits that can't be hot reloaded. To configure dotnet watch to always restart without a prompt for rude edits, set the `DOTNET_WATCH_RESTART_ON_RUDE_EDIT` environment variable to `true`.

Developer exception page dark mode

Dark mode support has been added to the developer exception page, thanks to a contribution by Patrick Westerhoff. To test dark mode in a browser, from the developer tools page, set the mode to dark. For example, in Firefox:

Internal Server Error
https://localhost:7121/Privacy
An unhandled exception occurred while processing the
NotImplementedException: The method or operation is not implemented.
DarkEx.Pages.PrivacyModel.OnGet() in Privacy.cshtml.cs, line 17

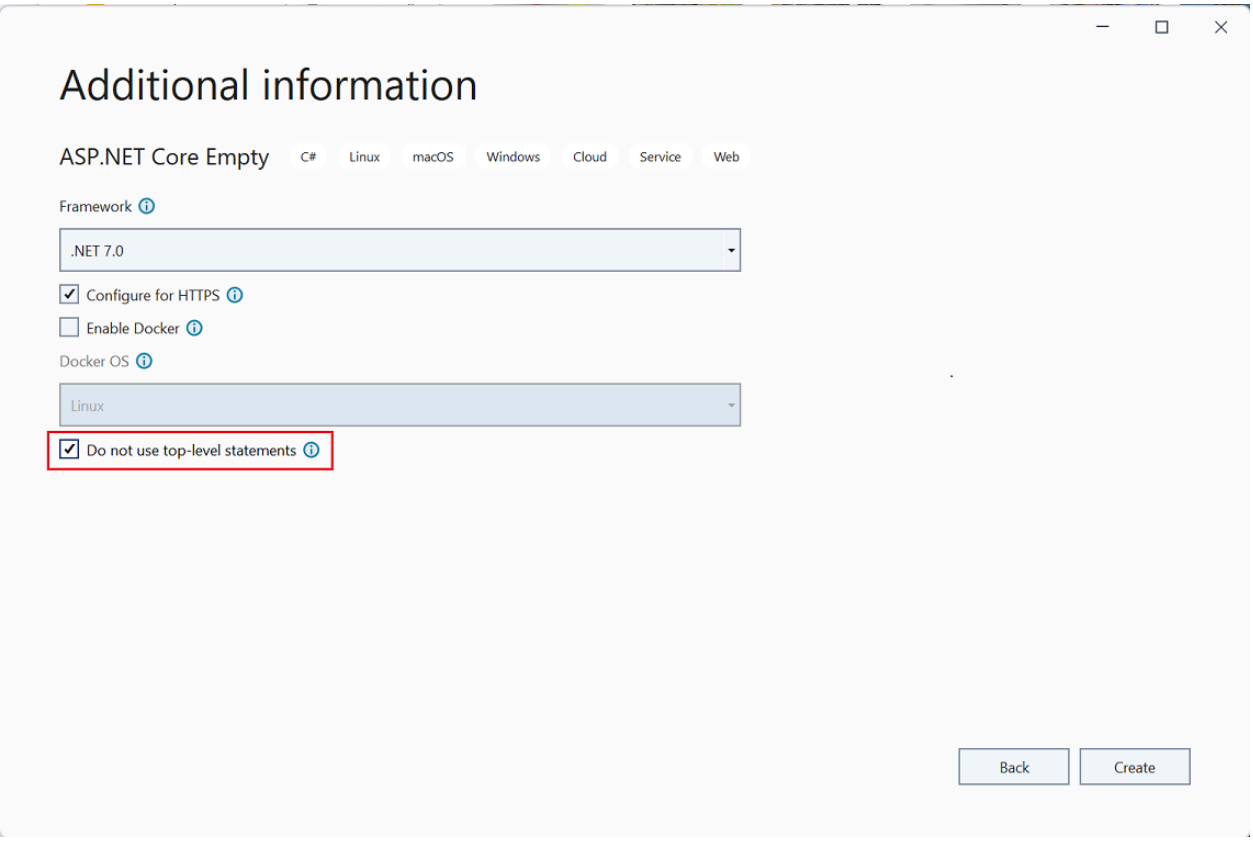
Project template option to use Program.Main method instead of top-level statements



The .NET 7 templates include an option to not use top-level statements and generate a `namespace` and a `Main` method declared on a `Program` class.

Using the .NET CLI, use the `--use-program-main` option:

.NET CLI

```
dotnet new web --use-program-main
```

With Visual Studio, select the new **Do not use top-level statements** checkbox during project creation:

Updated Angular and React templates

The Angular project template has been updated to Angular 14. The React project template has been updated to React 18.2.

Manage JSON Web Tokens in development with dotnet user-jwts

The new `dotnet user-jwts` command line tool can create and manage app specific local JSON Web Tokens (JWTs). For more information, see Manage JSON Web Tokens in development with dotnet user-jwts.

Support for additional request headers in W3CLogger

You can now specify additional request headers to log when using the W3C logger by calling `AdditionalRequestHeaders()` on W3CLoggerOptions:

C#

```
services.AddW3CLogging(logging =>
{
    logging.AdditionalRequestHeaders.Add("x-forwarded-for");
    logging.AdditionalRequestHeaders.Add("x-client-ssl-protocol");
});
```

For more information, see W3CLogger options.

Request decompression

The new Request decompression middleware:

- Enables API endpoints to accept requests with compressed content.
- Uses the Content-Encoding HTTP header to automatically identify and decompress requests which contain compressed content.
- Eliminates the need to write code to handle compressed requests.

For more information, see Request decompression middleware.

What's new in ASP.NET Core 6.0

Article • 10/18/2024

This article highlights the most significant changes in ASP.NET Core 6.0 with links to relevant documentation.

ASP.NET Core MVC and Razor improvements

Minimal APIs

Minimal APIs are architected to create HTTP APIs with minimal dependencies. They are ideal for microservices and apps that want to include only the minimum files, features, and dependencies in ASP.NET Core. For more information, see:

- Tutorial: Create a minimal API with ASP.NET Core
- Differences between minimal APIs and APIs with controllers
- Minimal APIs quick reference
- Code samples migrated to the new minimal hosting model in 6.0

SignalR

Long running activity tag for SignalR connections

SignalR uses the new Microsoft.AspNetCore.Http.Features.IHttpActivityFeature.Activity to add an `http.long_running` tag to the request activity. `IHttpActivityFeature.Activity` is used by APM services like Azure Monitor Application Insights to filter SignalR requests from creating long running request alerts.

SignalR performance improvements

- Allocate HubCallerClients once per connection instead of every hub method call.
- Avoid closure allocation in SignalR `DefaultHubDispatcher.Invoke`. State is passed to a local static function via parameters to avoid a closure allocation. For more information, see this GitHub pull request.
- Allocate a single StreamItemMessage per stream instead of per stream item in server-to-client streaming. For more information, see this GitHub pull request.

Razor compiler

Razor compiler updated to use source generators

The Razor compiler is now based on C# source generators. Source generators run during compilation and inspect what is being compiled to produce additional files that are compiled along with the rest of the project. Using source generators simplifies the Razor compiler and significantly speeds up build times.

Razor compiler no longer produces a separate Views assembly

The Razor compiler previously utilized a two-step compilation process that produced a separate Views assembly that contained the generated views and pages (`.cshtml` files) defined in the app. The generated types were public and under the `AspNetCore` namespace.

The updated Razor compiler builds the views and pages types into the main project assembly. These types are now generated by default as internal sealed in the `AspNetCoreGeneratedDocument` namespace. This change improves build performance, enables single file deployment, and enables these types to participate in Hot Reload.

For more information about this change, see the related announcement issue on GitHub.

ASP.NET Core performance and API improvements

Many changes were made to reduce allocations and improve performance across the stack:

- Non-allocating app.Use extension method. The new overload of `app.Use` requires passing the context to `next` which saves two internal per-request allocations that are required when using the other overload.
- Reduced memory allocations when accessing HttpRequest.Cookies. For more information, see this GitHub issue.
- Use LoggerMessage.Define for the windows only HTTP.sys web server. The ILogger extension methods calls have been replaced with calls to `LoggerMessage.Define`.
- Reduce the per connection overhead in SocketConnection by ~30%. For more information, see this GitHub pull request.

- Reduce allocations by removing logging delegates in generic types. For more information, see this GitHub pull request.
- Faster GET access (about 50%) to commonly-used features such as IHttpRequestFeature, IHttpResponseFeature, IHttpResponseBodyFeature, IRouteValuesFeature, and IEndpointFeature. For more information, see this GitHub pull request.
- Use single instance strings for known header names, even if they aren't in the preserved header block. Using single instance string helps prevent multiple duplicates of the same string in long lived connections, for example, in Microsoft.AspNetCore.WebSockets. For more information, see this GitHub issue.
- Reuse HttpProtocol CancellationTokenSource in Kestrel. Use the new CancellationTokenSource.TryReset method on `CancellationTokenSource` to reuse tokens if they haven't been canceled. For more information, see this GitHub issue and this video.
- Implement and use an AdaptiveCapacityDictionary in Microsoft.AspNetCore.Http RequestCookieCollection for more efficient access to dictionaries. For more information, see this GitHub pull request.

Reduced memory footprint for idle TLS connections

For long running TLS connections where data is only occasionally sent back and forth, we've significantly reduced the memory footprint of ASP.NET Core apps in .NET 6. This should help improve the scalability of scenarios such as WebSocket servers. This was possible due to numerous improvements in System.IO.Pipelines, SslStream, and Kestrel. The following sections detail some of the improvements that have contributed to the reduced memory footprint:

Reduce the size of `System.IO.Pipelines.Pipe`

For every connection that is established, two pipes are allocated in Kestrel:

- The transport layer to the app for the request.
- The application layer to the transport for the response.

By shrinking the size of System.IO.Pipelines.Pipe from 368 bytes to 264 bytes (about a 28.2% reduction), 208 bytes per connection are saved (104 bytes per Pipe).

Pool SocketSender

`SocketSender` objects (that subclass SocketAsyncEventArgs) are around 350 bytes at runtime. Instead of allocating a new `SocketSender` object per connection, they can be

pooled. `SocketSender` objects can be pooled because sends are usually very fast. Pooling reduces the per connection overhead. Instead of allocating 350 bytes per connection, only pay 350 bytes per `IOQueue` are allocated. Allocation is done per queue to avoid contention. Our WebSocket server with 5000 idle connections went from allocating ~1.75 MB (350 bytes * 5000) to allocating ~2.8 kb (350 bytes * 8) for `SocketSender` objects.

Zero bytes reads with SslStream

Bufferless reads are a technique employed in ASP.NET Core to avoid renting memory from the memory pool if there's no data available on the socket. Prior to this change, our WebSocket server with 5000 idle connections required ~200 MB without TLS compared to ~800 MB with TLS. Some of these allocations (4k per connection) were from Kestrel having to hold on to an ArrayPool<T> buffer while waiting for the reads on SslStream to complete. Given that these connections were idle, none of reads completed and returned their buffers to the `ArrayPool`, forcing the `ArrayPool` to allocate more memory. The remaining allocations were in `SslStream` itself: 4k buffer for TLS handshakes and 32k buffer for normal reads. In .NET 6, when the user performs a zero byte read on `SslStream` and it has no data available, `SslStream` internally performs a zero-byte read on the underlying wrapped stream. In the best case (idle connection), these changes result in a savings of 40 Kb per connection while still allowing the consumer (Kestrel) to be notified when data is available without holding on to any unused buffers.

Zero byte reads with PipeReader

With bufferless reads supported on `SslStream`, an option was added to perform zero byte reads to `StreamPipeReader`, the internal type that adapts a `Stream` into a `PipeReader`. In Kestrel, a `StreamPipeReader` is used to adapt the underlying `SslStream` into a `PipeReader`. Therefore it was necessary to expose these zero byte read semantics on the `PipeReader`.

A `PipeReader` can now be created that supports zero bytes reads over any underlying `Stream` that supports zero byte read semantics (e.g,. `SslStream`, NetworkStream, etc) using the following API:

.NET CLI

```
var reader = PipeReader.Create(stream, new
StreamPipeReaderOptions(useZeroByteReads: true));
```

Remove slabs from the `SlabMemoryPool`

To reduce fragmentation of the heap, Kestrel employed a technique where it allocated slabs of memory of 128 KB as part of its memory pool. The slabs were then further divided into 4 KB blocks that were used by Kestrel internally. The slabs had to be larger than 85 KB to force allocation on the large object heap to try and prevent the GC from relocating this array. However, with the introduction of the new GC generation, Pinned Object Heap (POH), it no longer makes sense to allocate blocks on slab. Kestrel now directly allocates blocks on the POH, reducing the complexity involved in managing the memory pool. This change should make easier to perform future improvements such as making it easier to shrink the memory pool used by Kestrel.

IAsyncDisposable supported

IAsyncDisposable is now available for controllers, Razor Pages, and View Components. Asynchronous versions have been added to the relevant interfaces in factories and activators:

- The new methods offer a default interface implementation that delegates to the synchronous version and calls Dispose.
- The implementations override the default implementation and handle disposing `IAsyncDisposable` implementations.
- The implementations favor `IAsyncDisposable` over `IDisposable` when both interfaces are implemented.
- Extenders must override the new methods included to support `IAsyncDisposable` instances.

`IAsyncDisposable` is beneficial when working with:

- Asynchronous enumerators, for example, in asynchronous streams.
- Unmanaged resources that have resource-intensive I/O operations to release.

When implementing this interface, use the `DisposeAsync` method to release resources.

Consider a controller that creates and uses a Utf8JsonWriter. `Utf8JsonWriter` is an `IAsyncDisposable` resource:

```
C#

public class HomeController : Controller, IAsyncDisposable
{
    private Utf8JsonWriter? _jsonWriter;
    private readonly ILogger<HomeController> _logger;
```

```
    public HomeController(ILogger<HomeController> logger)
    {
        _logger = logger;
        _jsonWriter = new Utf8JsonWriter(new MemoryStream());
    }
```

`IAsyncDisposable` must implement `DisposeAsync`:

C#

```
public async ValueTask DisposeAsync()
{
    if (_jsonWriter is not null)
    {
        await _jsonWriter.DisposeAsync();
    }

    _jsonWriter = null;
}
```

Vcpkg port for SignalR C++ client

Vcpkg is a cross-platform command-line package manager for C and C++ libraries. We've recently added a port to `vcpkg` to add `CMake` native support for the SignalR C++ client. `vcpkg` also works with MSBuild.

The SignalR client can be added to a CMake project with the following snippet when the vcpkg is included in the toolchain file:

.NET CLI

```
find_package(microsoft-signalr CONFIG REQUIRED)
link_libraries(microsoft-signalr::microsoft-signalr)
```

With the preceding snippet, the SignalR C++ client is ready to use #include and used in a project without any additional configuration. For a complete example of a C++ application that utilizes the SignalR C++ client, see the halter73/SignalR-Client-Cpp-Sample repository.

Blazor

Project template changes

Several project template changes were made for Blazor apps, including the use of the `Pages/_Layout.cshtml` file for layout content that appeared in the `_Host.cshtml` file for earlier Blazor Server apps. Study the changes by creating an app from a 6.0 project template or accessing the ASP.NET Core reference source for the project templates:

- Blazor Server
- Blazor WebAssembly

Blazor WebAssembly native dependencies support

Blazor WebAssembly apps can use native dependencies built to run on WebAssembly. For more information, see ASP.NET Core Blazor WebAssembly native dependencies.

WebAssembly Ahead-of-time (AOT) compilation and runtime relinking

Blazor WebAssembly supports ahead-of-time (AOT) compilation, where you can compile your .NET code directly into WebAssembly. AOT compilation results in runtime performance improvements at the expense of a larger app size. Relinking the .NET WebAssembly runtime trims unused runtime code and thus improves download speed. For more information, see Ahead-of-time (AOT) compilation and Runtime relinking.

Persist prerendered state

Blazor supports persisting state in a prerendered page so that the state doesn't need to be recreated when the app is fully loaded. For more information, see Prerender and integrate ASP.NET Core Razor components.

Error boundaries

Error boundaries provide a convenient approach for handling exceptions on the UI level. For more information, see Handle errors in ASP.NET Core Blazor apps.

SVG support

The <foreignObject> element element is supported to display arbitrary HTML within an SVG. For more information, see ASP.NET Core Razor components.

Blazor Server support for byte array transfer in JS Interop

Blazor supports optimized byte array JS interop that avoids encoding and decoding byte arrays into Base64. For more information, see the following resources:

- Call JavaScript functions from .NET methods in ASP.NET Core Blazor
- Call .NET methods from JavaScript functions in ASP.NET Core Blazor

Query string enhancements

Support for working with query strings is improved. For more information, see ASP.NET Core Blazor routing and navigation.

Binding to select multiple

Binding supports multiple option selection with `<input>` elements. For more information, see the following resources:

- ASP.NET Core Blazor data binding
- ASP.NET Core Blazor input components

Head (`<head>`) content control

Razor components can modify the HTML `<head>` element content of a page, including setting the page's title (`<title>` element) and modifying metadata (`<meta>` elements). For more information, see Control <head> content in ASP.NET Core Blazor apps.

Generate Angular and React components

Generate framework-specific JavaScript components from Razor components for web frameworks, such as Angular or React. For more information, see ASP.NET Core Razor components.

Render components from JavaScript

Render Razor components dynamically from JavaScript for existing JavaScript apps. For more information, see ASP.NET Core Razor components.

Custom elements

Experimental support is available for building custom elements, which use standard HTML interfaces. For more information, see ASP.NET Core Razor components.

Infer component generic types from ancestor components

An ancestor component can cascade a type parameter by name to descendants using the new `[CascadingTypeParameter]` attribute. For more information, see ASP.NET Core Razor components.

Dynamically rendered components

Use the new built-in `DynamicComponent` component to render components by type. For more information, see Dynamically-rendered ASP.NET Core Razor components.

Improved Blazor accessibility

Use the new `FocusOnNavigate` component to set the UI focus to an element based on a CSS selector after navigating from one page to another. For more information, see ASP.NET Core Blazor routing and navigation.

Custom event argument support

Blazor supports custom event arguments, which enable you to pass arbitrary data to .NET event handlers with custom events. For more information, see ASP.NET Core Blazor event handling.

Required parameters

Apply the new `[EditorRequired]` attribute to specify a required component parameter. For more information, see ASP.NET Core Razor components.

Collocation of JavaScript files with pages, views, and components

Collocate JavaScript files for pages, views, and Razor components as a convenient way to organize scripts in an app. For more information, see ASP.NET Core Blazor JavaScript interoperability (JS interop).

JavaScript initializers

JavaScript initializers execute logic before and after a Blazor app loads. For more information, see ASP.NET Core Blazor JavaScript interoperability (JS interop).

Streaming JavaScript interop

Blazor now supports streaming data directly between .NET and JavaScript. For more information, see the following resources:

- Stream from .NET to JavaScript
- Stream from JavaScript to .NET

Generic type constraints

Generic type parameters are now supported. For more information, see ASP.NET Core Razor components.

WebAssembly deployment layout

Use a deployment layout to enable Blazor WebAssembly app downloads in restricted security environments. For more information, see Deployment layout for ASP.NET Core hosted Blazor WebAssembly apps.

New Blazor articles

In addition to the Blazor features described in the preceding sections, new Blazor articles are available on the following subjects:

- ASP.NET Core Blazor file downloads: Learn how to download a file using native `byte[]` streaming interop to ensure efficient transfer to the client.
- Display images and documents in ASP.NET Core Blazor: Discover how to work with images and documents in Blazor apps, including how to stream image and document data.

Build Blazor Hybrid apps with .NET MAUI, WPF, and Windows Forms

Use Blazor Hybrid to blend desktop and mobile native client frameworks with .NET and Blazor:

- .NET Multi-platform App UI (.NET MAUI) is a cross-platform framework for creating native mobile and desktop apps with C# and XAML.
- Blazor Hybrid apps can be built with Windows Presentation Foundation (WPF) and Windows Forms frameworks.

> **ⓘ Important**
>
> Blazor Hybrid is in preview and shouldn't be used in production apps until final release.

For more information, see the following resources:

- Preview ASP.NET Core Blazor Hybrid documentation
- What is .NET MAUI?
- Microsoft .NET Blog (category: ".NET MAUI")

Kestrel

HTTP/3 is currently in draft and therefore subject to change. HTTP/3 support in ASP.NET Core is not released, it's a preview feature included in .NET 6.

Kestrel now supports HTTP/3. For more information, see Use HTTP/3 with the ASP.NET Core Kestrel web server and the blog entry HTTP/3 support in .NET 6.

New Kestrel logging categories for selected logging

Prior to this change, enabling verbose logging for Kestrel was prohibitively expensive as all of Kestrel shared the `Microsoft.AspNetCore.Server.Kestrel` logging category name. `Microsoft.AspNetCore.Server.Kestrel` is still available, but the following new subcategories allow for more control of logging:

- `Microsoft.AspNetCore.Server.Kestrel` (current category): `ApplicationError`, `ConnectionHeadResponseBodyWrite`, `ApplicationNeverCompleted`, `RequestBodyStart`, `RequestBodyDone`, `RequestBodyNotEntirelyRead`, `RequestBodyDrainTimedOut`, `ResponseMinimumDataRateNotSatisfied`, `InvalidResponseHeaderRemoved`, `HeartbeatSlow`.
- `Microsoft.AspNetCore.Server.Kestrel.BadRequests`: `ConnectionBadRequest`, `RequestProcessingError`, `RequestBodyMinimumDataRateNotSatisfied`.
- `Microsoft.AspNetCore.Server.Kestrel.Connections`: `ConnectionAccepted`, `ConnectionStart`, `ConnectionStop`, `ConnectionPause`, `ConnectionResume`,

`ConnectionKeepAlive`, `ConnectionRejected`, `ConnectionDisconnect`, `NotAllConnectionsClosedGracefully`, `NotAllConnectionsAborted`, `ApplicationAbortedConnection`.

- `Microsoft.AspNetCore.Server.Kestrel.Http2`: `Http2ConnectionError`, `Http2ConnectionClosing`, `Http2ConnectionClosed`, `Http2StreamError`, `Http2StreamResetAbort`, `HPackDecodingError`, `HPackEncodingError`, `Http2FrameReceived`, `Http2FrameSending`, `Http2MaxConcurrentStreamsReached`.
- `Microsoft.AspNetCore.Server.Kestrel.Http3`: `Http3ConnectionError`, `Http3ConnectionClosing`, `Http3ConnectionClosed`, `Http3StreamAbort`, `Http3FrameReceived`, `Http3FrameSending`.

Existing rules continue to work, but you can now be more selective on which rules you enable. For example, the observability overhead of enabling `Debug` logging for just bad requests is greatly reduced and can be enabled with the following configuration:

XML

```
{
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "Microsoft.AspNetCore": "Warning",
      "Microsoft.AspNetCore.Kestrel.BadRequests": "Debug"
    }
  }
```

Log filtering applies rules with the longest matching category prefix. For more information, see How filtering rules are applied

Emit KestrelServerOptions via EventSource event

The KestrelEventSource emits a new event containing the JSON-serialized KestrelServerOptions when enabled with verbosity `EventLevel.LogAlways`. This event makes it easier to reason about the server behavior when analyzing collected traces. The following JSON is an example of the event payload:

JSON

```
{
  "AllowSynchronousIO": false,
  "AddServerHeader": true,
  "AllowAlternateSchemes": false,
  "AllowResponseHeaderCompression": true,
  "EnableAltSvc": false,
```

```
  "IsDevCertLoaded": true,
  "RequestHeaderEncodingSelector": "default",
  "ResponseHeaderEncodingSelector": "default",
  "Limits": {
    "KeepAliveTimeout": "00:02:10",
    "MaxConcurrentConnections": null,
    "MaxConcurrentUpgradedConnections": null,
    "MaxRequestBodySize": 30000000,
    "MaxRequestBufferSize": 1048576,
    "MaxRequestHeaderCount": 100,
    "MaxRequestHeadersTotalSize": 32768,
    "MaxRequestLineSize": 8192,
    "MaxResponseBufferSize": 65536,
    "MinRequestBodyDataRate": "Bytes per second: 240, Grace Period:
00:00:05",
    "MinResponseDataRate": "Bytes per second: 240, Grace Period: 00:00:05",
    "RequestHeadersTimeout": "00:00:30",
    "Http2": {
      "MaxStreamsPerConnection": 100,
      "HeaderTableSize": 4096,
      "MaxFrameSize": 16384,
      "MaxRequestHeaderFieldSize": 16384,
      "InitialConnectionWindowSize": 131072,
      "InitialStreamWindowSize": 98304,
      "KeepAlivePingDelay": "10675199.02:48:05.4775807",
      "KeepAlivePingTimeout": "00:00:20"
    },
    "Http3": {
      "HeaderTableSize": 0,
      "MaxRequestHeaderFieldSize": 16384
    }
  },
  "ListenOptions": [
    {
      "Address": "https://127.0.0.1:7030",
      "IsTls": true,
      "Protocols": "Http1AndHttp2"
    },
    {
      "Address": "https://[::1]:7030",
      "IsTls": true,
      "Protocols": "Http1AndHttp2"
    },
    {
      "Address": "http://127.0.0.1:5030",
      "IsTls": false,
      "Protocols": "Http1AndHttp2"
    },
    {
      "Address": "http://[::1]:5030",
      "IsTls": false,
      "Protocols": "Http1AndHttp2"
    }
  ]
}
```

New DiagnosticSource event for rejected HTTP requests

Kestrel now emits a new `DiagnosticSource` event for HTTP requests rejected at the server layer. Prior to this change, there was no way to observe these rejected requests. The new `DiagnosticSource` event `Microsoft.AspNetCore.Server.Kestrel.BadRequest` contains a IBadRequestExceptionFeature that can be used to introspect the reason for rejecting the request.

C#

```
using Microsoft.AspNetCore.Http.Features;
using System.Diagnostics;

var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();
var diagnosticSource = app.Services.GetRequiredService<DiagnosticListener>
();
using var badRequestListener = new BadRequestEventListener(diagnosticSource,
    (badRequestExceptionFeature) =>
{
    app.Logger.LogError(badRequestExceptionFeature.Error, "Bad request
received");
});
app.MapGet("/", () => "Hello world");

app.Run();

class BadRequestEventListener : IObserver<KeyValuePair<string, object>>,
IDisposable
{
    private readonly IDisposable _subscription;
    private readonly Action<IBadRequestExceptionFeature> _callback;

    public BadRequestEventListener(DiagnosticListener diagnosticListener,
                                   Action<IBadRequestExceptionFeature>
callback)
    {
        _subscription = diagnosticListener.Subscribe(this!, IsEnabled);
        _callback = callback;
    }
    private static readonly Predicate<string> IsEnabled = (provider) =>
provider switch
    {
        "Microsoft.AspNetCore.Server.Kestrel.BadRequest" => true,
        _ => false
    };
    public void OnNext(KeyValuePair<string, object> pair)
    {
        if (pair.Value is IFeatureCollection featureCollection)
```

```
        {
            var badRequestFeature =
featureCollection.Get<IBadRequestExceptionFeature>();

            if (badRequestFeature is not null)
            {
                _callback(badRequestFeature);
            }
        }
    }
    public void OnError(Exception error) { }
    public void OnCompleted() { }
    public virtual void Dispose() => _subscription.Dispose();
}
```

For more information, see Logging and diagnostics in Kestrel.

Create a ConnectionContext from an Accept Socket

The new SocketConnectionContextFactory makes it possible to create a ConnectionContext from an accepted socket. This makes it possible to build a custom socket-based IConnectionListenerFactory without losing out on all the performance work and pooling happening in SocketConnection.

See this example of a custom IConnectionListenerFactory which shows how to use this `SocketConnectionContextFactory`.

Kestrel is the default launch profile for Visual Studio

The default launch profile for all new dotnet web projects is Kestrel. Starting Kestrel is significantly faster and results in a more responsive experience while developing apps.

IIS Express is still available as a launch profile for scenarios such as Windows Authentication or port sharing.

Localhost ports for Kestrel are random

See Template generated ports for Kestrel in this document for more information.

Authentication and authorization

Authentication servers

.NET 3 to .NET 5 used IdentityServer4 as part of our template to support the issuing of JWT tokens for SPA and Blazor applications. The templates now use the Duende Identity Server.

If you are extending the identity models and are updating existing projects, update the namespaces in your code from `IdentityServer4.IdentityServer` to `Duende.IdentityServer` and follow their migration instructions.

The license model for Duende Identity Server has changed to a reciprocal license, which may require license fees when it's used commercially in production. See the Duende license page for more details.

Delayed client certificate negotiation

Developers can now opt-in to using delayed client certificate negotiation by specifying ClientCertificateMode.DelayCertificate on the HttpsConnectionAdapterOptions. This only works with HTTP/1.1 connections because HTTP/2 forbids delayed certificate renegotiation. The caller of this API must buffer the request body before requesting the client certificate:

C#

```
using Microsoft.AspNetCore.Server.Kestrel.Https;
using Microsoft.AspNetCore.WebUtilities;

var builder = WebApplication.CreateBuilder(args);
builder.WebHost.UseKestrel(options =>
{
    options.ConfigureHttpsDefaults(adapterOptions =>
    {
        adapterOptions.ClientCertificateMode =
ClientCertificateMode.DelayCertificate;
    });
});

var app = builder.Build();
app.Use(async (context, next) =>
{
    bool desiredState = GetDesiredState();
    // Check if your desired criteria is met
    if (desiredState)
    {
        // Buffer the request body
        context.Request.EnableBuffering();
        var body = context.Request.Body;
        await body.DrainAsync(context.RequestAborted);
        body.Position = 0;
```

```
        // Request client certificate
        var cert = await context.Connection.GetClientCertificateAsync();

        //  Disable buffering on future requests if the client doesn't
provide a cert
    }
    await next(context);
});

app.MapGet("/", () => "Hello World!");
app.Run();
```

`OnCheckSlidingExpiration` event for controlling cookie renewal

Cookie authentication sliding expiration can now be customized or suppressed using the new OnCheckSlidingExpiration. For example, this event can be used by a single-page app that needs to periodically ping the server without affecting the authentication session.

Miscellaneous

Hot Reload

Quickly make UI and code updates to running apps without losing app state for faster and more productive developer experience using Hot Reload. For more information, see .NET Hot Reload support for ASP.NET Core and Update on .NET Hot Reload progress and Visual Studio 2022 Highlights.

Improved single-page app (SPA) templates

The ASP.NET Core project templates have been updated for Angular and React to use an improved pattern for single-page apps that is more flexible and more closely aligns with common patterns for modern front-end web development.

Previously, the ASP.NET Core template for Angular and React used specialized middleware during development to launch the development server for the front-end framework and then proxy requests from ASP.NET Core to the development server. The logic for launching the front-end development server was specific to the command-line interface for the corresponding front-end framework. Supporting additional front-end frameworks using this pattern meant adding additional logic to ASP.NET Core.

The updated ASP.NET Core templates for Angular and React in .NET 6 flips this arrangement around and take advantage of the built-in proxying support in the development servers of most modern front-end frameworks. When the ASP.NET Core app is launched, the front-end development server is launched just as before, but the development server is configured to proxy requests to the backend ASP.NET Core process. All of the front-end specific configuration to setup proxying is part of the app, not ASP.NET Core. Setting up ASP.NET Core projects to work with other front-end frameworks is now straight-forward: setup the front-end development server for the chosen framework to proxy to the ASP.NET Core backend using the pattern established in the Angular and React templates.

The startup code for the ASP.NET Core app no longer needs any single-page app-specific logic. The logic for starting the front-end development server during development is injecting into the app at runtime by the new Microsoft.AspNetCore.SpaProxy package. Fallback routing is handled using endpoint routing instead of SPA-specific middleware.

Templates that follow this pattern can still be run as a single project in Visual Studio or using `dotnet run` from the command-line. When the app is published, the front-end code in the *ClientApp* folder is built and collected as before into the web root of the host ASP.NET Core app and served as static files. Scripts included in the template configure the front-end development server to use HTTPS using the ASP.NET Core development certificate.

Draft HTTP/3 support in .NET 6

HTTP/3 is currently in draft and therefore subject to change. HTTP/3 support in ASP.NET Core is not released, it's a preview feature included in .NET 6.

See the blog entry HTTP/3 support in .NET 6.

Nullable Reference Type Annotations

Portions of the ASP.NET Core 6.0 source code has had nullability annotations applied.

By utilizing the new Nullable feature in C# 8, ASP.NET Core can provide additional compile-time safety in the handling of reference types. For example, protecting against `null` reference exceptions. Projects that have opted in to using nullable annotations may see new build-time warnings from ASP.NET Core APIs.

To enable nullable reference types, add the following property to project files:

```
```

XML

```xml
<PropertyGroup>
    <Nullable>enable</Nullable>
</PropertyGroup>
```

For more information, see Nullable reference types.

Source Code Analysis

Several .NET compiler platform analyzers were added that inspect application code for problems such as incorrect middleware configuration or order, routing conflicts, etc. For more information, see Code analysis in ASP.NET Core apps.

Web app template improvements

The web app templates:

- Use the new minimal hosting model.
- Significantly reduces the number of files and lines of code required to create an app. For example, the ASP.NET Core empty web app creates one C# file with four lines of code and is a complete app.
- Unifies `Startup.cs` and `Program.cs` into a single `Program.cs` file.
- Uses top-level statements to minimize the code required for an app.
- Uses global using directives to eliminate or minimize the number of using statement lines required.

Template generated ports for Kestrel

Random ports are assigned during project creation for use by the Kestrel web server. Random ports help minimize a port conflict when multiple projects are run on the same machine.

When a project is created, a random HTTP port between 5000-5300 and a random HTTPS port between 7000-7300 is specified in the generated `Properties/launchSettings.json` file. The ports can be changed in the `Properties/launchSettings.json` file. If no port is specified, Kestrel defaults to the HTTP 5000 and HTTPS 5001 ports. For more information, see Configure endpoints for the ASP.NET Core Kestrel web server.

New logging defaults

The following changes were made to both `appsettings.json` and `appsettings.Development.json`:

```diff
- "Microsoft": "Warning",
- "Microsoft.Hosting.Lifetime": "Information"
+ "Microsoft.AspNetCore": "Warning"
```

The change from `"Microsoft": "Warning"` to `"Microsoft.AspNetCore": "Warning"` results in logging all informational messages from the `Microsoft` namespace ***except*** `Microsoft.AspNetCore`. For example, `Microsoft.EntityFrameworkCore` is now logged at the informational level.

Developer exception page Middleware added automatically

In the development environment, the DeveloperExceptionPageMiddleware is added by default. It's no longer necessary to add the following code to web UI apps:

```C#
if (app.Environment.IsDevelopment())
{
    app.UseDeveloperExceptionPage();
}
```

Support for Latin1 encoded request headers in HttpSysServer

`HttpSysServer` now supports decoding request headers that are `Latin1` encoded by setting the UseLatin1RequestHeaders property on HttpSysOptions to `true`:

```C#
var builder = WebApplication.CreateBuilder(args);
builder.WebHost.UseHttpSys(o => o.UseLatin1RequestHeaders = true);

var app = builder.Build();

app.MapGet("/", () => "Hello World!");

app.Run();
```

The ASP.NET Core Module logs include timestamps and PID

The ASP.NET Core Module (ANCM) for IIS (ANCM) enhanced diagnostic logs include timestamps and PID of the process emitting the logs. Logging timestamps and PID makes it easier to diagnose issues with overlapping process restarts in IIS when multiple IIS worker processes are running.

The resulting logs now resemble the sample output show below:

.NET CLI

```
[2021-07-28T19:23:44.076Z, PID: 11020] [aspnetcorev2.dll] Initializing logs
for 'C:\<path>\aspnetcorev2.dll'. Process Id: 11020. File Version:
16.0.21209.0. Description: IIS ASP.NET Core Module V2. Commit:
96475a2acdf50d7599ba8e96583fa73efbe27912.
[2021-07-28T19:23:44.079Z, PID: 11020] [aspnetcorev2.dll] Resolving hostfxr
parameters for application: '.\InProcessWebSite.exe' arguments: '' path:
'C:\Temp\e86ac4e9ced24bb6bacf1a9415e70753\'
[2021-07-28T19:23:44.080Z, PID: 11020] [aspnetcorev2.dll] Known dotnet.exe
location: ''
```

Configurable unconsumed incoming buffer size for IIS

The IIS server previously only buffered 64 KiB of unconsumed request bodies. The 64 KiB buffering resulted in reads being constrained to that maximum size, which impacts the performance with large incoming bodies such as uploads. In .NET 6 , the default buffer size changes from 64 KiB to 1 MiB which should improve throughput for large uploads. In our tests, a 700 MiB upload that used to take 9 seconds now only takes 2.5 seconds.

The downside of a larger buffer size is an increased per-request memory consumption when the app isn't quickly reading from the request body. So, in addition to changing the default buffer size, the buffer size configurable, allowing apps to configure the buffer size based on workload.

View Components Tag Helpers

Consider a view component with an optional parameter, as shown in the following code:

C#

```
class MyViewComponent
{
```

```
    IViewComponentResult Invoke(bool showSomething = false) { ... }
}
```

With ASP.NET Core 6, the tag helper can be invoked without having to specify a value for the `showSomething` parameter:

razor

```
<vc:my />
```

Angular template updated to Angular 12

The ASP.NET Core 6.0 template for Angular now uses Angular 12.

The React template has been updated to React 17.

Configurable buffer threshold before writing to disk in Json.NET output formatter

Note: We recommend using the System.Text.Json output formatter except when the `Newtonsoft.Json` serializer is required for compatibility reasons. The `System.Text.Json` serializer is fully `async` and works efficiently for larger payloads.

The `Newtonsoft.Json` output formatter by default buffers responses up to 32 KiB in memory before buffering to disk. This is to avoid performing synchronous IO, which can result in other side-effects such as thread starvation and application deadlocks. However, if the response is larger than 32 KiB, considerable disk I/O occurs. The memory threshold is now configurable via the MvcNewtonsoftJsonOptions.OutputFormatterMemoryBufferThreshold property before buffering to disk:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages()
            .AddNewtonsoftJson(options =>
            {
                options.OutputFormatterMemoryBufferThreshold = 48 * 1024;
            });

var app = builder.Build();
```

For more information, see this GitHub pull request and the NewtonsoftJsonOutputFormatterTest.cs file.

Faster get and set for HTTP headers

New APIs were added to expose all common headers available on Microsoft.Net.Http.Headers.HeaderNames as properties on the IHeaderDictionary resulting in an easier to use API. For example, the in-line middleware in the following code gets and sets both request and response headers using the new APIs:

```C#
var builder = WebApplication.CreateBuilder(args);

var app = builder.Build();

app.MapGet("/", () => "Hello World!");

app.Use(async (context, next) =>
{
    var hostHeader = context.Request.Headers.Host;
    app.Logger.LogInformation("Host header: {host}", hostHeader);
    context.Response.Headers.XPoweredBy = "ASP.NET Core 6.0";
    await next.Invoke(context);
    var dateHeader = context.Response.Headers.Date;
    app.Logger.LogInformation("Response date: {date}", dateHeader);
});

app.Run();
```

For implemented headers the get and set accessors are implemented by going directly to the field and bypassing the lookup. For non-implemented headers, the accessors can bypass the initial lookup against implemented headers and directly perform the `Dictionary<string, StringValues>` lookup. Avoiding the lookup results in faster access for both scenarios.

Async streaming

ASP.NET Core now supports asynchronous streaming from controller actions and responses from the JSON formatter. Returning an `IAsyncEnumerable` from an action no longer buffers the response content in memory before it gets sent. Not buffering helps reduce memory usage when returning large datasets that can be asynchronously enumerated.

Note that Entity Framework Core provides implementations of `IAsyncEnumerable` for querying the database. The improved support for `IAsyncEnumerable` in ASP.NET Core in .NET 6 can make using EF Core with ASP.NET Core more efficient. For example, the following code no longer buffers the product data into memory before sending the response:

C#

```
public IActionResult GetMovies()
{
    return Ok(_context.Movie);
}
```

However, when using lazy loading in EF Core, this new behavior may result in errors due to concurrent query execution while the data is being enumerated. Apps can revert back to the previous behavior by buffering the data:

C#

```
public async Task<IActionResult> GetMovies2()
{
    return Ok(await _context.Movie.ToListAsync());
}
```

See the related announcement for additional details about this change in behavior.

HTTP logging middleware

HTTP logging is a new built-in middleware that logs information about HTTP requests and HTTP responses including the headers and entire body:

C#

```
var builder = WebApplication.CreateBuilder(args);

var app = builder.Build();
app.UseHttpLogging();

app.MapGet("/", () => "Hello World!");

app.Run();
```

Navigating to `/` with the previous code logs information similar to the following output:

.NET CLI

```
info: Microsoft.AspNetCore.HttpLogging.HttpLoggingMiddleware[1]
      Request:
      Protocol: HTTP/2
      Method: GET
      Scheme: https
      PathBase:
      Path: /
      Accept:
text/html,application/xhtml+xml,application/xml;q=0.9,image/webp,image/apng,
*/*;q=0.8,application/signed-exchange;v=b3;q=0.9
      Accept-Encoding: gzip, deflate, br
      Accept-Language: en-US,en;q=0.9
      Cache-Control: max-age=0
      Connection: close
      Cookie: [Redacted]
      Host: localhost:44372
      User-Agent: Mozilla/5.0 (Windows NT 10.0; Win64; x64)
AppleWebKit/537.36 (KHTML, like Gecko) Chrome/95.0.4638.54 Safari/537.36
Edg/95.0.1020.30
      sec-ch-ua: [Redacted]
      sec-ch-ua-mobile: [Redacted]
      sec-ch-ua-platform: [Redacted]
      upgrade-insecure-requests: [Redacted]
      sec-fetch-site: [Redacted]
      sec-fetch-mode: [Redacted]
      sec-fetch-user: [Redacted]
      sec-fetch-dest: [Redacted]
info: Microsoft.AspNetCore.HttpLogging.HttpLoggingMiddleware[2]
      Response:
      StatusCode: 200
      Content-Type: text/plain; charset=utf-8
```

The preceding output was enabled with the following `appsettings.Development.json` file:

JSON

```
{
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "Microsoft.AspNetCore": "Warning",
      "Microsoft.AspNetCore.HttpLogging.HttpLoggingMiddleware":
"Information"
    }
  }
}
```

HTTP logging provides logs of:

- HTTP Request information

- Common properties
- Headers
- Body
- HTTP Response information

To configure the HTTP logging middleware, specify HttpLoggingOptions:

C#

```
using Microsoft.AspNetCore.HttpLogging;

var builder = WebApplication.CreateBuilder(args);
builder.Services.AddHttpLogging(logging =>
{
    // Customize HTTP logging.
    logging.LoggingFields = HttpLoggingFields.All;
    logging.RequestHeaders.Add("My-Request-Header");
    logging.ResponseHeaders.Add("My-Response-Header");
    logging.MediaTypeOptions.AddText("application/javascript");
    logging.RequestBodyLogLimit = 4096;
    logging.ResponseBodyLogLimit = 4096;
});

var app = builder.Build();
app.UseHttpLogging();

app.MapGet("/", () => "Hello World!");

app.Run();
```

IConnectionSocketFeature

The IConnectionSocketFeature request feature provides access to the underlying accept socket associated with the current request. It can be accessed via the FeatureCollection on `HttpContext`.

For example, the following app sets the LingerState property on the accepted socket:

C#

```
var builder = WebApplication.CreateBuilder(args);
builder.WebHost.ConfigureKestrel(serverOptions =>
{
    serverOptions.ConfigureEndpointDefaults(listenOptions =>
listenOptions.Use((connection, next) =>
    {
        var socketFeature =
connection.Features.Get<IConnectionSocketFeature>();
        socketFeature.Socket.LingerState = new LingerOption(true, seconds:
```

```
10);
        return next();
    }));
});
var app = builder.Build();
app.MapGet("/", (Func<string>)(() => "Hello world"));
await app.RunAsync();
```

Generic type constraints in Razor

When defining generic type parameters in Razor using the `@typeparam` directive, generic type constraints can now be specified using the standard C# syntax:

Smaller SignalR, Blazor Server, and MessagePack scripts

The SignalR, MessagePack, and Blazor Server scripts are now significantly smaller, enabling smaller downloads, less JavaScript parsing and compiling by the browser, and faster start-up. The size reductions:

- `signalr.js`: 70%
- `blazor.server.js`: 45%

The smaller scripts are a result of a community contribution from Ben Adams. For more information on the details of the size reduction, see Ben's GitHub pull request.

Enable Redis profiling sessions

A community contribution from Gabriel Lucaci enables Redis profiling session with Microsoft.Extensions.Caching.StackExchangeRedis:

C#

```
using StackExchange.Redis.Profiling;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddStackExchangeRedisCache(options =>
{
    options.ProfilingSession = () => new ProfilingSession();
});
```

For more information, see StackExchange.Redis Profiling.

Shadow copying in IIS

An experimental feature has been added to the ASP.NET Core Module (ANCM) for IIS to add support for shadow copying application assemblies. Currently .NET locks application binaries when running on Windows making it impossible to replace binaries when the app is running. While our recommendation remains to use an app offline file, we recognize there are certain scenarios (for example FTP deployments) where it isn't possible to do so.

In such scenarios, enable shadow copying by customizing the ASP.NET Core module handler settings. In most cases, ASP.NET Core apps do not have a `web.config` checked into source control that you can modify. In ASP.NET Core, `web.config` is ordinarily generated by the SDK. The following sample `web.config` can be used to get started:

XML

```
<?xml version="1.0" encoding="utf-8"?>
<configuration>
  <!-- To customize the asp.net core module uncomment and edit the following
section.
  For more info see https://go.microsoft.com/fwlink/?linkid=838655 -->

  <system.webServer>
    <handlers>
      <remove name="aspNetCore"/>
      <add name="aspNetCore" path="*" verb="*" modules="AspNetCoreModuleV2"
resourceType="Unspecified"/>
    </handlers>
    <aspNetCore processPath="%LAUNCHER_PATH%" arguments="%LAUNCHER_ARGS%"
stdoutLogEnabled="false" stdoutLogFile=".\logs\stdout">
      <handlerSettings>
        <handlerSetting name="experimentalEnableShadowCopy" value="true" />
        <handlerSetting name="shadowCopyDirectory"
value="../ShadowCopyDirectory/" />
        <!-- Only enable handler logging if you encounter issues-->
        <!--<handlerSetting name="debugFile" value=".\logs\aspnetcore-
debug.log" />-->
        <!--<handlerSetting name="debugLevel" value="FILE,TRACE" />-->
      </handlerSettings>
    </aspNetCore>
  </system.webServer>
</configuration>
```

Shadow copying in IIS is an experimental feature that is not guaranteed to be part of ASP.NET Core. Please leave feedback on IIS Shadow copying in this GitHub issue.

What's new in ASP.NET Core 5.0

Article • 09/27/2024

This article highlights the most significant changes in ASP.NET Core 5.0 with links to relevant documentation.

ASP.NET Core MVC and Razor improvements

Model binding DateTime as UTC

Model binding now supports binding UTC time strings to `DateTime`. If the request contains a UTC time string, model binding binds it to a UTC `DateTime`. For example, the following time string is bound the UTC `DateTime`:

`https://example.com/mycontroller/myaction?time=2019-06-14T02%3A30%3A04.0576719Z`

Model binding and validation with C# 9 record types

C# 9 record types can be used with model binding in an MVC controller or a Razor Page. Record types are a good way to model data being transmitted over the network.

For example, the following `PersonController` uses the `Person` record type with model binding and form validation:

C#

```
public record Person([Required] string Name, [Range(0, 150)] int Age);

public class PersonController
{
   public IActionResult Index() => View();

   [HttpPost]
   public IActionResult Index(Person person)
   {
          // ...
   }
}
```

The `Person/Index.cshtml` file:

CSHTML

```
@model Person

<label>Name: <input asp-for="Model.Name" /></label>
<span asp-validation-for="Model.Name" />

<label>Age: <input asp-for="Model.Age" /></label>
<span asp-validation-for="Model.Age" />
```

Improvements to DynamicRouteValueTransformer

ASP.NET Core 3.1 introduced DynamicRouteValueTransformer as a way to use custom endpoint to dynamically select an MVC controller action or a Razor page. ASP.NET Core 5.0 apps can pass state to a `DynamicRouteValueTransformer` and filter the set of endpoints chosen.

Miscellaneous

- The [Compare] attribute can be applied to properties on a Razor Page model.
- Parameters and properties bound from the body are considered required by default.

Web API

OpenAPI Specification on by default

OpenAPI Specification is an industry standard for describing HTTP APIs and integrating them into complex business processes or with third parties. OpenAPI is widely supported by all cloud providers and many API registries. Apps that emit OpenAPI documents from web APIs have a variety of new opportunities in which those APIs can be used. In partnership with the maintainers of the open-source project Swashbuckle.AspNetCore, the ASP.NET Core API template contains a NuGet dependency on Swashbuckle. Swashbuckle is a popular open-source NuGet package that emits OpenAPI documents dynamically. Swashbuckle does this by introspecting over the API controllers and generating the OpenAPI document at run-time, or at build time using the Swashbuckle CLI.

In ASP.NET Core 5.0, the web API templates enable the OpenAPI support by default. To disable OpenAPI:

- From the command line:

.NET CLI

```
dotnet new webapi --no-openapi true
```

- From Visual Studio: Uncheck **Enable OpenAPI support**.

All `.csproj` files created for web API projects contain the Swashbuckle.AspNetCore NuGet package reference.

XML

```
<ItemGroup>
    <PackageReference Include="Swashbuckle.AspNetCore" Version="5.5.1" />
</ItemGroup>
```

The template generated code contains code in `Startup.ConfigureServices` that activates OpenAPI document generation:

C#

```
public void ConfigureServices(IServiceCollection services)
{

    services.AddControllers();
    services.AddSwaggerGen(c =>
    {
        c.SwaggerDoc("v1", new OpenApiInfo { Title = "WebApp1", Version =
"v1" });
    });
}
```

The `Startup.Configure` method adds the Swashbuckle middleware, which enables the:

- Document generation process.
- Swagger UI page by default in development mode.

The template generated code won't accidentally expose the API's description when publishing to production.

C#

```
public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
        app.UseSwagger();  // UseSwaggerUI Protected by if
```

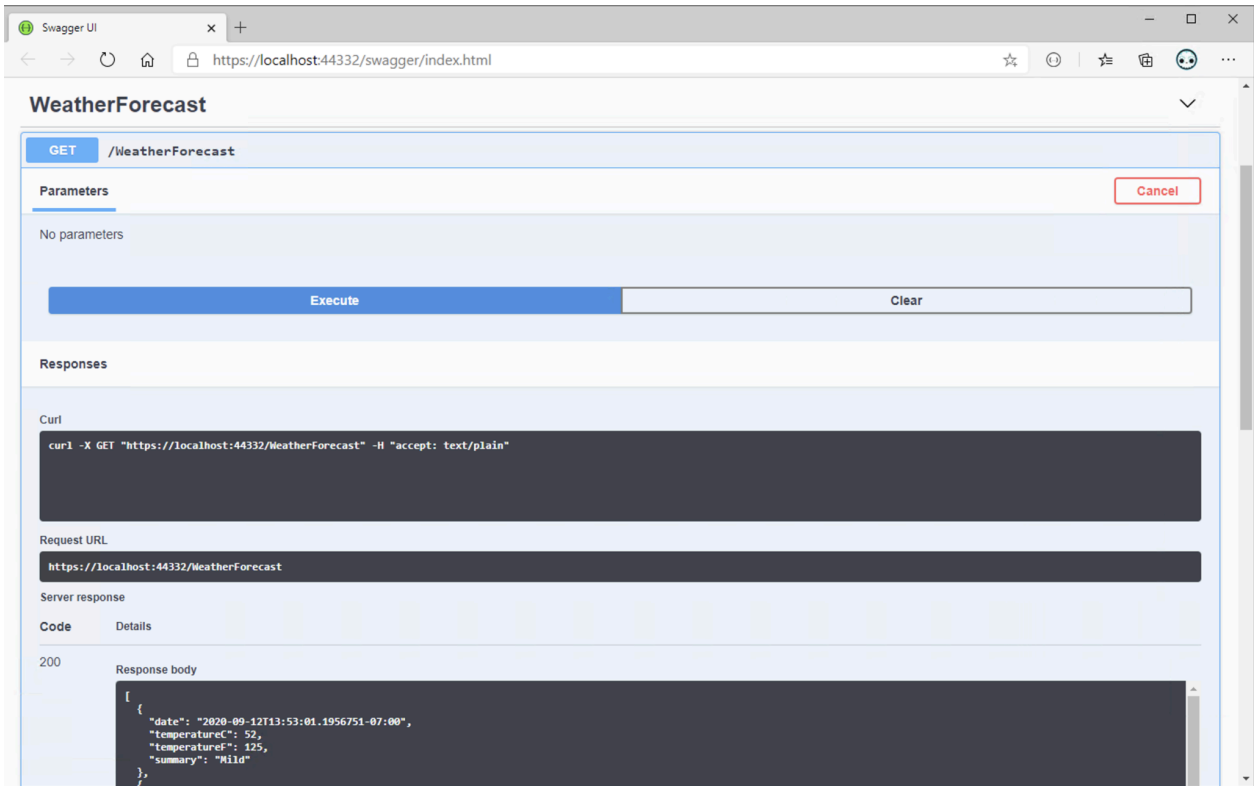
```
(env.IsDevelopment())
        app.UseSwaggerUI(c => c.SwaggerEndpoint("/swagger/v1/swagger.json",
                            "WebApp1 v1"));
    }

    app.UseHttpsRedirection();

    app.UseRouting();

    app.UseAuthorization();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapControllers();
    });
}
```



Azure API Management Import

When ASP.NET Core API projects enable OpenAPI, the Visual Studio 2019 version 16.8 and later publishing automatically offer an additional step in the publishing flow. Developers who use Azure API Management have an opportunity to automatically import the APIs into Azure API Management during the publish flow:

Better launch experience for web API projects

With OpenAPI enabled by default, the app launching experience (F5) for web API developers significantly improves. With ASP.NET Core 5.0, the web API template comes pre-configured to load up the Swagger UI page. The Swagger UI page provides both the documentation added for the published API, and enables testing the APIs with a single click.

Blazor

Performance improvements

For .NET 5, we made significant improvements to .NET WebAssembly runtime performance with a specific focus on complex UI rendering and JSON serialization. In our performance tests, Blazor WebAssembly in .NET 5 is two to three times faster for most scenarios. For more information, see ASP.NET Blog: ASP.NET Core updates in .NET 5 Release Candidate 1.

CSS isolation

Blazor now supports defining CSS styles that are scoped to a given component. Component-specific CSS styles make it easier to reason about the styles in an app and to avoid unintentional side effects of global styles. For more information, see ASP.NET Core Blazor CSS isolation.

New `InputFile` component

The `InputFile` component allows reading one or more files selected by a user for upload. For more information, see ASP.NET Core Blazor file uploads.

New `InputRadio` and `InputRadioGroup` components

Blazor has built-in `InputRadio` and `InputRadioGroup` components that simplify data binding to radio button groups with integrated validation. For more information, see ASP.NET Core Blazor input components.

Component virtualization

Improve the perceived performance of component rendering using the Blazor framework's built-in virtualization support. For more information, see ASP.NET Core Razor component virtualization.

`ontoggle` event support

Blazor events now support the `ontoggle` DOM event. For more information, see ASP.NET Core Blazor event handling.

Set UI focus in Blazor apps

Use the `FocusAsync` convenience method on element references to set the UI focus to that element. For more information, see ASP.NET Core Blazor event handling.

Custom validation CSS class attributes

Custom validation CSS class attributes are useful when integrating with CSS frameworks, such as Bootstrap. For more information, see ASP.NET Core Blazor forms validation.

IAsyncDisposable support

Razor components now support the IAsyncDisposable interface for the asynchronous release of allocated resources.

JavaScript isolation and object references

Blazor enables JavaScript isolation in standard JavaScript modules. For more information, see Call JavaScript functions from .NET methods in ASP.NET Core Blazor.

Form components support display name

The following built-in components support display names with the `DisplayName` parameter:

- `InputDate`
- `InputNumber`
- `InputSelect`

For more information, see ASP.NET Core Blazor forms overview.

Catch-all route parameters

Catch-all route parameters, which capture paths across multiple folder boundaries, are supported in components. For more information, see ASP.NET Core Blazor routing and navigation.

Debugging improvements

Debugging Blazor WebAssembly apps is improved in ASP.NET Core 5.0. Additionally, debugging is now supported on Visual Studio for Mac. For more information, see Debug ASP.NET Core Blazor apps.

Microsoft Identity v2.0 and MSAL v2.0

Blazor security now uses Microsoft Identity v2.0 (Microsoft.Identity.Web and Microsoft.Identity.Web.UI) and MSAL v2.0. For more information, see the topics in the Blazor Security and Identity node.

Protected Browser Storage for Blazor Server

Blazor Server apps can now use built-in support for storing app state in the browser that has been protected from tampering using ASP.NET Core data protection. Data can be stored in either local browser storage or session storage. For more information, see ASP.NET Core Blazor state management.

Blazor WebAssembly prerendering

Component integration is improved across hosting models, and Blazor WebAssembly apps can now prerender output on the server.

Trimming/linking improvements

Blazor WebAssembly performs Intermediate Language (IL) trimming/linking during a build to trim unnecessary IL from the app's output assemblies. With the release of ASP.NET Core 5.0, Blazor WebAssembly performs improved trimming with additional configuration options. For more information, see Configure the Trimmer for ASP.NET Core Blazor and Trimming options.

Browser compatibility analyzer

Blazor WebAssembly apps target the full .NET API surface area, but not all .NET APIs are supported on WebAssembly due to browser sandbox constraints. Unsupported APIs throw PlatformNotSupportedException when running on WebAssembly. A platform compatibility analyzer warns the developer when the app uses APIs that aren't supported by the app's target platforms. For more information, see Consume ASP.NET Core Razor components from a Razor class library (RCL).

Lazy load assemblies

Blazor WebAssembly app startup performance can be improved by deferring the loading of some application assemblies until they're required. For more information, see Lazy load assemblies in ASP.NET Core Blazor WebAssembly.

Updated globalization support

Globalization support is available for Blazor WebAssembly based on International Components for Unicode (ICU). For more information, see ASP.NET Core Blazor globalization and localization.

gRPC

Many preformance improvements have been made in gRPC. For more information, see gRPC performance improvements in .NET 5.

For more gRPC information, see Overview for gRPC on .NET.

SignalR

SignalR Hub filters

SignalR Hub filters, called Hub pipelines in ASP.NET SignalR, is a feature that allows code to run before and after Hub methods are called. Running code before and after Hub methods are called is similar to how middleware has the ability to run code before and after an HTTP request. Common uses include logging, error handling, and argument validation.

For more information, see Use hub filters in ASP.NET Core SignalR.

SignalR parallel hub invocations

ASP.NET Core SignalR is now capable of handling parallel hub invocations. The default behavior can be changed to allow clients to invoke more than one hub method at a time:

C#

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddSignalR(options =>
    {
        options.MaximumParallelInvocationsPerClient = 5;
    });
}
```

Added Messagepack support in SignalR Java client

A new package, com.microsoft.signalr.messagepack, adds MessagePack support to the SignalR Java client. To use the MessagePack hub protocol, add `.withHubProtocol(new MessagePackHubProtocol())` to the connection builder:

Java

```
HubConnection hubConnection = HubConnectionBuilder.create(
                              "http://localhost:53353/MyHub")
                .withHubProtocol(new MessagePackHubProtocol())
                .build();
```

Kestrel

- Reloadable endpoints via configuration: Kestrel can detect changes to configuration passed to KestrelServerOptions.Configure and unbind from existing

endpoints and bind to new endpoints without requiring an application restart when the `reloadOnChange` parameter is `true`. By default when using ConfigureWebHostDefaults or CreateDefaultBuilder, Kestrel binds to the "Kestrel" configuration subsection with `reloadOnChange` enabled. Apps must pass `reloadOnChange: true` when calling `KestrelServerOptions.Configure` manually to get reloadable endpoints.

- HTTP/2 response headers improvements. For more information, see Performance improvements in the next section.

- Support for additional endpoints types in the sockets transport: Adding to the new API introduced in System.Net.Sockets, the sockets default transport in Kestrel allows binding to both existing file handles and Unix domain sockets. Support for binding to existing file handles enables using the existing `Systemd` integration without requiring the `libuv` transport.

- Custom header decoding in Kestrel: Apps can specify which Encoding to use to interpret incoming headers based on the header name instead of defaulting to UTF-8. Set the `Microsoft.AspNetCore.Server.Kestrel.KestrelServerOptions.RequestHeaderEncodingSelector` property to specify which encoding to use:

```
C#
```

```
public static IHostBuilder CreateHostBuilder(string[] args) =>
  Host.CreateDefaultBuilder(args)
      .ConfigureWebHostDefaults(webBuilder =>
      {
          webBuilder.ConfigureKestrel(options =>
          {
              options.RequestHeaderEncodingSelector = encoding =>
              {
                    return encoding switch
                    {
                        "Host" => System.Text.Encoding.Latin1,
                        _ => System.Text.Encoding.UTF8,
                    };
              };
          });
          webBuilder.UseStartup<Startup>();
      });
```

Kestrel endpoint-specific options via configuration

Support has been added for configuring Kestrel's endpoint-specific options via configuration. The endpoint-specific configurations includes the:

- HTTP protocols used
- TLS protocols used
- Certificate selected
- Client certificate mode

Configuration allows specifying which certificate is selected based on the specified server name. The server name is part of the Server Name Indication (SNI) extension to the TLS protocol as indicated by the client. Kestrel's configuration also supports a wildcard prefix in the host name.

The following example shows how to specify endpoint-specific using a configuration file:

JSON

```
{
  "Kestrel": {
    "Endpoints": {
      "EndpointName": {
        "Url": "https://*",
        "Sni": {
          "a.example.org": {
            "Protocols": "Http1AndHttp2",
            "SslProtocols": [ "Tls11", "Tls12"],
            "Certificate": {
              "Path": "testCert.pfx",
              "Password": "testPassword"
            },
            "ClientCertificateMode" : "NoCertificate"
          },
          "*.example.org": {
            "Certificate": {
              "Path": "testCert2.pfx",
              "Password": "testPassword"
            }
          },
          "*": {
            // At least one sub-property needs to exist per
            // SNI section or it cannot be discovered via
            // IConfiguration
            "Protocols": "Http1",
          }
        }
      }
    }
  }
}
```

Server Name Indication (SNI) is a TLS extension to include a virtual domain as a part of SSL negotiation. What this effectively means is that the virtual domain name, or a hostname, can be used to identify the network end point.

Performance improvements

HTTP/2

- Significant reductions in allocations in the HTTP/2 code path.
- Support for HPack dynamic compression of HTTP/2 response headers in Kestrel. For more information, see Header table size and HPACK: the silent killer (feature) of HTTP/2.
- Sending HTTP/2 PING frames: HTTP/2 has a mechanism for sending PING frames to ensure an idle connection is still functional. Ensuring a viable connection is especially useful when working with long-lived streams that are often idle but only intermittently see activity, for example, gRPC streams. Apps can send periodic PING frames in Kestrel by setting limits on KestrelServerOptions:

```
C#
```

```
public static IHostBuilder CreateHostBuilder(string[] args) =>
  Host.CreateDefaultBuilder(args)
      .ConfigureWebHostDefaults(webBuilder =>
      {
          webBuilder.ConfigureKestrel(options =>
          {
              options.Limits.Http2.KeepAlivePingInterval =
                                              TimeSpan.FromSeconds(10);
              options.Limits.Http2.KeepAlivePingTimeout =
                                              TimeSpan.FromSeconds(1);
          });
          webBuilder.UseStartup<Startup>();
      });
```

Containers

Prior to .NET 5.0, building and publishing a *Dockerfile* for an ASP.NET Core app required pulling the entire .NET Core SDK and the ASP.NET Core image. With this release, pulling the SDK images bytes is reduced and the bytes pulled for the ASP.NET Core image is largely eliminated. For more information, see this GitHub issue comment.

Authentication and authorization

Microsoft Entra ID authentication with Microsoft.Identity.Web

The ASP.NET Core project templates now integrate with Microsoft.Identity.Web to handle authentication with Microsoft Entra ID. The Microsoft.Identity.Web package provides:

- A better experience for authentication through Microsoft Entra ID.
- An easier way to access Azure resources on behalf of your users, including Microsoft Graph. See the Microsoft.Identity.Web sample, which starts with a basic login and advances through multi-tenancy, using Azure APIs, using Microsoft Graph, and protecting your own APIs. `Microsoft.Identity.Web` is available alongside .NET 5.

Allow anonymous access to an endpoint

The `AllowAnonymous` extension method allows anonymous access to an endpoint:

C#

```
public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    app.UseRouting();

    app.UseAuthentication();
    app.UseAuthorization();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapGet("/", async context =>
        {
            await context.Response.WriteAsync("Hello World!");
        })
        .AllowAnonymous();
    });
}
```

Custom handling of authorization failures

Custom handling of authorization failures is now easier with the new IAuthorizationMiddlewareResultHandler interface that is invoked by the authorization Middleware. The default implementation remains the same, but a custom handler can

be registered in [Dependency injection, which allows custom HTTP responses based on why authorization failed. See this sample that demonstrates usage of the `IAuthorizationMiddlewareResultHandler`.

Authorization when using endpoint routing

Authorization when using endpoint routing now receives the `HttpContext` rather than the endpoint instance. This allows the authorization middleware to access the `RouteData` and other properties of the `HttpContext` that were not accessible though the Endpoint class. The endpoint can be fetched from the context using context.GetEndpoint.

Role-based access control with Kerberos authentication and LDAP on Linux

See Kerberos authentication and role-based access control (RBAC)

API improvements

JSON extension methods for HttpRequest and HttpResponse

JSON data can be read and written to from an `HttpRequest` and `HttpResponse` using the new ReadFromJsonAsync and `WriteAsJsonAsync` extension methods. These extension methods use the System.Text.Json serializer to handle the JSON data. The new `HasJsonContentType` extension method can also check if a request has a JSON content type.

The JSON extension methods can be combined with endpoint routing to create JSON APIs in a style of programming we call ***route to code***. It is a new option for developers who want to create basic JSON APIs in a lightweight way. For example, a web app that has only a handful of endpoints might choose to use route to code rather than the full functionality of ASP.NET Core MVC:

C#

```
endpoints.MapGet("/weather/{city:alpha}", async context =>
{
    var city = (string)context.Request.RouteValues["city"];
    var weather = GetFromDatabase(city);
```

```
    await context.Response.WriteAsJsonAsync(weather);
});
```

System.Diagnostics.Activity

The default format for System.Diagnostics.Activity now defaults to the W3C format. This makes distributed tracing support in ASP.NET Core interoperable with more frameworks by default.

FromBodyAttribute

FromBodyAttribute now supports configuring an option that allows these parameters or properties to be considered optional:

C#

```
public IActionResult Post([FromBody(EmptyBodyBehavior =
EmptyBodyBehavior.Allow)]
                          MyModel model)
{
    ...
}
```

Miscellaneous improvements

We've started applying nullable annotations to ASP.NET Core assemblies. We plan to annotate most of the common public API surface of the .NET 5 framework.

Control Startup class activation

An additional UseStartup overload has been added that lets an app provide a factory method for controlling `Startup` class activation. Controlling `Startup` class activation is useful to pass additional parameters to `Startup` that are initialized along with the host:

C#

```
public class Program
{
    public static async Task Main(string[] args)
    {
        var logger = CreateLogger();
        var host = Host.CreateDefaultBuilder()
            .ConfigureWebHost(builder =>
```

```
            {
                builder.UseStartup(context => new Startup(logger));
            })
            .Build();

        await host.RunAsync();
    }
}
```

Auto refresh with dotnet watch

In .NET 5, running dotnet watch on an ASP.NET Core project both launches the default browser and auto refreshes the browser as changes are made to the code. This means you can:

- Open an ASP.NET Core project in a text editor.
- Run `dotnet watch`.
- Focus on the code changes while the tooling handles rebuilding, restarting, and reloading the app.

Console Logger Formatter

Improvements have been made to the console log provider in the `Microsoft.Extensions.Logging` library. Developers can now implement a custom `ConsoleFormatter` to exercise complete control over formatting and colorization of the console output. The formatter APIs allow for rich formatting by implementing a subset of the VT-100 escape sequences. VT-100 is supported by most modern terminals. The console logger can parse out escape sequences on unsupported terminals allowing developers to author a single formatter for all terminals.

JSON Console Logger

In addition to support for custom formatters, we've also added a built-in JSON formatter that emits structured JSON logs to the console. The following code shows how to switch from the default logger to JSON:

C#

```
public static IHostBuilder CreateHostBuilder(string[] args) =>
           Host.CreateDefaultBuilder(args)
  .ConfigureLogging(logging =>
  {
     logging.AddJsonConsole(options =>
     {
```

```
            options.JsonWriterOptions = new JsonWriterOptions()
            { Indented = true };
        });
    })
    .ConfigureWebHostDefaults(webBuilder =>
    {
      webBuilder.UseStartup<Startup>();
    });
```

Log messages emitted to the console are JSON formatted:

JSON

```
{
  "EventId": 0,
  "LogLevel": "Information",
  "Category": "Microsoft.Hosting.Lifetime",
  "Message": "Now listening on: https://localhost:5001",
  "State": {
    "Message": "Now listening on: https://localhost:5001",
    "address": "https://localhost:5001",
    "{OriginalFormat}": "Now listening on: {address}"
  }
}
```

What's new in ASP.NET Core 3.1

Article • 09/25/2023

This article highlights the most significant changes in ASP.NET Core 3.1 with links to relevant documentation.

Partial class support for Razor components

Razor components are now generated as partial classes. Code for a Razor component can be written using a code-behind file defined as a partial class rather than defining all the code for the component in a single file. For more information, see Partial class support.

Component Tag Helper and pass parameters to top-level components

In Blazor with ASP.NET Core 3.0, components were rendered into pages and views using an HTML Helper (`Html.RenderComponentAsync`). In ASP.NET Core 3.1, render a component from a page or view with the new Component Tag Helper:

CSHTML

```
<component type="typeof(Counter)" render-mode="ServerPrerendered" />
```

The HTML Helper remains supported in ASP.NET Core 3.1, but the Component Tag Helper is recommended.

Blazor Server apps can now pass parameters to top-level components during the initial render. Previously you could only pass parameters to a top-level component with RenderMode.Static. With this release, both RenderMode.Server and RenderMode.ServerPrerendered are supported. Any specified parameter values are serialized as JSON and included in the initial response.

For example, prerender a `Counter` component with an increment amount (`IncrementAmount`):

CSHTML

```
<component type="typeof(Counter)" render-mode="ServerPrerendered"
    param-IncrementAmount="10" />
```

For more information, see Integrate components into Razor Pages and MVC apps.

Support for shared queues in HTTP.sys

HTTP.sys supports creating anonymous request queues. In ASP.NET Core 3.1, we've added the ability to create or attach to an existing named HTTP.sys request queue. Creating or attaching to an existing named HTTP.sys request queue enables scenarios where the HTTP.sys controller process that owns the queue is independent of the listener process. This independence makes it possible to preserve existing connections and enqueued requests between listener process restarts:

C#

```
public static IHostBuilder CreateHostBuilder(string[] args) =>
     Host.CreateDefaultBuilder(args)
        .ConfigureWebHostDefaults(webBuilder =>
        {
            // ...
            webBuilder.UseHttpSys(options =>
            {
                options.RequestQueueName = "MyExistingQueue";
                options.RequestQueueMode = RequestQueueMode.CreateOrAttach;
            });
        });
```

Breaking changes for SameSite cookies

The behavior of SameSite cookies has changed to reflect upcoming browser changes. This may affect authentication scenarios like AzureAd, OpenIdConnect, or WsFederation. For more information, see Work with SameSite cookies in ASP.NET Core.

Prevent default actions for events in Blazor apps

Use the `@on{EVENT}:preventDefault` directive attribute to prevent the default action for an event. In the following example, the default action of displaying the key's character in the text box is prevented:

razor

```
<input value="@_count" @onkeypress="KeyHandler" @onkeypress:preventDefault
/>
```

For more information, see Prevent default actions.

Stop event propagation in Blazor apps

Use the `@on{EVENT}:stopPropagation` directive attribute to stop event propagation. In the following example, selecting the checkbox prevents click events from the child `<div>` from propagating to the parent `<div>`:

razor

```
<input @bind="_stopPropagation" type="checkbox" />

<div @onclick="OnSelectParentDiv">
    <div @onclick="OnSelectChildDiv"
@onclick:stopPropagation="_stopPropagation">
        ...
    </div>
</div>

@code {
    private bool _stopPropagation = false;
}
```

For more information, see Stop event propagation.

Detailed errors during Blazor app development

When a Blazor app isn't functioning properly during development, receiving detailed error information from the app assists in troubleshooting and fixing the issue. When an error occurs, Blazor apps display a gold bar at the bottom of the screen:

- During development, the gold bar directs you to the browser console, where you can see the exception.
- In production, the gold bar notifies the user that an error has occurred and recommends refreshing the browser.

For more information, see Handle errors in ASP.NET Core Blazor apps.

What's new in ASP.NET Core 3.0

Article • 09/27/2023

This article highlights the most significant changes in ASP.NET Core 3.0 with links to relevant documentation.

Blazor

Blazor is a new framework in ASP.NET Core for building interactive client-side web UI with .NET:

- Create rich interactive UIs using C#.
- Share server-side and client-side app logic written in .NET.
- Render the UI as HTML and CSS for wide browser support, including mobile browsers.

Blazor framework supported scenarios:

- Reusable UI components (Razor components)
- Client-side routing
- Component layouts
- Support for dependency injection
- Forms and validation
- Supply Razor components in Razor class libraries
- JavaScript interop

For more information, see ASP.NET Core Blazor.

Blazor Server

Blazor decouples component rendering logic from how UI updates are applied. Blazor Server provides support for hosting Razor components on the server in an ASP.NET Core app. UI updates are handled over a SignalR connection. Blazor Server is supported in ASP.NET Core 3.0.

Blazor WebAssembly (Preview)

Blazor apps can also be run directly in the browser using a WebAssembly-based .NET runtime. Blazor WebAssembly is in preview and *not* supported in ASP.NET Core 3.0. Blazor WebAssembly will be supported in a future release of ASP.NET Core.

Razor components

Blazor apps are built from components. Components are self-contained chunks of user interface (UI), such as a page, dialog, or form. Components are normal .NET classes that define UI rendering logic and client-side event handlers. You can create rich interactive web apps without JavaScript.

Components in Blazor are typically authored using Razor syntax, a natural blend of HTML and C#. Razor components are similar to Razor Pages and MVC views in that they both use Razor. Unlike pages and views, which are based on a request-response model, components are used specifically for handling UI composition.

gRPC

gRPC:

- Is a popular, high-performance RPC (remote procedure call) framework.
- Offers an opinionated contract-first approach to API development.
- Uses modern technologies such as:
  - HTTP/2 for transport.
  - Protocol Buffers as the interface description language.
  - Binary serialization format.
- Provides features such as:
  - Authentication
  - Bidirectional streaming and flow control.
  - Cancellation and timeouts.

gRPC functionality in ASP.NET Core 3.0 includes:

- Grpc.AspNetCore: An ASP.NET Core framework for hosting gRPC services. gRPC on ASP.NET Core integrates with standard ASP.NET Core features like logging, dependency injection (DI), authentication, and authorization.
- Grpc.Net.Client: A gRPC client for .NET Core that builds upon the familiar `HttpClient`.
- Grpc.Net.ClientFactory: gRPC client integration with `HttpClientFactory`.

For more information, see Overview for gRPC on .NET.

SignalR

See Update SignalR code for migration instructions. SignalR now uses `System.Text.Json` to serialize/deserialize JSON messages. See Switch to Newtonsoft.Json for instructions to restore the `Newtonsoft.Json`-based serializer.

In the JavaScript and .NET Clients for SignalR, support was added for automatic reconnection. By default, the client tries to reconnect immediately and retry after 2, 10, and 30 seconds if necessary. If the client successfully reconnects, it receives a new connection ID. Automatic reconnect is opt-in:

JavaScript

```
const connection = new signalR.HubConnectionBuilder()
    .withUrl("/chathub")
    .withAutomaticReconnect()
    .build();
```

The reconnection intervals can be specified by passing an array of millisecond-based durations:

JavaScript

```
.withAutomaticReconnect([0, 3000, 5000, 10000, 15000, 30000])
//.withAutomaticReconnect([0, 2000, 10000, 30000]) The default intervals.
```

A custom implementation can be passed in for full control of the reconnection intervals.

If the reconnection fails after the last reconnect interval:

- The client considers the connection is offline.
- The client stops trying to reconnect.

During reconnection attempts, update the app UI to notify the user that the reconnection is being attempted.

To provide UI feedback when the connection is interrupted, the SignalR client API has been expanded to include the following event handlers:

- `onreconnecting`: Gives developers an opportunity to disable UI or to let users know the app is offline.
- `onreconnected`: Gives developers an opportunity to update the UI once the connection is reestablished.

The following code uses `onreconnecting` to update the UI while trying to connect:

JavaScript

```
connection.onreconnecting((error) => {
    const status = `Connection lost due to error "${error}". Reconnecting.`;
    document.getElementById("messageInput").disabled = true;
    document.getElementById("sendButton").disabled = true;
    document.getElementById("connectionStatus").innerText = status;
});
```

The following code uses `onreconnected` to update the UI on connection:

JavaScript

```
connection.onreconnected((connectionId) => {
    const status = `Connection reestablished. Connected.`;
    document.getElementById("messageInput").disabled = false;
    document.getElementById("sendButton").disabled = false;
    document.getElementById("connectionStatus").innerText = status;
});
```

SignalR 3.0 and later provides a custom resource to authorization handlers when a hub method requires authorization. The resource is an instance of `HubInvocationContext`. The `HubInvocationContext` includes the:

- `HubCallerContext`
- Name of the hub method being invoked.
- Arguments to the hub method.

Consider the following example of a chat room app allowing multiple organization sign-in via Azure Active Directory. Anyone with a Microsoft account can sign in to chat, but only members of the owning organization can ban users or view users' chat histories. The app could restrict certain functionality from specific users.

C#

```
public class DomainRestrictedRequirement :
    AuthorizationHandler<DomainRestrictedRequirement, HubInvocationContext>,
    IAuthorizationRequirement
{
    protected override Task
HandleRequirementAsync(AuthorizationHandlerContext context,
        DomainRestrictedRequirement requirement,
        HubInvocationContext resource)
    {
        if (context.User?.Identity?.Name == null)
        {
            return Task.CompletedTask;
        }
```

```
        if (IsUserAllowedToDoThis(resource.HubMethodName,
context.User.Identity.Name))
        {
            context.Succeed(requirement);
        }

        return Task.CompletedTask;
    }

    private bool IsUserAllowedToDoThis(string hubMethodName, string
currentUsername)
    {
        if (hubMethodName.Equals("banUser",
StringComparison.OrdinalIgnoreCase))
        {
            return currentUsername.Equals("bob42@jabbr.net",
StringComparison.OrdinalIgnoreCase);
        }

        return currentUsername.EndsWith("@jabbr.net",
StringComparison.OrdinalIgnoreCase));
    }
}
```

In the preceding code, `DomainRestrictedRequirement` serves as a custom `IAuthorizationRequirement`. Because the `HubInvocationContext` resource parameter is being passed in, the internal logic can:

- Inspect the context in which the Hub is being called.
- Make decisions on allowing the user to execute individual Hub methods.

Individual Hub methods can be marked with the name of the policy the code checks at run-time. As clients attempt to call individual Hub methods, the `DomainRestrictedRequirement` handler runs and controls access to the methods. Based on the way the `DomainRestrictedRequirement` controls access:

- All logged-in users can call the `SendMessage` method.
- Only users who have logged in with a `@jabbr.net` email address can view users' histories.
- Only `bob42@jabbr.net` can ban users from the chat room.

C#

```
[Authorize]
public class ChatHub : Hub
{
    public void SendMessage(string message)
    {
    }
```

```
    [Authorize("DomainRestricted")]
    public void BanUser(string username)
    {
    }

    [Authorize("DomainRestricted")]
    public void ViewUserHistory(string username)
    {
    }
}
```

Creating the `DomainRestricted` policy might involve:

- In `Startup.cs`, adding the new policy.
- Provide the custom `DomainRestrictedRequirement` requirement as a parameter.
- Registering `DomainRestricted` with the authorization middleware.

C#

```
services
    .AddAuthorization(options =>
    {
        options.AddPolicy("DomainRestricted", policy =>
        {
            policy.Requirements.Add(new DomainRestrictedRequirement());
        });
    });
```

SignalR hubs use Endpoint Routing. SignalR hub connection was previously done explicitly:

C#

```
app.UseSignalR(routes =>
{
    routes.MapHub<ChatHub>("hubs/chat");
});
```

In the previous version, developers needed to wire up controllers, Razor pages, and hubs in a variety of places. Explicit connection results in a series of nearly-identical routing segments:

C#

```
app.UseSignalR(routes =>
{
    routes.MapHub<ChatHub>("hubs/chat");
```

```
});

app.UseRouting(routes =>
{
    routes.MapRazorPages();
});
```

SignalR 3.0 hubs can be routed via endpoint routing. With endpoint routing, typically all routing can be configured in `UseRouting`:

C#

```
app.UseRouting(routes =>
{
    routes.MapRazorPages();
    routes.MapHub<ChatHub>("hubs/chat");
});
```

ASP.NET Core 3.0 SignalR added:

Client-to-server streaming. With client-to-server streaming, server-side methods can take instances of either an `IAsyncEnumerable<T>` or `ChannelReader<T>`. In the following C# sample, the `UploadStream` method on the Hub will receive a stream of strings from the client:

C#

```
public async Task UploadStream(IAsyncEnumerable<string> stream)
{
    await foreach (var item in stream)
    {
        // process content
    }
}
```

.NET client apps can pass either an `IAsyncEnumerable<T>` or `ChannelReader<T>` instance as the `stream` argument of the `UploadStream` Hub method above.

After the `for` loop has completed and the local function exits, the stream completion is sent:

C#

```
async IAsyncEnumerable<string> clientStreamData()
{
    for (var i = 0; i < 5; i++)
    {
```

```
        var data = await FetchSomeData();
        yield return data;
    }
}

await connection.SendAsync("UploadStream", clientStreamData());
```

JavaScript client apps use the SignalR `Subject` (or an RxJS Subject) for the `stream` argument of the `UploadStream` Hub method above.

JavaScript

```
let subject = new signalR.Subject();
await connection.send("StartStream", "MyAsciiArtStream", subject);
```

The JavaScript code could use the `subject.next` method to handle strings as they are captured and ready to be sent to the server.

JavaScript

```
subject.next("example");
subject.complete();
```

Using code like the two preceding snippets, real-time streaming experiences can be created.

New JSON serialization

ASP.NET Core 3.0 now uses System.Text.Json by default for JSON serialization:

- Reads and writes JSON asynchronously.
- Is optimized for UTF-8 text.
- Typically higher performance than `Newtonsoft.Json`.

To add Json.NET to ASP.NET Core 3.0, see Add Newtonsoft.Json-based JSON format support.

New Razor directives

The following list contains new Razor directives:

- @attribute: The `@attribute` directive applies the given attribute to the class of the generated page or view. For example, `@attribute [Authorize]`.

- @implements: The `@implements` directive implements an interface for the generated class. For example, `@implements IDisposable`.

IdentityServer4 supports authentication and authorization for web APIs and SPAs

ASP.NET Core 3.0 offers authentication in Single Page Apps (SPAs) using the support for web API authorization. ASP.NET Core Identity for authenticating and storing users is combined with IdentityServer4 for implementing OpenID Connect.

IdentityServer4 is an OpenID Connect and OAuth 2.0 framework for ASP.NET Core 3.0. It enables the following security features:

- Authentication as a Service (AaaS)
- Single sign-on/off (SSO) over multiple application types
- Access control for APIs
- Federation Gateway

For more information, see the IdentityServer4 documentation or Authentication and authorization for SPAs.

Certificate and Kerberos authentication

Certificate authentication requires:

- Configuring the server to accept certificates.
- Adding the authentication middleware in `Startup.Configure`.
- Adding the certificate authentication service in `Startup.ConfigureServices`.

C#

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddAuthentication(
        CertificateAuthenticationDefaults.AuthenticationScheme)
            .AddCertificate();
    // Other service configuration removed.
}

public void Configure(IApplicationBuilder app, IHostingEnvironment env)
{
    app.UseAuthentication();
    // Other app configuration removed.
}
```

Options for certificate authentication include the ability to:

- Accept self-signed certificates.
- Check for certificate revocation.
- Check that the proffered certificate has the right usage flags in it.

A default user principal is constructed from the certificate properties. The user principal contains an event that enables supplementing or replacing the principal. For more information, see Configure certificate authentication in ASP.NET Core.

Windows Authentication has been extended onto Linux and macOS. In previous versions, Windows Authentication was limited to IIS and HTTP.sys. In ASP.NET Core 3.0, Kestrel has the ability to use Negotiate, Kerberos, and NTLM on Windows, Linux, and macOS for Windows domain-joined hosts. Kestrel support of these authentication schemes is provided by the Microsoft.AspNetCore.Authentication.Negotiate NuGet package. As with the other authentication services, configure authentication app wide, then configure the service:

C#

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddAuthentication(NegotiateDefaults.AuthenticationScheme)
        .AddNegotiate();
    // Other service configuration removed.
}

public void Configure(IApplicationBuilder app, IHostingEnvironment env)
{
    app.UseAuthentication();
    // Other app configuration removed.
}
```

Host requirements:

- Windows hosts must have Service Principal Names (SPNs) added to the user account hosting the app.
- Linux and macOS machines must be joined to the domain.
  - SPNs must be created for the web process.
  - Keytab files must be generated and configured on the host machine.

For more information, see Configure Windows Authentication in ASP.NET Core.

Template changes

The web UI templates (Razor Pages, MVC with controller and views) have the following removed:

- The cookie consent UI is no longer included. To enable the cookie consent feature in an ASP.NET Core 3.0 template-generated app, see General Data Protection Regulation (GDPR) support in ASP.NET Core.
- Scripts and related static assets are now referenced as local files instead of using CDNs. For more information, see Scripts and related static assets are now referenced as local files instead of using CDNs based on the current environment (dotnet/AspNetCore.Docs #14350).

The Angular template updated to use Angular 8.

The Razor class library (RCL) template defaults to Razor component development by default. A new template option in Visual Studio provides template support for pages and views. When creating an RCL from the template in a command shell, pass the `--support-pages-and-views` option (`dotnet new razorclasslib --support-pages-and-views`).

Generic Host

The ASP.NET Core 3.0 templates use .NET Generic Host in ASP.NET Core. Previous versions used WebHostBuilder. Using the .NET Core Generic Host (HostBuilder) provides better integration of ASP.NET Core apps with other server scenarios that aren't web-specific. For more information, see HostBuilder replaces WebHostBuilder.

Host configuration

Prior to the release of ASP.NET Core 3.0, environment variables prefixed with `ASPNETCORE_` were loaded for host configuration of the Web Host. In 3.0, `AddEnvironmentVariables` is used to load environment variables prefixed with `DOTNET_` for host configuration with `CreateDefaultBuilder`.

Changes to Startup constructor injection

The Generic Host only supports the following types for `Startup` constructor injection:

- IHostEnvironment
- `IWebHostEnvironment`
- IConfiguration

All services can still be injected directly as arguments to the `Startup.Configure` method. For more information, see Generic Host restricts Startup constructor injection (aspnet/Announcements #353).

Kestrel

- Kestrel configuration has been updated for the migration to the Generic Host. In 3.0, Kestrel is configured on the web host builder provided by `ConfigureWebHostDefaults`.
- Connection Adapters have been removed from Kestrel and replaced with Connection Middleware, which is similar to HTTP Middleware in the ASP.NET Core pipeline but for lower-level connections.
- The Kestrel transport layer has been exposed as a public interface in `Connections.Abstractions`.
- Ambiguity between headers and trailers has been resolved by moving trailing headers to a new collection.
- Synchronous I/O APIs, such as `HttpRequest.Body.Read`, are a common source of thread starvation leading to app crashes. In 3.0, `AllowSynchronousIO` is disabled by default.

For more information, see Migrate from ASP.NET Core 2.2 to 3.0.

HTTP/2 enabled by default

HTTP/2 is enabled by default in Kestrel for HTTPS endpoints. HTTP/2 support for IIS or HTTP.sys is enabled when supported by the operating system.

EventCounters on request

The Hosting EventSource, `Microsoft.AspNetCore.Hosting`, emits the following new EventCounter types related to incoming requests:

- `requests-per-second`
- `total-requests`
- `current-requests`
- `failed-requests`

Endpoint routing

Endpoint Routing, which allows frameworks (for example, MVC) to work well with middleware, is enhanced:

- The order of middleware and endpoints is configurable in the request processing pipeline of `Startup.Configure`.
- Endpoints and middleware compose well with other ASP.NET Core-based technologies, such as Health Checks.
- Endpoints can implement a policy, such as CORS or authorization, in both middleware and MVC.
- Filters and attributes can be placed on methods in controllers.

For more information, see Routing in ASP.NET Core.

Health Checks

Health Checks use endpoint routing with the Generic Host. In `Startup.Configure`, call `MapHealthChecks` on the endpoint builder with the endpoint URL or relative path:

```
C#

app.UseEndpoints(endpoints =>
{
    endpoints.MapHealthChecks("/health");
});
```

Health Checks endpoints can:

- Specify one or more permitted hosts/ports.
- Require authorization.
- Require CORS.

For more information, see the following articles:

- Migrate from ASP.NET Core 2.2 to 3.0
- Health checks in ASP.NET Core

Pipes on HttpContext

It's now possible to read the request body and write the response body using the System.IO.Pipelines API. The `HttpRequest.BodyReader` property provides a PipeReader that can be used to read the request body. The `HttpResponse.BodyWriter` property provides a PipeWriter that can be used to write the response body.

`HttpRequest.BodyReader` is an analogue of the `HttpRequest.Body` stream.
`HttpResponse.BodyWriter` is an analogue of the `HttpResponse.Body` stream.

Improved error reporting in IIS

Startup errors when hosting ASP.NET Core apps in IIS now produce richer diagnostic data. These errors are reported to the Windows Event Log with stack traces wherever applicable. In addition, all warnings, errors, and unhandled exceptions are logged to the Windows Event Log.

Worker Service and Worker SDK

.NET Core 3.0 introduces the new Worker Service app template. This template provides a starting point for writing long running services in .NET Core.

For more information, see:

- .NET Core Workers as Windows Services
- Background tasks with hosted services in ASP.NET Core
- Host ASP.NET Core in a Windows Service

Forwarded Headers Middleware improvements

In previous versions of ASP.NET Core, calling UseHsts and UseHttpsRedirection were problematic when deployed to an Azure Linux or behind any reverse proxy other than IIS. The fix for previous versions is documented in Forward the scheme for Linux and non-IIS reverse proxies.

This scenario is fixed in ASP.NET Core 3.0. The host enables the Forwarded Headers Middleware when the `ASPNETCORE_FORWARDEDHEADERS_ENABLED` environment variable is set to `true`. `ASPNETCORE_FORWARDEDHEADERS_ENABLED` is set to `true` in our container images.

Performance improvements

ASP.NET Core 3.0 includes many improvements that reduce memory usage and improve throughput:

- Reduction in memory usage when using the built-in dependency injection container for scoped services.

- Reduction in allocations across the framework, including middleware scenarios and routing.
- Reduction in memory usage for WebSocket connections.
- Memory reduction and throughput improvements for HTTPS connections.
- New optimized and fully asynchronous JSON serializer.
- Reduction in memory usage and throughput improvements in form parsing.

ASP.NET Core 3.0 only runs on .NET Core 3.0

As of ASP.NET Core 3.0, .NET Framework is no longer a supported target framework. Projects targeting .NET Framework can continue in a fully supported fashion using the .NET Core 2.1 LTS release. Most ASP.NET Core 2.1.x related packages will be supported indefinitely, beyond the three-year LTS period for .NET Core 2.1.

For migration information, see Port your code from .NET Framework to .NET Core.

Use the ASP.NET Core shared framework

The ASP.NET Core 3.0 shared framework, contained in the Microsoft.AspNetCore.App metapackage, no longer requires an explicit `<PackageReference />` element in the project file. The shared framework is automatically referenced when using the `Microsoft.NET.Sdk.Web` SDK in the project file:

XML

```
<Project Sdk="Microsoft.NET.Sdk.Web">
```

Assemblies removed from the ASP.NET Core shared framework

The most notable assemblies removed from the ASP.NET Core 3.0 shared framework are:

- Newtonsoft.Json (Json.NET). To add Json.NET to ASP.NET Core 3.0, see Add Newtonsoft.Json-based JSON format support. ASP.NET Core 3.0 introduces `System.Text.Json` for reading and writing JSON. For more information, see New JSON serialization in this document.
- Entity Framework Core

For a complete list of assemblies removed from the shared framework, see Assemblies being removed from Microsoft.AspNetCore.App 3.0. For more information on the motivation for this change, see Breaking changes to Microsoft.AspNetCore.App in 3.0 and A first look at changes coming in ASP.NET Core 3.0.

What's new in ASP.NET Core 2.2

Article • 08/14/2024

This article highlights the most significant changes in ASP.NET Core 2.2, with links to relevant documentation.

OpenAPI Analyzers & Conventions

OpenAPI (formerly known as Swagger) is a language-agnostic specification for describing REST APIs. The OpenAPI ecosystem has tools that allow for discovering, testing, and producing client code using the specification. Support for generating and visualizing OpenAPI documents in ASP.NET Core MVC is provided via community driven projects such as NSwag and Swashbuckle.AspNetCore. ASP.NET Core 2.2 provides improved tooling and runtime experiences for creating OpenAPI documents.

For more information, see the following resources:

- Use web API analyzers
- Use web API conventions
- ASP.NET Core 2.2.0-preview1: OpenAPI Analyzers & Conventions

Problem details support

ASP.NET Core 2.1 introduced `ProblemDetails`, based on the RFC 7807 specification for carrying details of an error with an HTTP Response. In 2.2, `ProblemDetails` is the standard response for client error codes in controllers attributed with `ApiControllerAttribute`. An `IActionResult` returning a client error status code (4xx) now returns a `ProblemDetails` body. The result also includes a correlation ID that can be used to correlate the error using request logs. For client errors, `ProducesResponseType` defaults to using `ProblemDetails` as the response type. This is documented in OpenAPI / Swagger output generated using NSwag or Swashbuckle.AspNetCore.

Endpoint Routing

ASP.NET Core 2.2 uses a new *endpoint routing* system for improved dispatching of requests. The changes include new link generation API members and route parameter transformers.

For more information, see the following resources:

- Endpoint routing in 2.2
- Route parameter transformers (see **Routing** section)
- Differences between IRouter- and endpoint-based routing

Health checks

A new health checks service makes it easier to use ASP.NET Core in environments that require health checks, such as Kubernetes. Health checks includes middleware and a set of libraries that define an `IHealthCheck` abstraction and service.

Health checks are used by a container orchestrator or load balancer to quickly determine if a system is responding to requests normally. A container orchestrator might respond to a failing health check by halting a rolling deployment or restarting a container. A load balancer might respond to a health check by routing traffic away from the failing instance of the service.

Health checks are exposed by an application as an HTTP endpoint used by monitoring systems. Health checks can be configured for a variety of real-time monitoring scenarios and monitoring systems. The health checks service integrates with the BeatPulse project . which makes it easier to add checks for dozens of popular systems and dependencies.

For more information, see Health checks in ASP.NET Core.

HTTP/2 in Kestrel

ASP.NET Core 2.2 adds support for HTTP/2.

HTTP/2 is a major revision of the HTTP protocol. Notable features of HTTP/2 include:

- Support for header compression.
- Fully multiplexed streams over a single connection.

While HTTP/2 preserves HTTP's semantics (for example, HTTP headers and methods), it's a breaking change from HTTP/1.x on how data is framed and sent between the client and server.

As a consequence of this change in framing, servers and clients need to negotiate the protocol version used. Application-Layer Protocol Negotiation (ALPN) is a TLS extension that allows the server and client to negotiate the protocol version used as part of their TLS handshake. While it is possible to have prior knowledge between the server and the

client on the protocol, all major browsers support ALPN as the only way to establish an HTTP/2 connection.

For more information, see HTTP/2 support.

Kestrel configuration

In earlier versions of ASP.NET Core, Kestrel options are configured by calling `UseKestrel`. In 2.2, Kestrel options are configured by calling `ConfigureKestrel` on the host builder. This change resolves an issue with the order of `IServer` registrations for in-process hosting. For more information, see the following resources:

- Mitigate UseIIS conflict
- Configure Kestrel server options with ConfigureKestrel

IIS in-process hosting

In earlier versions of ASP.NET Core, IIS serves as a reverse proxy. In 2.2, the ASP.NET Core Module can boot the CoreCLR and host an app inside the IIS worker process (*w3wp.exe*). In-process hosting provides performance and diagnostic gains when running with IIS.

For more information, see in-process hosting for IIS.

SignalR Java client

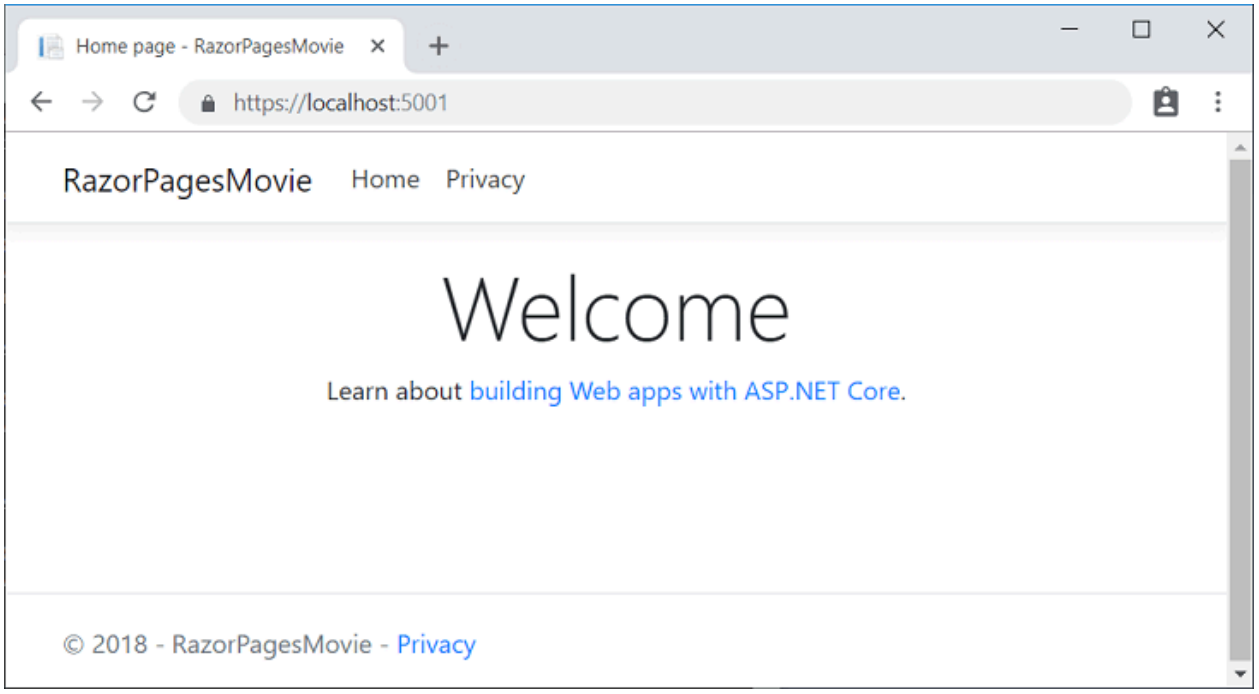
ASP.NET Core 2.2 introduces a Java Client for SignalR. This client supports connecting to an ASP.NET Core SignalR Server from Java code, including Android apps.

For more information, see ASP.NET Core SignalR Java client.

CORS improvements

In earlier versions of ASP.NET Core, CORS Middleware allows `Accept`, `Accept-Language`, `Content-Language`, and `Origin` headers to be sent regardless of the values configured in `CorsPolicy.Headers`. In 2.2, a CORS Middleware policy match is only possible when the headers sent in `Access-Control-Request-Headers` exactly match the headers stated in `WithHeaders`.

For more information, see CORS Middleware.



Response compression

ASP.NET Core 2.2 can compress responses with the Brotli compression format.

For more information, see Response Compression Middleware supports Brotli compression.

Project templates

ASP.NET Core web project templates were updated to Bootstrap 4 and Angular 6. The new look is visually simpler and makes it easier to see the important structures of the app.

Validation performance

MVC's validation system is designed to be extensible and flexible, allowing you to determine on a per request basis which validators apply to a given model. This is great for authoring complex validation providers. However, in the most common case an application only uses the built-in validators and don't require this extra flexibility. Built-in validators include DataAnnotations such as [Required] and [StringLength], and `IValidatableObject`.

In ASP.NET Core 2.2, MVC can short-circuit validation if it determines that a given model graph doesn't require validation. Skipping validation results in significant improvements when validating models that can't or don't have any validators. This includes objects

such as collections of primitives (such as `byte[]`, `string[]`, `Dictionary<string, string>`), or complex object graphs without many validators.

HTTP Client performance

In ASP.NET Core 2.2, the performance of `SocketsHttpHandler` was improved by reducing connection pool locking contention. For apps that make many outgoing HTTP requests, such as some microservices architectures, throughput is improved. Under load, `HttpClient` throughput can be improved by up to 60% on Linux and 20% on Windows.

For more information, see the pull request that made this improvement.

Additional information

For the complete list of changes, see the ASP.NET Core 2.2 Release Notes.

What's new in ASP.NET Core 2.1

Article • 08/30/2024

This article highlights the most significant changes in ASP.NET Core 2.1, with links to relevant documentation.

SignalR

SignalR has been rewritten for ASP.NET Core 2.1.

ASP.NET Core SignalR includes a number of improvements:

- A simplified scale-out model.
- A new JavaScript client with no jQuery dependency.
- A new compact binary protocol based on MessagePack.
- Support for custom protocols.
- A new streaming response model.
- Support for clients based on bare WebSockets.

For more information, see ASP.NET Core SignalR.

Razor class libraries

ASP.NET Core 2.1 makes it easier to build and include Razor-based UI in a library and share it across multiple projects. The new Razor SDK enables building Razor files into a class library project that can be packaged into a NuGet package. Views and pages in libraries are automatically discovered and can be overridden by the app. By integrating Razor compilation into the build:

- The app startup time is significantly faster.
- Fast updates to Razor views and pages at runtime are still available as part of an iterative development workflow.

For more information, see Reusable Razor UI in class libraries with ASP.NET Core.

Identity UI library & scaffolding

ASP.NET Core 2.1 provides ASP.NET Core Identity as a Razor class library. Apps that include Identity can apply the new Identity scaffolder to selectively add the source code contained in the Identity Razor class library (RCL). You might want to generate source

code so you can modify the code and change the behavior. For example, you could instruct the scaffolder to generate the code used in registration. Generated code takes precedence over the same code in the Identity RCL.

Apps that do **not** include authentication can apply the Identity scaffolder to add the RCL Identity package. You have the option of selecting Identity code to be generated.

For more information, see Scaffold Identity in ASP.NET Core projects.

HTTPS

With the increased focus on security and privacy, enabling HTTPS for web apps is important. HTTPS enforcement is becoming increasingly strict on the web. Sites that don't use HTTPS are considered insecure. Browsers (Chromium, Mozilla) are starting to enforce that web features must be used from a secure context. GDPR requires the use of HTTPS to protect user privacy. While using HTTPS in production is critical, using HTTPS in development can help prevent issues in deployment (for example, insecure links). ASP.NET Core 2.1 includes a number of improvements that make it easier to use HTTPS in development and to configure HTTPS in production. For more information, see Enforce HTTPS.

On by default

To facilitate secure website development, HTTPS is now enabled by default. Starting in 2.1, Kestrel listens on `https://localhost:5001` when a local development certificate is present. A development certificate is created:

- As part of the .NET Core SDK first-run experience, when you use the SDK for the first time.
- Manually using the new `dev-certs` tool.

Run `dotnet dev-certs https --trust` to trust the certificate.

HTTPS redirection and enforcement

Web apps typically need to listen on both HTTP and HTTPS, but then redirect all HTTP traffic to HTTPS. In 2.1, specialized HTTPS redirection middleware that intelligently redirects based on the presence of configuration or bound server ports has been introduced.

Use of HTTPS can be further enforced using HTTP Strict Transport Security Protocol (HSTS). HSTS instructs browsers to always access the site via HTTPS. ASP.NET Core 2.1

adds HSTS middleware that supports options for max age, subdomains, and the HSTS preload list.

Configuration for production

In production, HTTPS must be explicitly configured. In 2.1, default configuration schema for configuring HTTPS for Kestrel has been added. Apps can be configured to use:

- Multiple endpoints including the URLs. For more information, see Kestrel web server implementation: Endpoint configuration.
- The certificate to use for HTTPS either from a file on disk or from a certificate store.

GDPR

ASP.NET Core provides APIs and templates to help meet some of the EU General Data Protection Regulation (GDPR) requirements. For more information, see GDPR support in ASP.NET Core. A sample app shows how to use and lets you test most of the GDPR extension points and APIs added to the ASP.NET Core 2.1 templates.

Integration tests

A new package is introduced that streamlines test creation and execution. The Microsoft.AspNetCore.Mvc.Testing package handles the following tasks:

- Copies the dependency file (*.*deps*) from the tested app into the test project's *bin* folder.
- Sets the content root to the tested app's project root so that static files and pages/views are found when the tests are executed.
- Provides the WebApplicationFactory<TEntryPoint> class to streamline bootstrapping the tested app with TestServer.

The following test uses xUnit to check that the Index page loads with a success status code and with the correct Content-Type header:

C#

```
public class BasicTests
    : IClassFixture<WebApplicationFactory<RazorPagesProject.Startup>>
{
    private readonly HttpClient _client;

    public BasicTests(WebApplicationFactory<RazorPagesProject.Startup>
factory)
```

```
    {
        _client = factory.CreateClient();
    }

    [Fact]
    public async Task GetHomePage()
    {
        // Act
        var response = await _client.GetAsync("/");

        // Assert
        response.EnsureSuccessStatusCode(); // Status Code 200-299
        Assert.Equal("text/html; charset=utf-8",
            response.Content.Headers.ContentType.ToString());
    }
}
```

For more information, see the Integration tests topic.

[ApiController], ActionResult<T>

ASP.NET Core 2.1 adds new programming conventions that make it easier to build clean and descriptive web APIs. `ActionResult<T>` is a new type added to allow an app to return either a response type or any other action result (similar to IActionResult), while still indicating the response type. The `[ApiController]` attribute has also been added as the way to opt in to Web API-specific conventions and behaviors.

For more information, see Build Web APIs with ASP.NET Core.

IHttpClientFactory

ASP.NET Core 2.1 includes a new `IHttpClientFactory` service that makes it easier to configure and consume instances of `HttpClient` in apps. `HttpClient` already has the concept of delegating handlers that could be linked together for outgoing HTTP requests. The factory:

- Makes registering of instances of `HttpClient` per named client more intuitive.
- Implements a Polly handler that allows Polly policies to be used for Retry, CircuitBreakers, etc.

For more information, see Initiate HTTP Requests.

Kestrel libuv transport configuration

With the release of ASP.NET Core 2.1, Kestrel's default transport is no longer based on Libuv but instead based on managed sockets. For more information, see Kestrel web server implementation: Libuv transport configuration.

Generic host builder

The Generic Host Builder (`HostBuilder`) has been introduced. This builder can be used for apps that don't process HTTP requests (Messaging, background tasks, etc.).

For more information, see .NET Generic Host.

Updated SPA templates

The Single Page Application templates for Angular and React are updated to use the standard project structures and build systems for each framework.

The Angular template is based on the Angular CLI, and the React template is based on create-react-app.

For more information, see:

- Use Angular with ASP.NET Core
- Use React with ASP.NET Core

Razor Pages search for Razor assets

In 2.1, Razor Pages search for Razor assets (such as layouts and partials) in the following directories in the listed order:

1. Current Pages folder.
2. */Pages/Shared/*
3. */Views/Shared/*

Razor Pages in an area

Razor Pages now support areas. To see an example of areas, create a new Razor Pages web app with individual user accounts. A Razor Pages web app with individual user accounts includes */Areas/Identity/Pages*.

MVC compatibility version

The SetCompatibilityVersion method allows an app to opt-in or opt-out of potentially breaking behavior changes introduced in ASP.NET Core MVC 2.1 or later.

For more information, see Compatibility version for ASP.NET Core MVC.

Migrate from 2.0 to 2.1

See Migrate from ASP.NET Core 2.0 to 2.1.

Additional information

For the complete list of changes, see the ASP.NET Core 2.1 Release Notes.

What's new in ASP.NET Core 2.0

Article • 09/18/2024

This article highlights the most significant changes in ASP.NET Core 2.0, with links to relevant documentation.

Razor Pages

Razor Pages is a new feature of ASP.NET Core MVC that makes coding page-focused scenarios easier and more productive.

For more information, see the introduction and tutorial:

- Introduction to Razor Pages
- Get started with Razor Pages

ASP.NET Core metapackage

A new ASP.NET Core metapackage includes all of the packages made and supported by the ASP.NET Core and Entity Framework Core teams, along with their internal and 3rd-party dependencies. You no longer need to choose individual ASP.NET Core features by package. All features are included in the Microsoft.AspNetCore.All package. The default templates use this package.

For more information, see Microsoft.AspNetCore.All metapackage for ASP.NET Core 2.0.

Runtime Store

Applications that use the `Microsoft.AspNetCore.All` metapackage automatically take advantage of the new .NET Core Runtime Store. The Store contains all the runtime assets needed to run ASP.NET Core 2.0 applications. When you use the `Microsoft.AspNetCore.All` metapackage, no assets from the referenced ASP.NET Core NuGet packages are deployed with the application because they already reside on the target system. The assets in the Runtime Store are also precompiled to improve application startup time.

For more information, see Runtime store

.NET Standard 2.0

The ASP.NET Core 2.0 packages target .NET Standard 2.0. The packages can be referenced by other .NET Standard 2.0 libraries, and they can run on .NET Standard 2.0-compliant implementations of .NET, including .NET Core 2.0 and .NET Framework 4.6.1.

The `Microsoft.AspNetCore.All` metapackage targets .NET Core 2.0 only, because it's intended to be used with the .NET Core 2.0 Runtime Store.

Configuration update

An `IConfiguration` instance is added to the services container by default in ASP.NET Core 2.0. `IConfiguration` in the services container makes it easier for applications to retrieve configuration values from the container.

For information about the status of planned documentation, see the GitHub issue.

Logging update

In ASP.NET Core 2.0, logging is incorporated into the dependency injection (DI) system by default. You add providers and configure filtering in the `Program.cs` file instead of in the `Startup.cs` file. And the default `ILoggerFactory` supports filtering in a way that lets you use one flexible approach for both cross-provider filtering and specific-provider filtering.

For more information, see Introduction to Logging.

Authentication update

A new authentication model makes it easier to configure authentication for an application using DI.

New templates are available for configuring authentication for web apps and web APIs using Azure AD B2C.

For information about the status of planned documentation, see the GitHub issue.

Identity update

We've made it easier to build secure web APIs using Identity in ASP.NET Core 2.0. You can acquire access tokens for accessing your web APIs using the Microsoft Authentication Library (MSAL).

For more information on authentication changes in 2.0, see the following resources:

- Account confirmation and password recovery in ASP.NET Core
- Enable QR Code generation for authenticator apps in ASP.NET Core
- Migrate Authentication and Identity to ASP.NET Core 2.0

SPA templates

Single Page Application (SPA) project templates for Angular, Aurelia, Knockout.js, React.js, and React.js with Redux are available. The Angular template has been updated to Angular 4. The Angular and React templates are available by default; for information about how to get the other templates, see Create a new SPA project. For information about how to build a SPA in ASP.NET Core, see The features described in this article are obsolete as of ASP.NET Core 3.0.

Kestrel improvements

The Kestrel web server has new features that make it more suitable as an Internet-facing server. A number of server constraint configuration options are added in the `KestrelServerOptions` class's new `Limits` property. Add limits for the following:

- Maximum client connections
- Maximum request body size
- Minimum request body data rate

For more information, see Kestrel web server implementation in ASP.NET Core.

WebListener renamed to HTTP.sys

The packages `Microsoft.AspNetCore.Server.WebListener` and `Microsoft.Net.Http.Server` have been merged into a new package `Microsoft.AspNetCore.Server.HttpSys`. The namespaces have been updated to match.

For more information, see HTTP.sys web server implementation in ASP.NET Core.

Enhanced HTTP header support

When using MVC to transmit a `FileStreamResult` or a `FileContentResult`, you now have the option to set an `ETag` or a `LastModified` date on the content you transmit. You can set these values on the returned content with code similar to the following:

C#

```
var data = Encoding.UTF8.GetBytes("This is a sample text from a binary
array");
var entityTag = new EntityTagHeaderValue("\"MyCalculatedEtagValue\"");
return File(data, "text/plain", "downloadName.txt", lastModified:
DateTime.UtcNow.AddSeconds(-5), entityTag: entityTag);
```

The file returned to your visitors has the appropriate HTTP headers for the `ETag` and `LastModified` values.

If an application visitor requests content with a Range Request header, ASP.NET Core recognizes the request and handles the header. If the requested content can be partially delivered, ASP.NET Core appropriately skips and returns just the requested set of bytes. You don't need to write any special handlers into your methods to adapt or handle this feature; it's automatically handled for you.

Hosting startup and Application Insights

Hosting environments can now inject extra package dependencies and execute code during application startup, without the application needing to explicitly take a dependency or call any methods. This feature can be used to enable certain environments to "light-up" features unique to that environment without the application needing to know ahead of time.

In ASP.NET Core 2.0, this feature is used to automatically enable Application Insights diagnostics when debugging in Visual Studio and (after opting in) when running in Azure App Services. As a result, the project templates no longer add Application Insights packages and code by default.

For information about the status of planned documentation, see the GitHub issue.

Automatic use of antiforgery tokens

ASP.NET Core has always helped HTML-encode content by default, but with the new version an extra step is taken to help prevent cross-site request forgery (XSRF) attacks. ASP.NET Core will now emit antiforgery tokens by default and validate them on form POST actions and pages without extra configuration.

For more information, see Prevent Cross-Site Request Forgery (XSRF/CSRF) attacks in ASP.NET Core.

Automatic precompilation

Razor view pre-compilation is enabled during publish by default, reducing the publish output size and application startup time.

For more information, see Razor view compilation and precompilation in ASP.NET Core.

Razor support for C# 7.1

The Razor view engine has been updated to work with the new Roslyn compiler. That includes support for C# 7.1 features like Default Expressions, Inferred Tuple Names, and Pattern-Matching with Generics. To use C# 7.1 in your project, add the following property in your project file and then reload the solution:

XML

```
<LangVersion>latest</LangVersion>
```

For information about the status of C# 7.1 features, see the Roslyn GitHub repository.

Other documentation updates for 2.0

- Visual Studio publish profiles for ASP.NET Core app deployment
- Key Management
- Configure Facebook authentication
- Configure Twitter authentication
- Configure Google authentication
- Configure Microsoft Account authentication

Migration guidance

For guidance on how to migrate ASP.NET Core 1.x applications to ASP.NET Core 2.0, see the following resources:

- Migrate from ASP.NET Core 1.x to ASP.NET Core 2.0
- Migrate Authentication and Identity to ASP.NET Core 2.0

Additional Information

For the complete list of changes, see the ASP.NET Core 2.0 Release Notes.

To connect with the ASP.NET Core development team's progress and plans, tune in to the ASP.NET Community Standup.

What's new in ASP.NET Core 1.1

Article • 06/03/2022

ASP.NET Core 1.1 includes the following new features:

- URL Rewriting Middleware
- Response Caching Middleware
- View Components as Tag Helpers
- Middleware as MVC filters
- Cookie-based TempData provider
- Azure App Service logging provider
- Azure Key Vault configuration provider
- Azure and Redis Storage Data Protection Key Repositories
- WebListener Server for Windows
- WebSockets support

Choosing between versions 1.0 and 1.1 of ASP.NET Core

ASP.NET Core 1.1 has more features than ASP.NET Core 1.0. In general, we recommend you use the latest version.

Additional Information

- ASP.NET Core 1.1.0 Release Notes
- To connect with the ASP.NET Core development team's progress and plans, tune in to the ASP.NET Community Standup.

Choose an ASP.NET Core web UI

Article • 10/21/2024

ASP.NET Core is a complete UI framework. Choose which functionalities to combine that fit the app's web UI needs.

For new project development, we recommend ASP.NET Core Blazor.

ASP.NET Core Blazor

Blazor is a full-stack web UI framework and is recommended for most web UI scenarios.

Benefits of using Blazor:

- Reusable component model.
- Efficient diff-based component rendering.
- Flexibly render components from the server or client via WebAssembly.
- Build rich interactive web UI components in C#.
- Render components statically from the server.
- Progressively enhance server rendered components for smoother navigation and form handling and to enable streaming rendering.
- Share code for common logic on the client and server.
- Interop with JavaScript.
- Integrate components with existing MVC, Razor Pages, or JavaScript based apps.

For a complete overview of Blazor, its architecture and benefits, see ASP.NET Core Blazor and ASP.NET Core Blazor hosting models. To get started with your first Blazor app, see Build your first Blazor app.

ASP.NET Core Razor Pages

Razor Pages is a page-based model for building server rendered web UI. Razor pages UI are dynamically rendered on the server to generate the page's HTML and CSS in response to a browser request. The page arrives at the client ready to display. Support for Razor Pages is built on ASP.NET Core MVC.

Razor Pages benefits:

- Quickly build and update UI. Code for the page is kept with the page, while keeping UI and business logic concerns separate.
- Testable and scales to large apps.

- Keep your ASP.NET Core pages organized in a simpler way than ASP.NET MVC:
  - View specific logic and view models can be kept together in their own namespace and directory.
  - Groups of related pages can be kept in their own namespace and directory.

To get started with your first ASP.NET Core Razor Pages app, see Tutorial: Get started with Razor Pages in ASP.NET Core. For a complete overview of ASP.NET Core Razor Pages, its architecture and benefits, see: Introduction to Razor Pages in ASP.NET Core.

ASP.NET Core MVC

ASP.NET Core MVC renders UI on the server and uses a Model-View-Controller (MVC) architectural pattern. The MVC pattern separates an app into three main groups of components: models, views, and controllers. User requests are routed to a controller. The controller is responsible for working with the model to perform user actions or retrieve results of queries. The controller chooses the view to display to the user and provides it with any model data it requires.

ASP.NET Core MVC benefits:

- Based on a scalable and mature model for building large web apps.
- Clear separation of concerns for maximum flexibility.
- The Model-View-Controller separation of responsibilities ensures that the business model can evolve without being tightly coupled to low-level implementation details.

To get started with ASP.NET Core MVC, see Get started with ASP.NET Core MVC. For an overview of ASP.NET Core MVC's architecture and benefits, see Overview of ASP.NET Core MVC.

ASP.NET Core Single Page Applications (SPA) with frontend JavaScript frameworks

Build client-side logic for ASP.NET Core apps using popular JavaScript frameworks, like Angular, React, and Vue. ASP.NET Core provides project templates for Angular, React, and Vue, and it can be used with other JavaScript frameworks as well.

Benefits of ASP.NET Core SPA with JavaScript Frameworks, in addition to the client rendering benefits previously listed:

- The JavaScript runtime environment is already provided with the browser.
- Large community and mature ecosystem.

- Build client-side logic for ASP.NET Core apps using popular JS frameworks, like Angular, React, and Vue.

Downsides:

- More coding languages, frameworks, and tools required.
- Difficult to share code so some logic may be duplicated.

To get started, see:

- Create an ASP.NET Core app with Angular
- Create an ASP.NET Core app with React
- Create an ASP.NET Core app with Vue
- JavaScript and TypeScript in Visual Studio

Combine multiple web UI solutions: ASP.NET Core MVC or Razor Pages plus Blazor

MVC, Razor Pages, and Blazor are part of the ASP.NET Core framework and are designed to be used together. Razor components can be integrated into Razor Pages and MVC apps. When a view or page is rendered, components can be prerendered at the same time.

Benefits for MVC or Razor Pages plus Blazor, in addition to MVC or Razor Pages benefits:

- Prerendering executes Razor components on the server and renders them into a view or page, which improves the perceived load time of the app.
- Add interactivity to existing views or pages with the Component Tag Helper.

To get started with ASP.NET Core MVC or Razor Pages plus Blazor, see Integrate ASP.NET Core Razor components into ASP.NET Core apps.

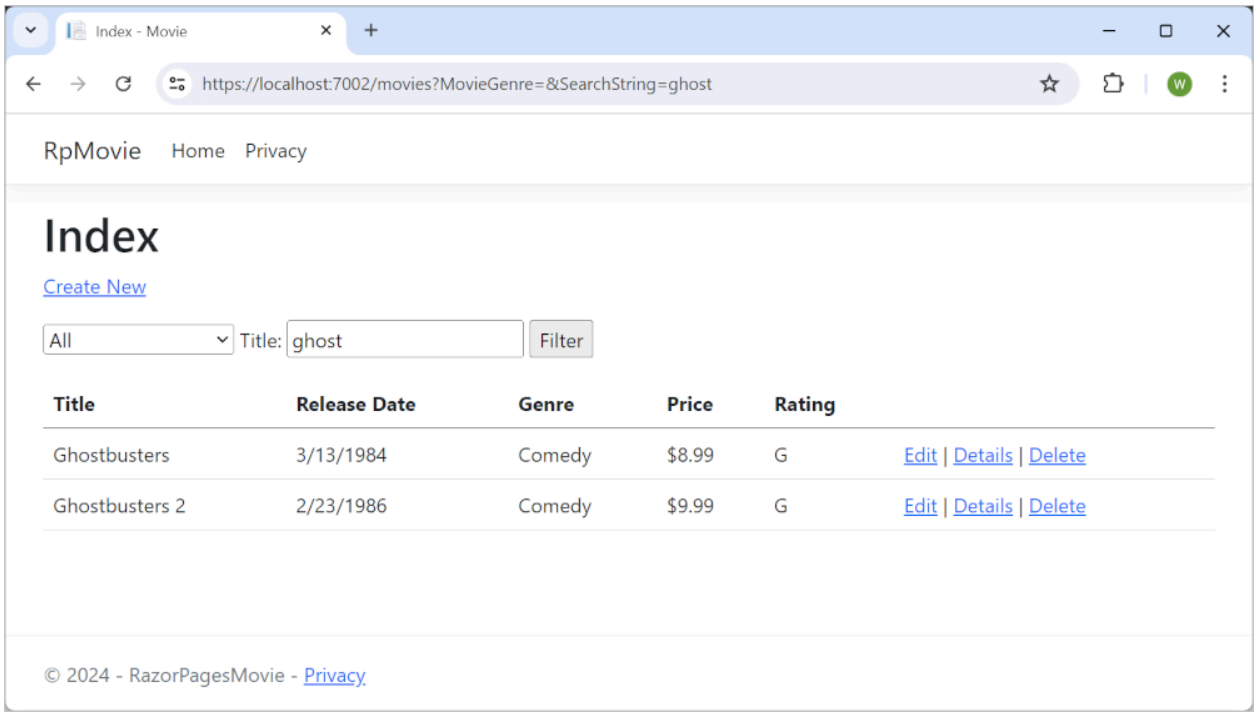
Tutorial: Create a Razor Pages web app with ASP.NET Core

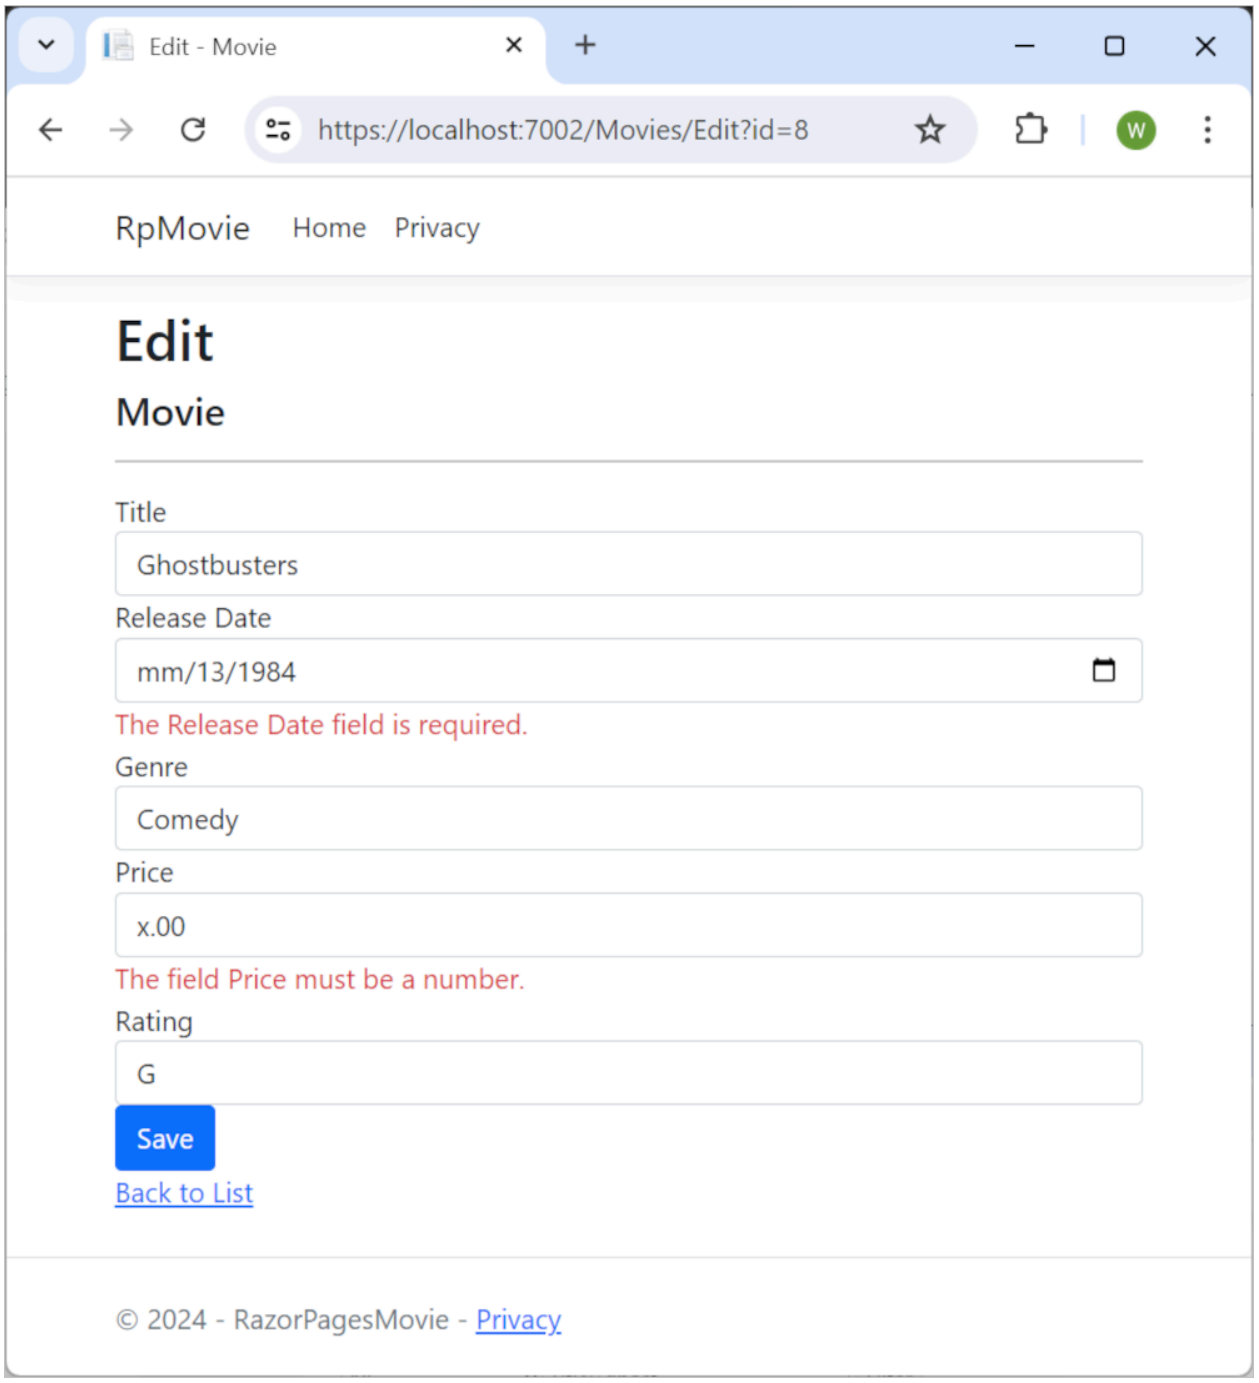
Article • 06/23/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

This series of tutorials explains the basics of building a Razor Pages web app.



For a more advanced introduction aimed at developers who are familiar with controllers and views, see Introduction to Razor Pages in ASP.NET Core.



If you're new to ASP.NET Core development and are unsure of which ASP.NET Core web UI solution will best fit your needs, see Choose an ASP.NET Core UI.

This series includes the following tutorials:

1. Create a Razor Pages web app
2. Add a model to a Razor Pages app
3. Scaffold (generate) Razor pages
4. Work with a database
5. Update Razor pages
6. Add search
7. Add a new field
8. Add validation

At the end, you'll have an app that can display and manage a database of movies.

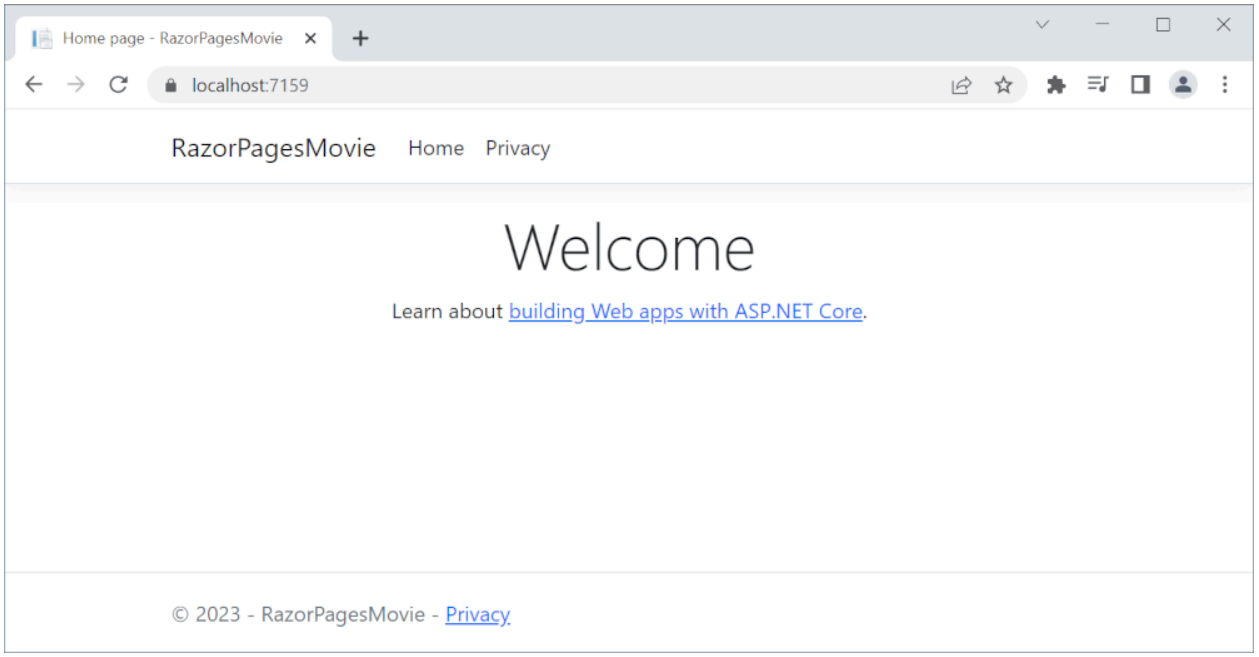
Tutorial: Get started with Razor Pages in ASP.NET Core

Article • 08/04/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

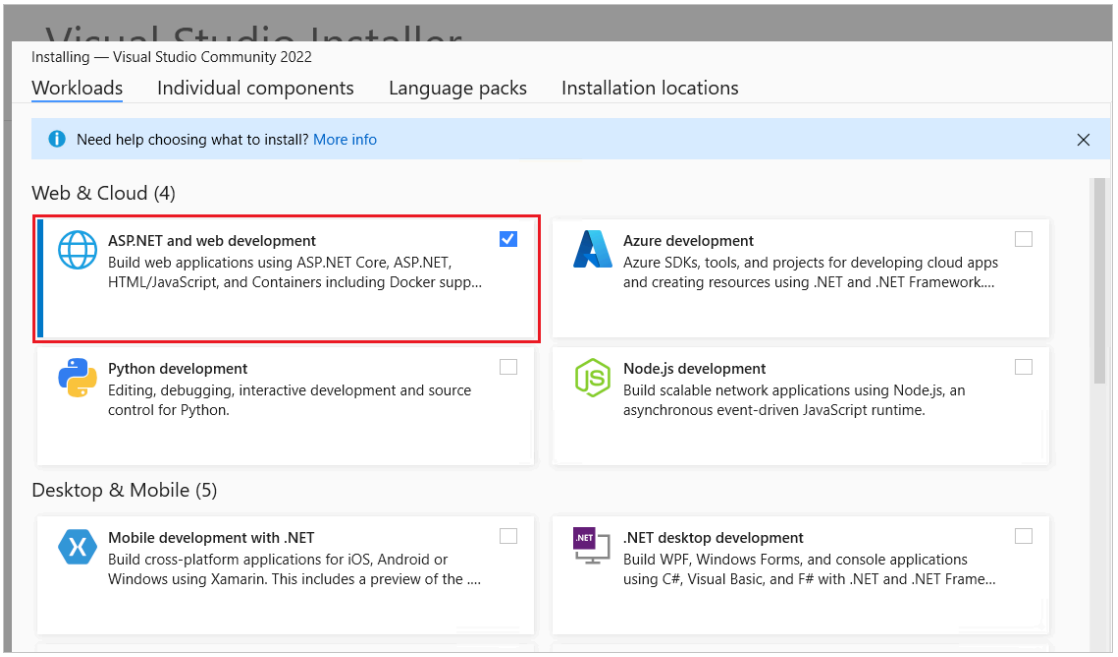


By Rick Anderson

This is the first tutorial of a series that teaches the basics of building an ASP.NET Core Razor Pages web app.

For a more advanced introduction aimed at developers who are familiar with controllers and views, see Introduction to Razor Pages. For a video introduction, see Entity Framework Core for Beginners.

If you're new to ASP.NET Core development and are unsure of which ASP.NET Core web UI solution will best fit your needs, see Choose an ASP.NET Core UI.

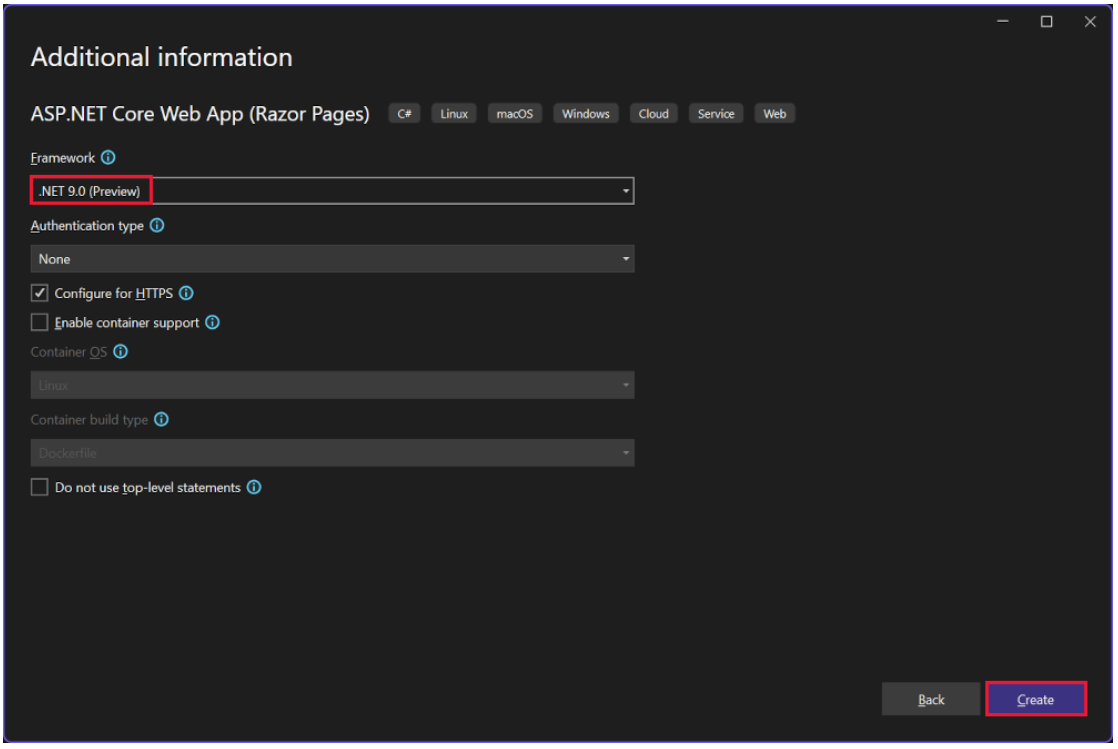


At the end of this tutorial, you'll have a Razor Pages web app that manages a database of movies.

Prerequisites

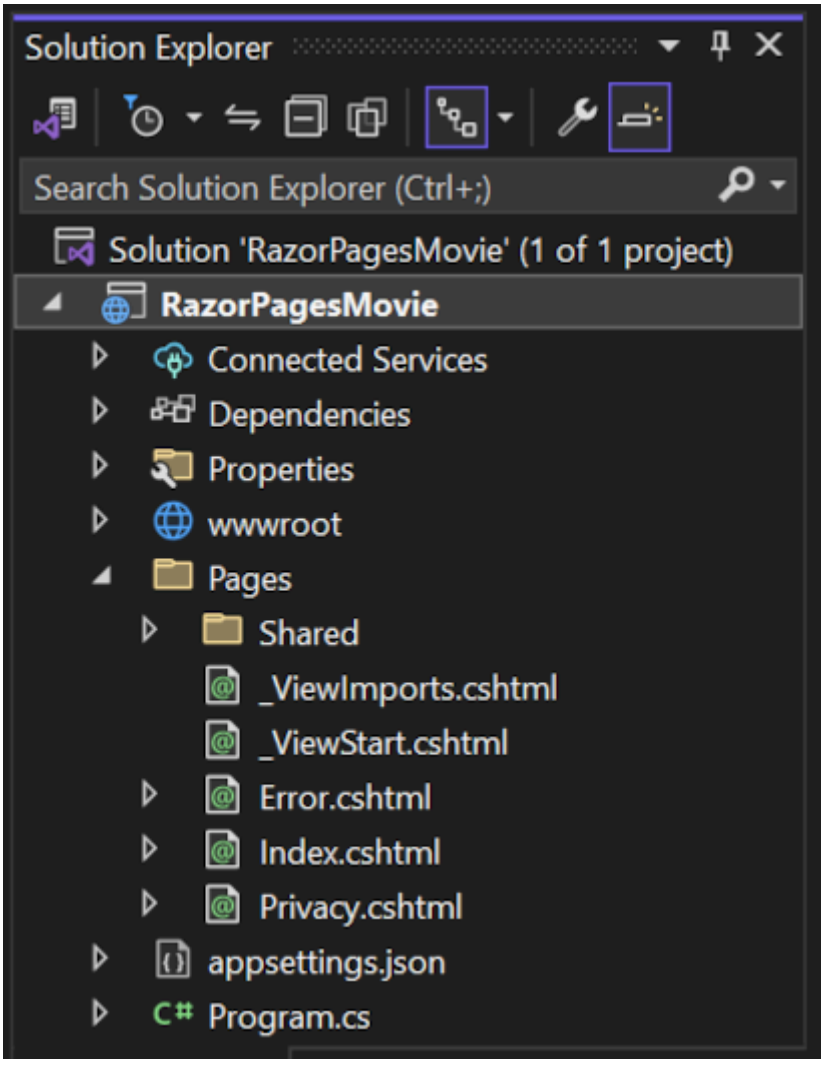
Visual Studio

- Visual Studio 2022 Preview with the **ASP.NET and web development** workload.



Create a Razor Pages web app

Visual Studio

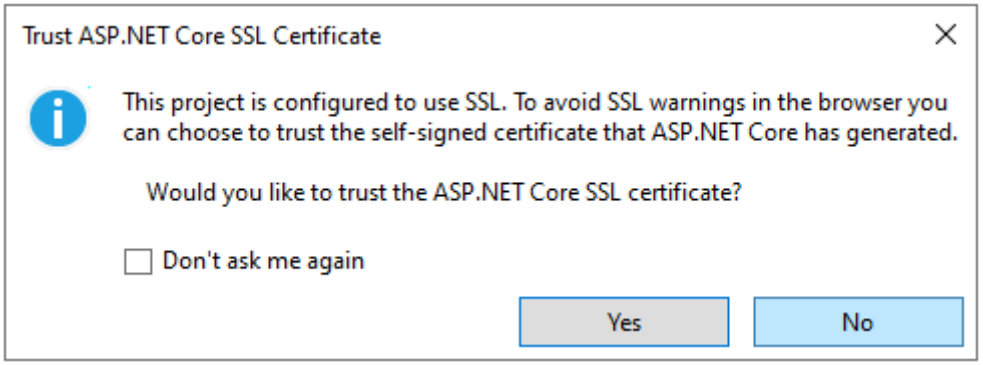


- Start Visual Studio and select **New project**.
- In the **Create a new project** dialog, select **ASP.NET Core Web App (Razor Pages)** > **Next**.
- In the **Configure your new project** dialog, enter `RazorPagesMovie` for **Project name**. It's important to name the project **RazorPagesMovie**, including matching the capitalization, so the namespaces will match when you copy and paste example code.
- Select **Next**.
- In the **Additional information** dialog:
  - Select **.NET 9.0 (Preview)**.

- Verify: **Do not use top-level statements** is unchecked.

- Select **Create**.

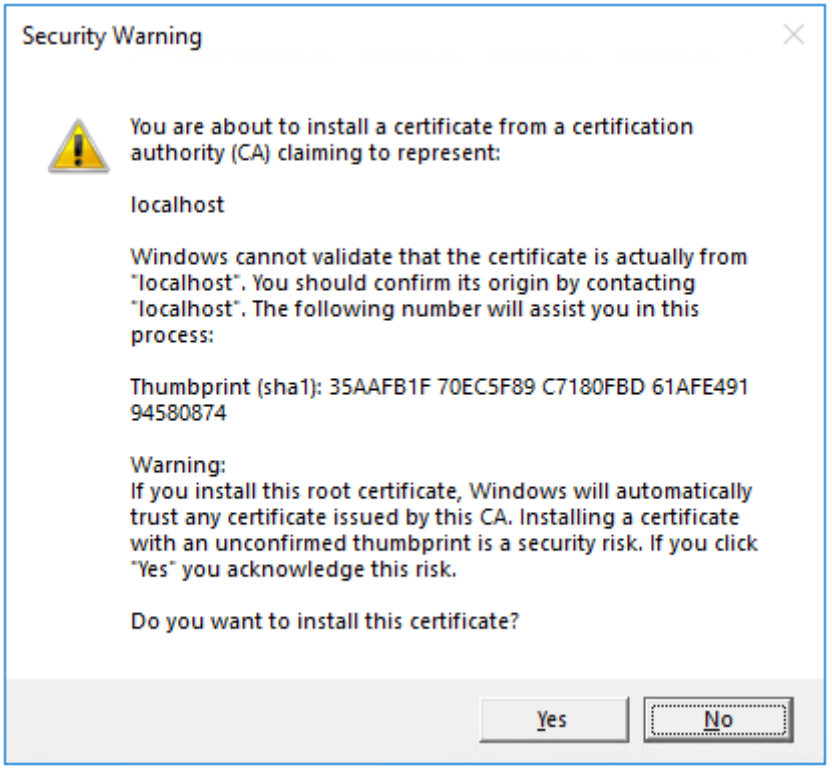
The following starter project is created:



For alternative approaches to create the project, see Create a new project in Visual Studio.

Run the app

Visual Studio



Select **RazorPagesMovie** in **Solution Explorer**, and then press `Ctrl`+`F5` to run the app without the debugger.

Visual Studio displays the following dialog when a project is not yet configured to use SSL:

Select **Yes** if you trust the IIS Express SSL certificate.

The following dialog is displayed:

Select **Yes** if you agree to trust the development certificate.

For information on trusting the Firefox browser, see Firefox SEC_ERROR_INADEQUATE_KEY_USAGE certificate error.

Visual Studio:

- Runs the app, which launches the Kestrel server.
- Launches the default browser at `https://localhost:<port>`, which displays the apps UI. `<port>` is the random port that is assigned when the app was created.

Close the browser window.

Examine the project files

The following sections contain an overview of the main project folders and files that you'll work with in later tutorials.

Pages folder

Contains Razor pages and supporting files. Each Razor page is a pair of files:

- A `.cshtml` file that has HTML markup with C# code using Razor syntax.
- A `.cshtml.cs` file that has C# code that handles page events.

Supporting files have names that begin with an underscore. For example, the `_Layout.cshtml` file configures UI elements common to all pages. `_Layout.cshtml` sets up the navigation menu at the top of the page and the copyright notice at the bottom of the page. For more information, see Layout in ASP.NET Core.

wwwroot folder

Contains static assets, like HTML files, JavaScript files, and CSS files. For more information, see Static files in ASP.NET Core.

`appsettings.json`

Contains configuration data, like connection strings. For more information, see Configuration in ASP.NET Core.

Program.cs

Contains the following code:

```
C#
```

```
var builder = WebApplication.CreateBuilder(args);

// Add services to the container.
builder.Services.AddRazorPages();

var app = builder.Build();

// Configure the HTTP request pipeline.
if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    // The default HSTS value is 30 days. You may want to change this for
production scenarios, see https://aka.ms/aspnetcore-hsts.
    app.UseHsts();
}

app.UseHttpsRedirection();

app.UseRouting();

app.UseAuthorization();

app.MapStaticAssets();
app.MapRazorPages();

app.Run();
```

The following lines of code in this file create a `WebApplicationBuilder` with preconfigured defaults, add Razor Pages support to the Dependency Injection (DI) container, and builds the app:

```
C#
```

```
var builder = WebApplication.CreateBuilder(args);

// Add services to the container.
builder.Services.AddRazorPages();

var app = builder.Build();
```

The developer exception page is enabled by default and provides helpful information on exceptions. Production apps should not be run in development mode because the developer exception page can leak sensitive information.

The following code sets the exception endpoint to `/Error` and enables HTTP Strict Transport Security Protocol (HSTS) when the app is ***not*** running in development mode:

```
C#
```

```
// Configure the HTTP request pipeline.
if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    // The default HSTS value is 30 days. You may want to change this for
production scenarios, see https://aka.ms/aspnetcore-hsts.
    app.UseHsts();
}
```

For example, the preceding code runs when the app is in production or test mode. For more information, see Use multiple environments in ASP.NET Core.

The following code enables various Middleware:

- `app.UseHttpsRedirection();` : Redirects HTTP requests to HTTPS.
- `app.UseRouting();` : Adds route matching to the middleware pipeline. For more information, see Routing in ASP.NET Core.
- `app.UseAuthorization();` : Authorizes a user to access secure resources. This app doesn't use authorization, therefore this line could be removed.
- `app.MapRazorPages();`: Configures endpoint routing for Razor Pages.
- `app.MapStaticAssets();` : Optimize the delivery of static assets in an app such as such as HTML, CSS, images, and JavaScript to be served. For more information, see What's new in ASP.NET Core 9.0.
- `app.Run();` : Runs the app.

Troubleshooting with the completed sample

If you run into a problem you can't resolve, compare your code to the completed project. View or download completed project (how to download).

Part 2, add a model to a Razor Pages app in ASP.NET Core

Article • 10/29/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

In this tutorial, classes are added for managing movies in a database. The app's model classes use Entity Framework Core (EF Core) to work with the database. EF Core is an object-relational mapper (O/RM) that simplifies data access. You write the model classes first, and EF Core creates the database.

The model classes are known as POCO classes (from "**P**lain-**O**ld **C**LR **O**bjects") because they don't have a dependency on EF Core. They define the properties of the data that are stored in the database.

Add a data model

Visual Studio

1. In **Solution Explorer**, right-click the *RazorPagesMovie* project > **Add** > **New Folder**. Name the folder `Models`.
2. Right-click the `Models` folder. Select **Add** > **Class**. Name the class *Movie*.
3. Add the following properties to the `Movie` class:

C#

```
using System.ComponentModel.DataAnnotations;

namespace RazorPagesMovie.Models;

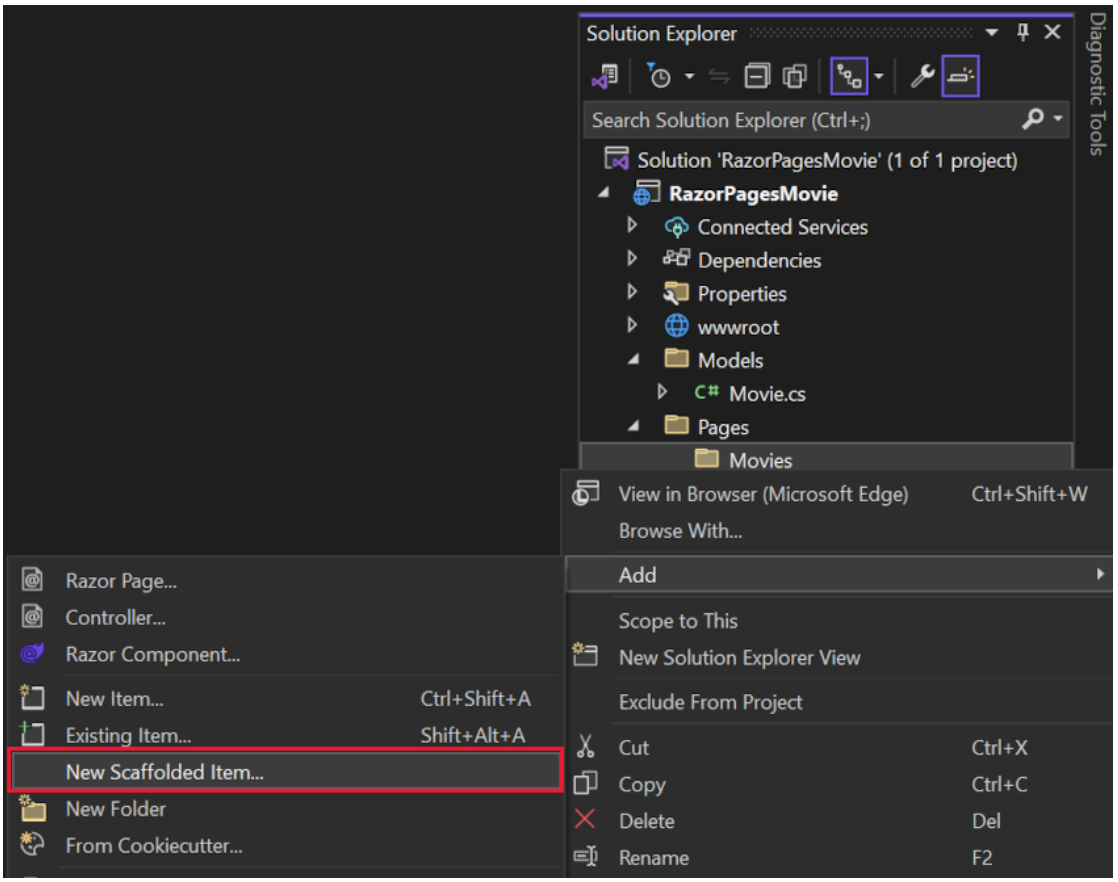
public class Movie
{
    public int Id { get; set; }
```

```
    public string? Title { get; set; }
    [DataType(DataType.Date)]
    public DateTime ReleaseDate { get; set; }
    public string? Genre { get; set; }
    public decimal Price { get; set; }
}
```

The `Movie` class contains:

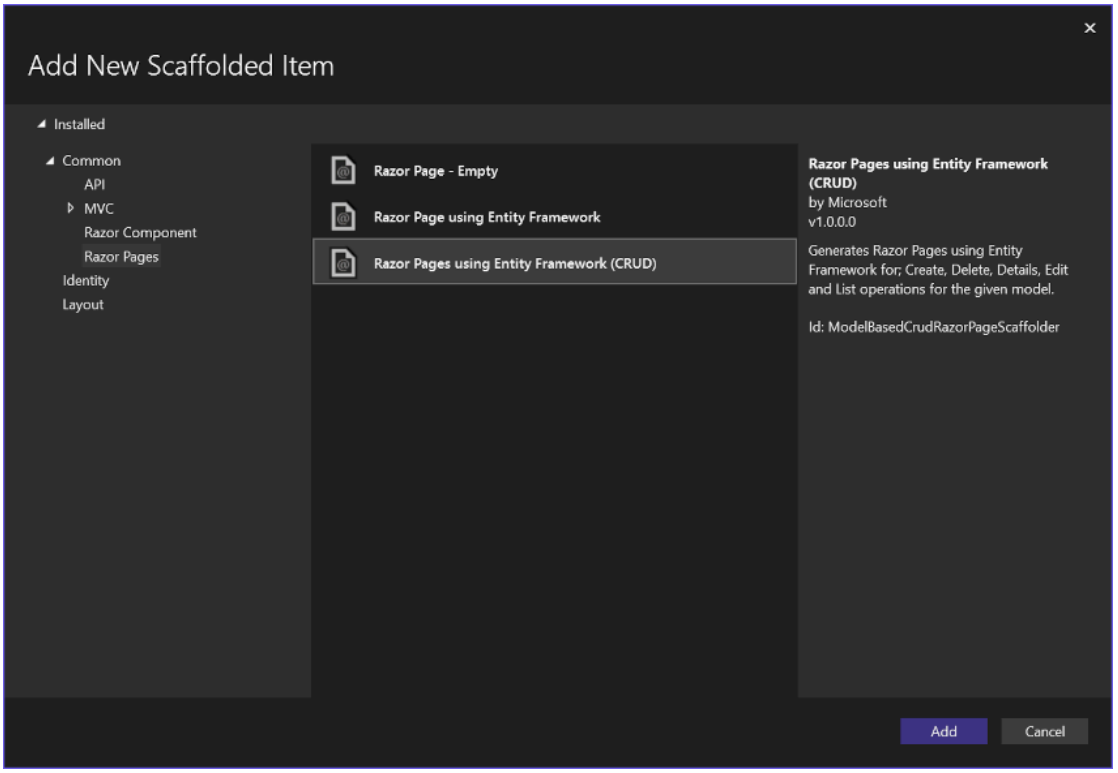
- The `ID` field is required by the database for the primary key.
- A [DataType] attribute that specifies the type of data in the `ReleaseDate` property. With this attribute:
  - The user isn't required to enter time information in the date field.
  - Only the date is displayed, not time information.
- The question mark after `string` indicates that the property is nullable. For more information, see Nullable reference types.

DataAnnotations are covered in a later tutorial.



Build the project to verify there are no compilation errors.

Scaffold the movie model

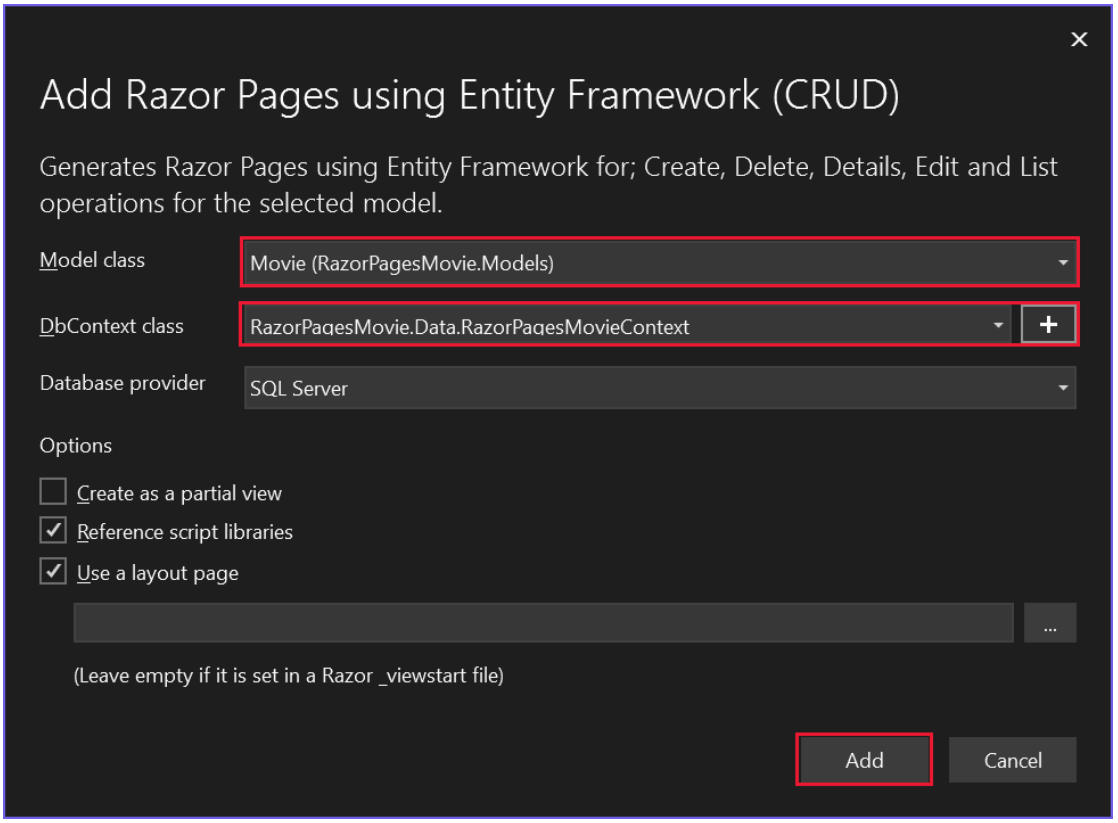


In this section, the movie model is scaffolded. That is, the scaffolding tool produces pages for Create, Read, Update, and Delete (CRUD) operations for the movie model.

Visual Studio

1. Create the *Pages/Movies* folder:
   a. Right-click on the *Pages* folder > **Add** > **New Folder**.
   b. Name the folder *Movies*.
2. Right-click on the *Pages/Movies* folder > **Add** > **New Scaffolded Item**.

3. In the **Add New Scaffold** dialog, select **Razor Pages using Entity Framework (CRUD)** > **Add**.



4. Complete the **Add Razor Pages using Entity Framework (CRUD)** dialog:
   a. In the **Model class** drop down, select **Movie (RazorPagesMovie.Models)**.
   b. In the **Data context class** row, select the + (plus) sign.

i. In the **Add Data Context** dialog, the class name `RazorPagesMovie.Data.RazorPagesMovieContext` is generated.

ii. In the **Database provider** drop down, select **SQL Server**.

c. Select **Add**.

The `appsettings.json` file is updated with the connection string used to connect to a local database.

> ⚠ **Warning**
>
> This article uses a local database that doesn't require the user to be authenticated. Production apps should use the most secure authentication flow available. For more information on authentication for deployed test and production apps, see Secure authentication flows.

Files created and updated

The scaffold process creates the following files:

- *Pages/Movies*: Create, Delete, Details, Edit, and Index.
- `Data/RazorPagesMovieContext.cs`

The created files are explained in the next tutorial.

The scaffold process adds the following highlighted code to the `Program.cs` file:

Visual Studio

C#

```
using Microsoft.EntityFrameworkCore;
using Microsoft.Extensions.DependencyInjection;
using RazorPagesMovie.Data;
var builder = WebApplication.CreateBuilder(args);

// Add services to the container.
builder.Services.AddRazorPages();
builder.Services.AddDbContext<RazorPagesMovieContext>(options =>

options.UseSqlServer(builder.Configuration.GetConnectionString("RazorPag
esMovieContext") ?? throw new InvalidOperationException("Connection
string 'RazorPagesMovieContext' not found.")));

var app = builder.Build();

// Configure the HTTP request pipeline.
if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    // The default HSTS value is 30 days. You may want to change this
for production scenarios, see https://aka.ms/aspnetcore-hsts.
    app.UseHsts();
}

app.UseHttpsRedirection();

app.UseRouting();

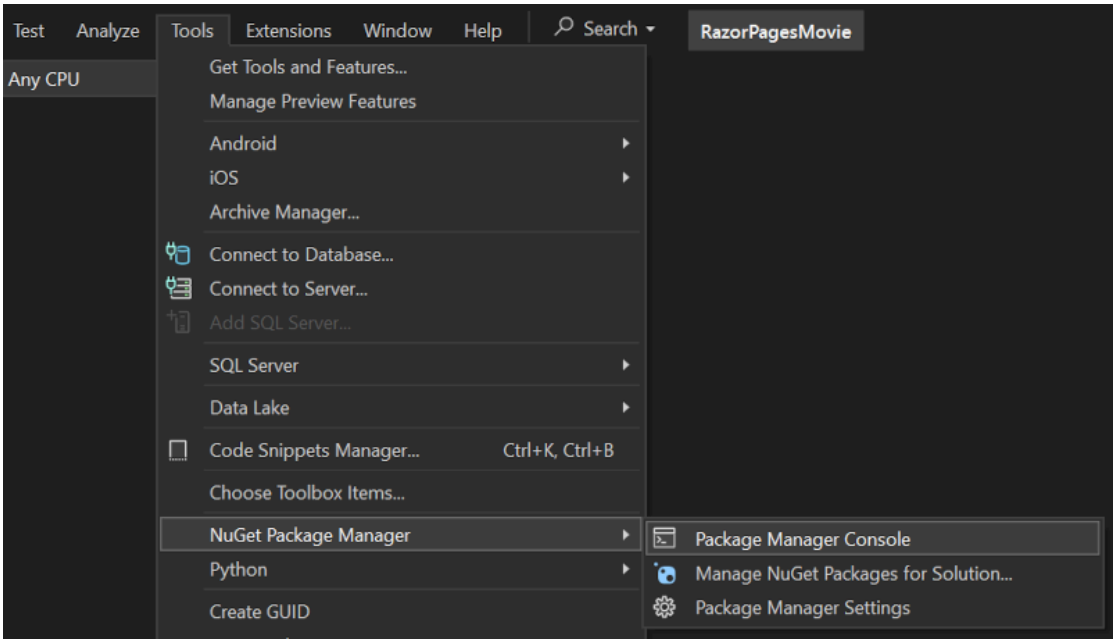
app.UseAuthorization();

app.MapStaticAssets();
app.MapRazorPages();

app.Run();
```

The `Program.cs` changes are explained later in this tutorial.

Create the initial database schema using EF's migration feature



The migrations feature in Entity Framework Core provides a way to:

- Create the initial database schema.
- Incrementally update the database schema to keep it in sync with the app's data model. Existing data in the database is preserved.

Visual Studio

In this section, the **Package Manager Console** (PMC) window is used to:

- Add an initial migration.
- Update the database with the initial migration.
- From the **Tools** menu, select **NuGet Package Manager** > **Package Manager Console**.

- In the PMC, enter the following command:

```
PowerShell

Add-Migration InitialCreate
```

- The `Add-Migration` command generates code to create the initial database schema. The schema is based on the model specified in `DbContext`. The `InitialCreate` argument is used to name the migration. Any name can be used, but by convention a name is selected that describes the migration.

The following warning is displayed, which is addressed in a later step:

> No type was specified for the decimal column 'Price' on entity type 'Movie'. This will cause values to be silently truncated if they do not fit in the default

> precision and scale. Explicitly specify the SQL server column type that can accommodate all the values using 'HasColumnType()'.

- In the PMC, enter the following command:

```
PowerShell
```

```
Update-Database
```

The `Update-Database` command runs the `Up` method in migrations that have not been applied. In this case, the command runs the `Up` method in the `Migrations/<time-stamp>_InitialCreate.cs` file, which creates the database.

The data context `RazorPagesMovieContext`:

- Derives from Microsoft.EntityFrameworkCore.DbContext.
- Specifies which entities are included in the data model.
- Coordinates EF Core functionality, such as Create, Read, Update and Delete, for the `Movie` model.

The `RazorPagesMovieContext` class in the generated file `Data/RazorPagesMovieContext.cs`:

```
C#
```

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;
using Microsoft.EntityFrameworkCore;
using RazorPagesMovie.Models;

namespace RazorPagesMovie.Data
{
    public class RazorPagesMovieContext : DbContext
    {
        public RazorPagesMovieContext
(DbContextOptions<RazorPagesMovieContext> options)
            : base(options)
        {
        }

        public DbSet<RazorPagesMovie.Models.Movie> Movie { get; set; } =
default!;
    }
}
```

The preceding code creates a DbSet<Movie> property for the entity set. In Entity Framework terminology, an entity set typically corresponds to a database table. An entity corresponds to a row in the table.

The name of the connection string is passed in to the context by calling a method on a DbContextOptions object. For local development, the Configuration system reads the connection string from the `appsettings.json` file.

Test the app

1. Run the app and append `/Movies` to the URL in the browser (`http://localhost:port/movies`).

   If you receive the following error:

   Console

   ```
   SqlException: Cannot open database "RazorPagesMovieContext-GUID"
   requested by the login. The login failed.
   Login failed for user 'User-name'.
   ```

   You missed the migrations step.

2. Test the **Create New** link.

> **Note**
>
> You may not be able to enter decimal commas in the `Price` field. To support jQuery validation for non-English locales that use a comma (",") for a decimal point and for non US-English date formats, the app must be globalized. For globalization instructions, see this GitHub issue.

3. Test the **Edit**, **Details**, and **Delete** links.

The next tutorial explains the files created by scaffolding.

Examine the context registered with dependency injection

ASP.NET Core is built with dependency injection. Services, such as the EF Core database context, are registered with dependency injection during application startup. Components that require these services (such as Razor Pages) are provided via constructor parameters. The constructor code that gets a database context instance is shown later in the tutorial.

The scaffolding tool automatically created a database context and registered it with the dependency injection container. The following highlighted code is added to the `Program.cs` file by the scaffolder:

Visual Studio

C#

```
using Microsoft.EntityFrameworkCore;
using Microsoft.Extensions.DependencyInjection;
using RazorPagesMovie.Data;
var builder = WebApplication.CreateBuilder(args);

// Add services to the container.
builder.Services.AddRazorPages();
builder.Services.AddDbContext<RazorPagesMovieContext>(options =>

options.UseSqlServer(builder.Configuration.GetConnectionString("RazorPag
esMovieContext") ?? throw new InvalidOperationException("Connection
string 'RazorPagesMovieContext' not found.")));

var app = builder.Build();

// Configure the HTTP request pipeline.
if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    // The default HSTS value is 30 days. You may want to change this
for production scenarios, see https://aka.ms/aspnetcore-hsts.
    app.UseHsts();
}

app.UseHttpsRedirection();

app.UseRouting();

app.UseAuthorization();

app.MapStaticAssets();
app.MapRazorPages();

app.Run();
```

Troubleshooting with the completed sample

If you run into a problem you can't resolve, compare your code to the completed project. View or download completed project (how to download).

Next steps

Previous: Get Started | Next: Scaffolded Razor Pages

Part 3, scaffolded Razor Pages in ASP.NET Core

Article • 06/23/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

By Rick Anderson

This tutorial examines the Razor Pages created by scaffolding in the previous tutorial.

The Create, Delete, Details, and Edit pages

Examine the `Pages/Movies/Index.cshtml.cs` Page Model:

C#

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.EntityFrameworkCore;
using RazorPagesMovie.Data;
using RazorPagesMovie.Models;
using Microsoft.AspNetCore.Mvc.Rendering;

namespace RazorPagesMovie.Pages.Movies
{
    public class IndexModel : PageModel
    {
        private readonly RazorPagesMovie.Data.RazorPagesMovieContext
_context;

        public IndexModel(RazorPagesMovie.Data.RazorPagesMovieContext
context)
        {
            _context = context;
        }
```

```
        public IList<Movie> Movie { get;set; } = default!;

        public async Task OnGetAsync()
        {
            Movie = await _context.Movie.ToListAsync();
        }
    }
}
```

Razor Pages are derived from PageModel. By convention, the `PageModel` derived class is named `PageNameModel`. For example, the Index page is named `IndexModel`.

The constructor uses dependency injection to add the `RazorPagesMovieContext` to the page:

C#

```
public class IndexModel : PageModel
{
    private readonly RazorPagesMovie.Data.RazorPagesMovieContext _context;

    public IndexModel(RazorPagesMovie.Data.RazorPagesMovieContext context)
    {
        _context = context;
    }
```

See Asynchronous code for more information on asynchronous programming with Entity Framework.

When a `GET` request is made for the page, the `OnGetAsync` method returns a list of movies to the Razor Page. On a Razor Page, `OnGetAsync` or `OnGet` is called to initialize the state of the page. In this case, `OnGetAsync` gets a list of movies and displays them.

When `OnGet` returns `void` or `OnGetAsync` returns `Task`, no return statement is used. For example, examine the Privacy Page:

C#

```
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;

namespace RazorPagesMovie.Pages
{
    public class PrivacyModel : PageModel
    {
        private readonly ILogger<PrivacyModel> _logger;
```

```
        public PrivacyModel(ILogger<PrivacyModel> logger)
        {
            _logger = logger;
        }

        public void OnGet()
        {
        }
    }

}
```

When the return type is IActionResult or `Task<IActionResult>`, a return statement must be provided. For example, the `Pages/Movies/Create.cshtml.cs OnPostAsync` method:

C#

```
public async Task<IActionResult> OnPostAsync()
{
    if (!ModelState.IsValid)
    {
        return Page();
    }

    _context.Movie.Add(Movie);
    await _context.SaveChangesAsync();

    return RedirectToPage("./Index");
}
```

Examine the `Pages/Movies/Index.cshtml` Razor Page:

CSHTML

```
@page
@model RazorPagesMovie.Pages.Movies.IndexModel

@{
    ViewData["Title"] = "Index";
}

<h1>Index</h1>

<p>
    <a asp-page="Create">Create New</a>
</p>
<table class="table">
    <thead>
        <tr>
            <th>
                @Html.DisplayNameFor(model => model.Movie[0].Title)
```

```
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Movie[0].ReleaseDate)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Movie[0].Genre)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Movie[0].Price)
            </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
@foreach (var item in Model.Movie) {
        <tr>
            <td>
                @Html.DisplayFor(modelItem => item.Title)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.ReleaseDate)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Genre)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Price)
            </td>
            <td>
                <a asp-page="./Edit" asp-route-id="@item.Id">Edit</a> |
                <a asp-page="./Details" asp-route-id="@item.Id">Details</a>
|
                <a asp-page="./Delete" asp-route-id="@item.Id">Delete</a>
            </td>
        </tr>
}
    </tbody>
</table>
```

Razor can transition from HTML into C# or into Razor-specific markup. When an `@` symbol is followed by a Razor reserved keyword, it transitions into Razor-specific markup, otherwise it transitions into C#.

The @page directive

The `@page` Razor directive makes the file an MVC action, which means that it can handle requests. `@page` must be the first Razor directive on a page. `@page` and `@model` are examples of transitioning into Razor-specific markup. See Razor syntax for more information.

The @model directive

```cshtml
@page
@model RazorPagesMovie.Pages.Movies.IndexModel
```

The `@model` directive specifies the type of the model passed to the Razor Page. In the preceding example, the `@model` line makes the `PageModel` derived class available to the Razor Page. The model is used in the `@Html.DisplayNameFor` and `@Html.DisplayFor` HTML Helpers on the page.

Examine the lambda expression used in the following HTML Helper:

```cshtml
@Html.DisplayNameFor(model => model.Movie[0].Title)
```

The DisplayNameFor HTML Helper inspects the `Title` property referenced in the lambda expression to determine the display name. The lambda expression is inspected rather than evaluated. That means there is no access violation when `model`, `model.Movie`, or `model.Movie[0]` is `null` or empty. When the lambda expression is evaluated, for example, with `@Html.DisplayFor(modelItem => item.Title)`, the model's property values are evaluated.

The layout page

Select the menu links **RazorPagesMovie**, **Home**, and **Privacy**. Each page shows the same menu layout. The menu layout is implemented in the `Pages/Shared/_Layout.cshtml` file.

Open and examine the `Pages/Shared/_Layout.cshtml` file.

Layout templates allow the HTML container layout to be:

- Specified in one place.
- Applied in multiple pages in the site.

Find the `@RenderBody()` line. `RenderBody` is a placeholder where all the page-specific views show up, *wrapped* in the layout page. For example, select the **Privacy** link and the `Pages/Privacy.cshtml` view is rendered inside the `RenderBody` method.

ViewData and layout

Consider the following markup from the `Pages/Movies/Index.cshtml` file:

CSHTML

```
@page
@model RazorPagesMovie.Pages.Movies.IndexModel

@{
    ViewData["Title"] = "Index";
}
```

The preceding highlighted markup is an example of Razor transitioning into C#. The `{` and `}` characters enclose a block of C# code.

The `PageModel` base class contains a `ViewData` dictionary property that can be used to pass data to a View. Objects are added to the `ViewData` dictionary using a ***key value*** pattern. In the preceding sample, the `Title` property is added to the `ViewData` dictionary.

The `Title` property is used in the `Pages/Shared/_Layout.cshtml` file. The following markup shows the first few lines of the `_Layout.cshtml` file.

CSHTML

```
<!DOCTYPE html>
<html lang="en">
<head>
    <meta charset="utf-8" />
    <meta name="viewport" content="width=device-width, initial-scale=1.0" />
    <title>@ViewData["Title"] - RazorPagesMovie</title>
    <link rel="stylesheet" href="~/lib/bootstrap/dist/css/bootstrap.css" />
    <link rel="stylesheet" href="~/css/site.css" asp-append-version="true"
/>
    <link rel="stylesheet" href="~/RazorPagesMovie.styles.css" asp-append-
version="true" />
```

Update the layout

1. Change the `<title>` element in the `Pages/Shared/_Layout.cshtml` file to display **Movie** rather than **RazorPagesMovie**.

   CSHTML

   ```
   <!DOCTYPE html>
   <html lang="en">
   <head>
   ```

```
    <meta charset="utf-8" />
    <meta name="viewport" content="width=device-width, initial-
scale=1.0" />
    <title>@ViewData["Title"] - Movie</title>
```

2. Find the following anchor element in the `Pages/Shared/_Layout.cshtml` file.

```
CSHTML

<a class="navbar-brand" asp-area="" asp-
page="/Index">RazorPagesMovie</a>
```

3. Replace the preceding element with the following markup:

```
CSHTML

<a class="navbar-brand" asp-page="/Movies/Index">RpMovie</a>
```

   The preceding anchor element is a Tag Helper. In this case, it's the Anchor Tag Helper. The `asp-page="/Movies/Index"` Tag Helper attribute and value creates a link to the `/Movies/Index` Razor Page. The `asp-area` attribute value is empty, so the area isn't used in the link. See Areas for more information.

4. Save the changes and test the app by selecting the **RpMovie** link. See the _Layout.cshtml file in GitHub if you have any problems.

5. Test the **Home**, **RpMovie**, **Create**, **Edit**, and **Delete** links. Each page sets the title, which you can see in the browser tab. When you bookmark a page, the title is used for the bookmark.

> **Note**
>
> You may not be able to enter decimal commas in the `Price` field. To support jQuery validation for non-English locales that use a comma (",") for a decimal point, and non US-English date formats, you must take steps to globalize the app. See this GitHub issue 4076 for instructions on adding decimal comma.

The `Layout` property is set in the `Pages/_ViewStart.cshtml` file:

```
CSHTML

@{
    Layout = "_Layout";
```

```
}
```

The preceding markup sets the layout file to `Pages/Shared/_Layout.cshtml` for all Razor files under the *Pages* folder. See Layout for more information.

The Create page model

Examine the `Pages/Movies/Create.cshtml.cs` page model:

C#

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.AspNetCore.Mvc.Rendering;
using RazorPagesMovie.Data;
using RazorPagesMovie.Models;

namespace RazorPagesMovie.Pages.Movies
{
    public class CreateModel : PageModel
    {
        private readonly RazorPagesMovie.Data.RazorPagesMovieContext
_context;

        public CreateModel(RazorPagesMovie.Data.RazorPagesMovieContext
context)
        {
            _context = context;
        }

        public IActionResult OnGet()
        {
            return Page();
        }

        [BindProperty]
        public Movie Movie { get; set; } = default!;

        // To protect from overposting attacks, see
https://aka.ms/RazorPagesCRUD
        public async Task<IActionResult> OnPostAsync()
        {
            if (!ModelState.IsValid)
            {
                return Page();
            }
```

```
            _context.Movie.Add(Movie);
            await _context.SaveChangesAsync();

            return RedirectToPage("./Index");
        }
    }
}
```

The `OnGet` method initializes any state needed for the page. The Create page doesn't have any state to initialize, so `Page` is returned. Later in the tutorial, an example of `OnGet` initializing state is shown. The `Page` method creates a `PageResult` object that renders the `Create.cshtml` page.

The `Movie` property uses the [BindProperty] attribute to opt-in to model binding. When the Create form posts the form values, the ASP.NET Core runtime binds the posted values to the `Movie` model.

The `OnPostAsync` method is run when the page posts form data:

C#

```
public async Task<IActionResult> OnPostAsync()
{
    if (!ModelState.IsValid)
    {
        return Page();
    }

    _context.Movie.Add(Movie);
    await _context.SaveChangesAsync();

    return RedirectToPage("./Index");
}
```

If there are any model errors, the form is redisplayed, along with any form data posted. Most model errors can be caught on the client-side before the form is posted. An example of a model error is posting a value for the date field that cannot be converted to a date. Client-side validation and model validation are discussed later in the tutorial.

If there are no model errors:

- The data is saved.
- The browser is redirected to the Index page.

The Create Razor Page

Examine the `Pages/Movies/Create.cshtml` Razor Page file:

CSHTML

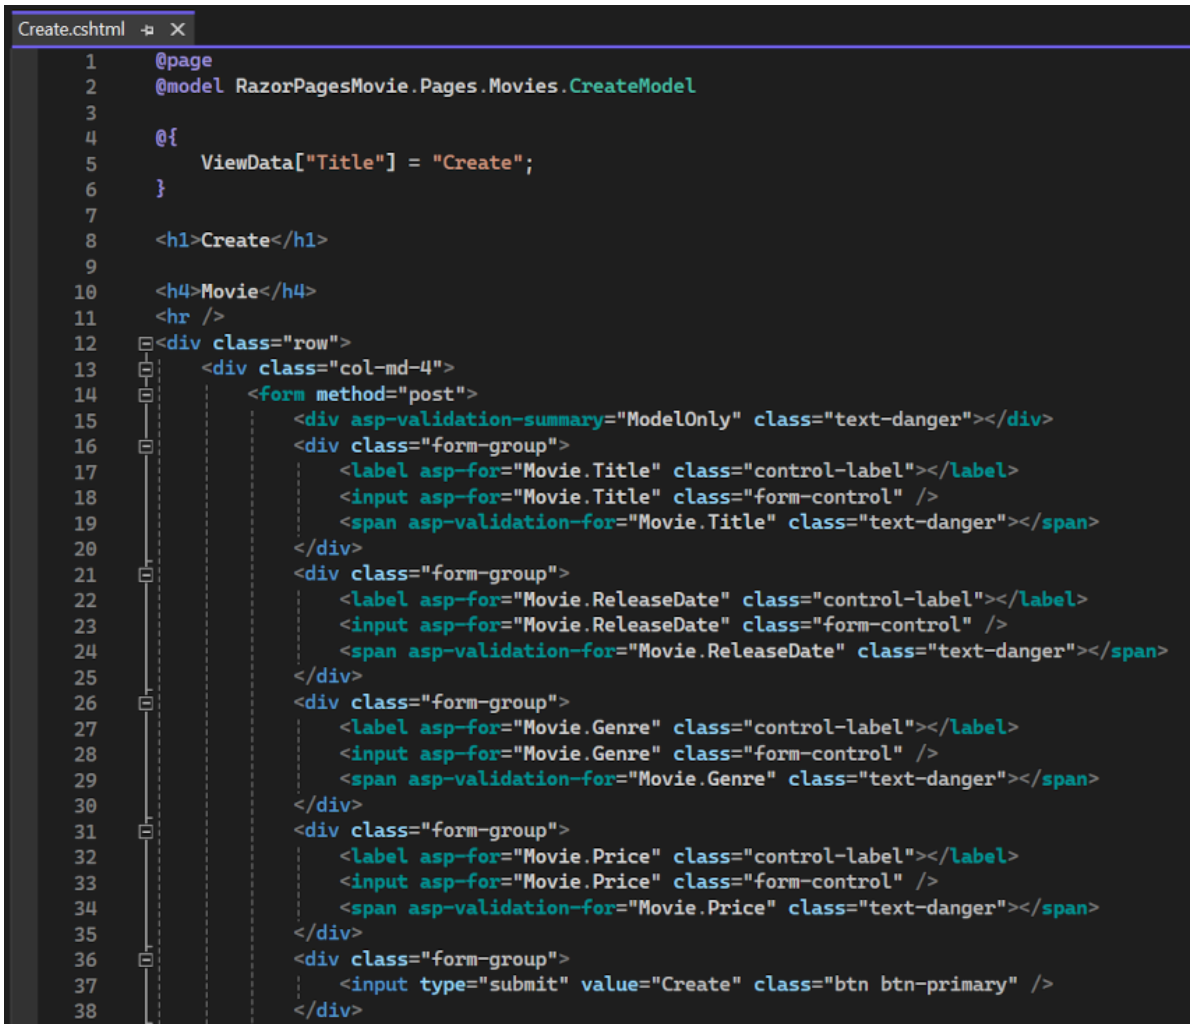
```
@page
@model RazorPagesMovie.Pages.Movies.CreateModel

@{
    ViewData["Title"] = "Create";
}

<h1>Create</h1>

<h4>Movie</h4>
<hr />
<div class="row">
    <div class="col-md-4">
        <form method="post">
            <div asp-validation-summary="ModelOnly" class="text-danger">
</div>
            <div class="form-group">
                <label asp-for="Movie.Title" class="control-label"></label>
                <input asp-for="Movie.Title" class="form-control" />
                <span asp-validation-for="Movie.Title" class="text-danger">
</span>
            </div>
            <div class="form-group">
                <label asp-for="Movie.ReleaseDate" class="control-label">
</label>
                <input asp-for="Movie.ReleaseDate" class="form-control" />
                <span asp-validation-for="Movie.ReleaseDate" class="text-
danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Movie.Genre" class="control-label"></label>
                <input asp-for="Movie.Genre" class="form-control" />
                <span asp-validation-for="Movie.Genre" class="text-danger">
</span>
            </div>
            <div class="form-group">
                <label asp-for="Movie.Price" class="control-label"></label>
                <input asp-for="Movie.Price" class="form-control" />
                <span asp-validation-for="Movie.Price" class="text-danger">
</span>
            </div>
            <div class="form-group">
                <input type="submit" value="Create" class="btn btn-primary"
/>
            </div>
        </form>
    </div>
</div>

<div>
```



```
    <a asp-page="Index">Back to List</a>
</div>

@section Scripts {
    @{await Html.RenderPartialAsync("_ValidationScriptsPartial");}
}
```

Visual Studio

Visual Studio displays the following tags in a distinctive bold font used for Tag Helpers:

- `<form method="post">`
- `<div asp-validation-summary="ModelOnly" class="text-danger"></div>`
- `<label asp-for="Movie.Title" class="control-label"></label>`
- `<input asp-for="Movie.Title" class="form-control" />`
- `<span asp-validation-for="Movie.Title" class="text-danger"></span>`

The `<form method="post">` element is a Form Tag Helper. The Form Tag Helper automatically includes an antiforgery token.

The scaffolding engine creates Razor markup for each field in the model, except the ID, similar to the following:

CSHTML

```
<div asp-validation-summary="ModelOnly" class="text-danger"></div>
<div class="form-group">
    <label asp-for="Movie.Title" class="control-label"></label>
    <input asp-for="Movie.Title" class="form-control" />
    <span asp-validation-for="Movie.Title" class="text-danger"></span>
</div>
```

The Validation Tag Helpers (`<div asp-validation-summary` and `<span asp-validation-for`) display validation errors. Validation is covered in more detail later in this series.

The Label Tag Helper (`<label asp-for="Movie.Title" class="control-label"></label>`) generates the label caption and `[for]` attribute for the `Title` property.

The Input Tag Helper (`<input asp-for="Movie.Title" class="form-control">`) uses the DataAnnotations attributes and produces HTML attributes needed for jQuery Validation on the client-side.

For more information on Tag Helpers such as `<form method="post">`, see Tag Helpers in ASP.NET Core.

By Joe Audette

The `RazorPagesMovieContext` object handles the task of connecting to the database and mapping `Movie` objects to database records. The database context is registered with the Dependency Injection container in `Program.cs`:

Visual Studio

C#

```
using Microsoft.EntityFrameworkCore;
using Microsoft.Extensions.DependencyInjection;
using RazorPagesMovie.Data;
var builder = WebApplication.CreateBuilder(args);

// Add services to the container.
builder.Services.AddRazorPages();
builder.Services.AddDbContext<RazorPagesMovieContext>(options =>

options.UseSqlServer(builder.Configuration.GetConnectionString("RazorPag
esMovieContext") ?? throw new InvalidOperationException("Connection
string 'RazorPagesMovieContext' not found.")));
```

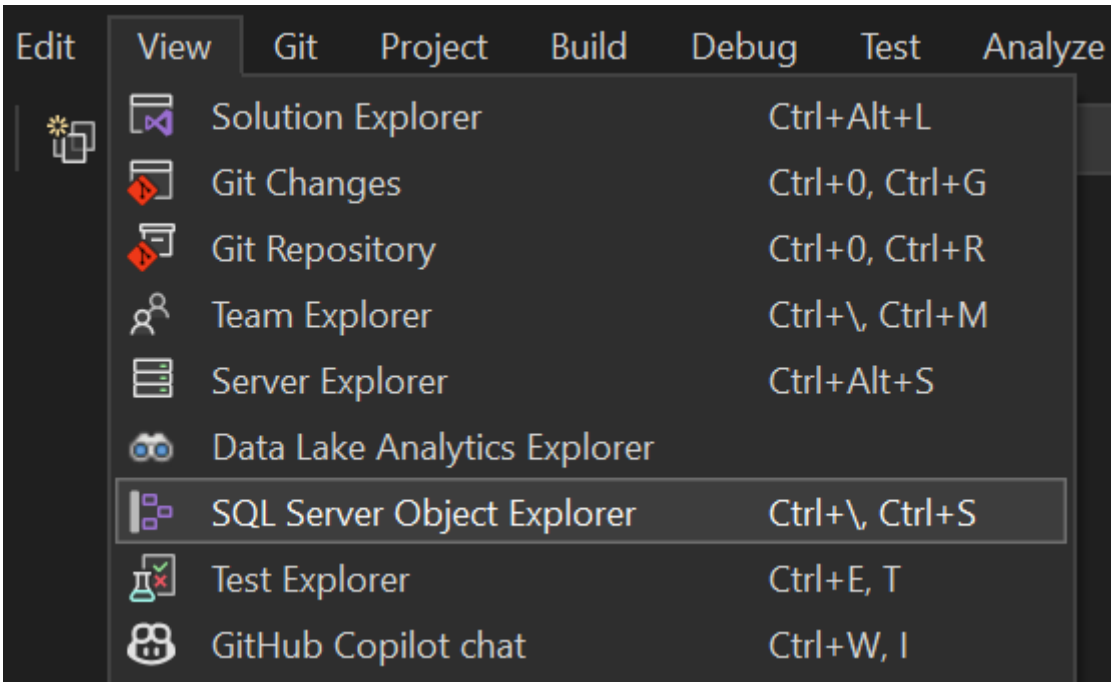
The ASP.NET Core Configuration system reads the `ConnectionString` key. For local development, configuration gets the connection string from the `appsettings.json` file.

Visual Studio

The generated connection string is similar to the following JSON:

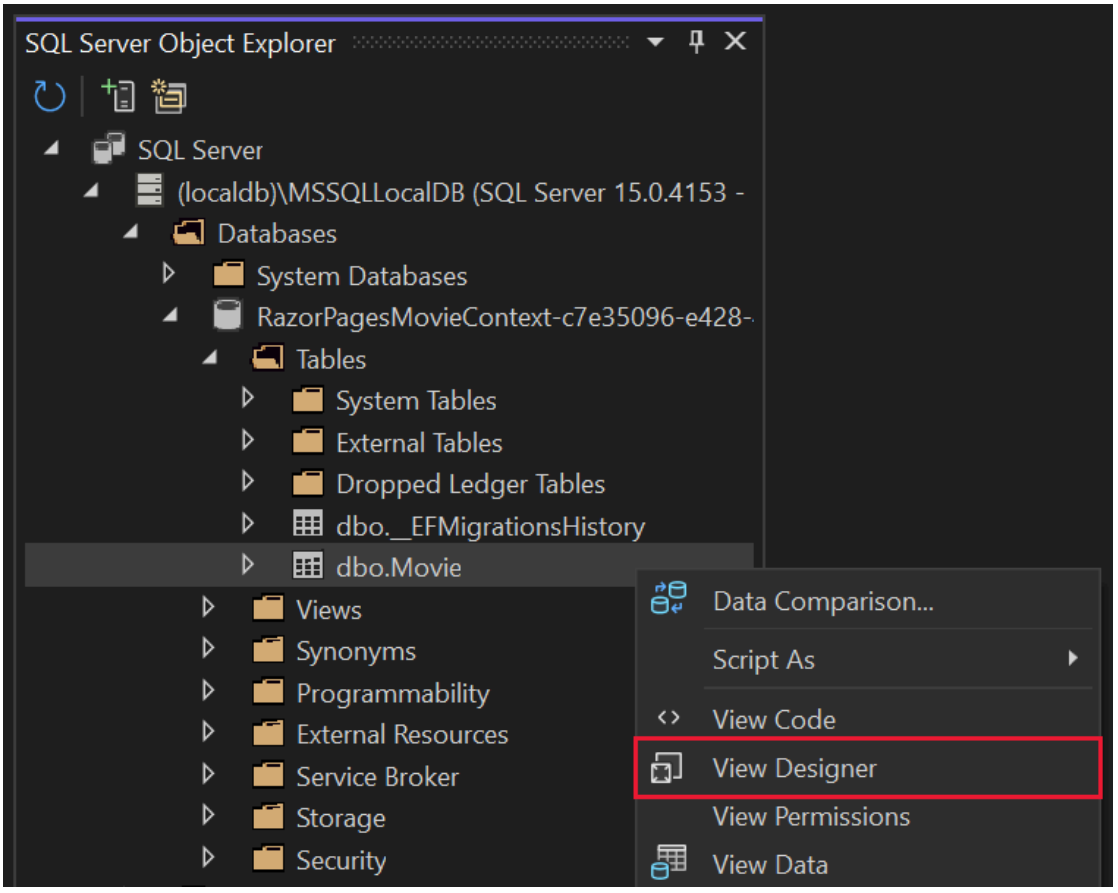
JSON

```
{
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "Microsoft.AspNetCore": "Warning"
    }
  },
  "AllowedHosts": "*",
  "ConnectionStrings": {
    "RazorPagesMovieContext": "Server=
(localdb)\\mssqllocaldb;Database=RazorPagesMovieContext-f2e0482c-952d-
4b1c-afe9-
a1a3dfe52e55;Trusted_Connection=True;MultipleActiveResultSets=true"
  }
}
```

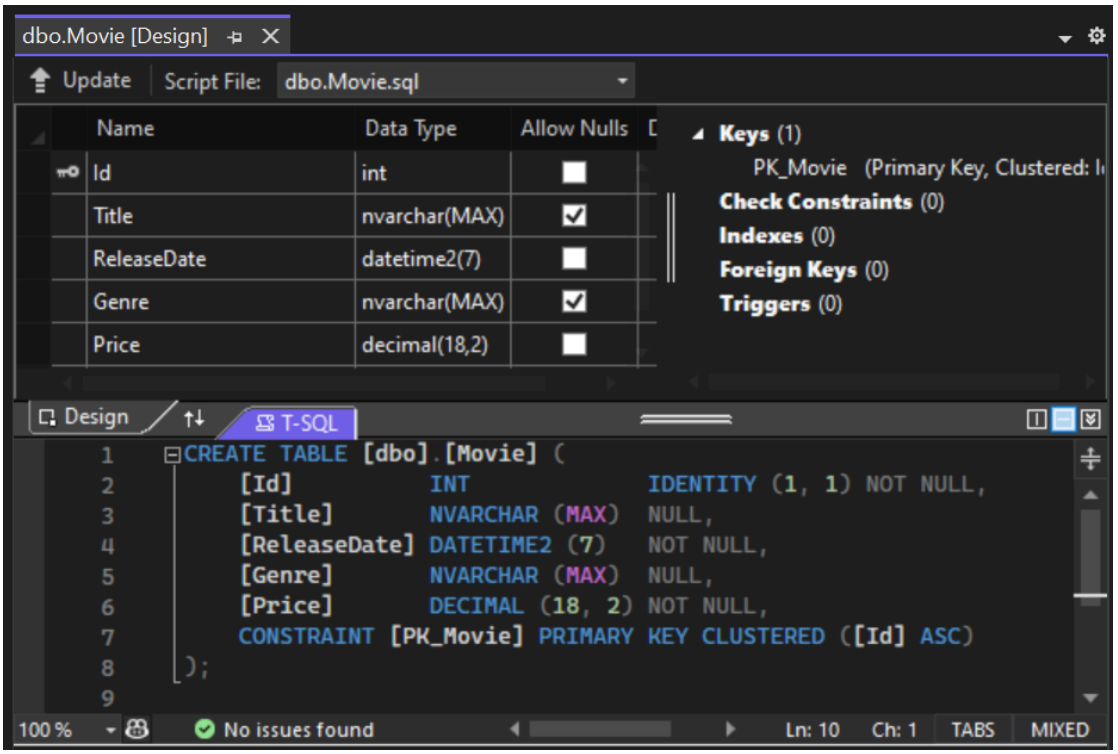


> ⚠ **Warning**
>
> This article uses a local database that doesn't require the user to be authenticated. Production apps should use the most secure authentication flow available. For more information on authentication for deployed test and production apps, see Secure authentication flows.

Visual Studio

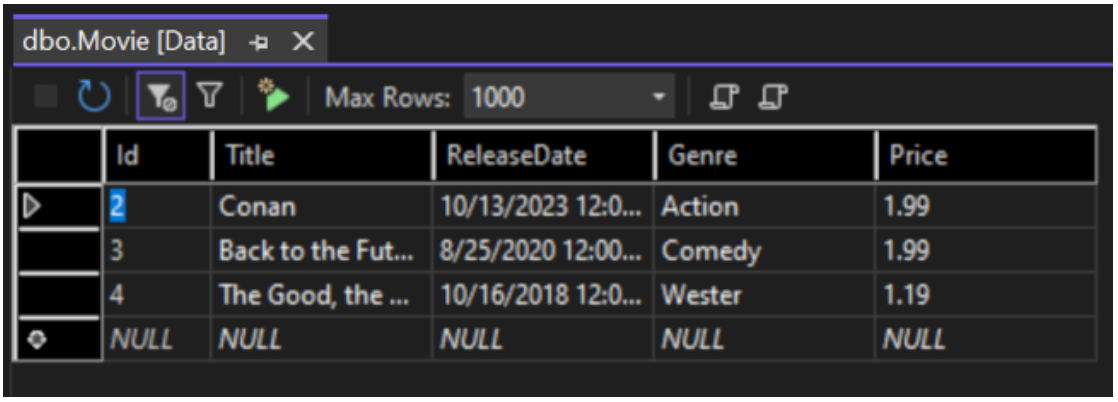


SQL Server Express LocalDB



LocalDB is a lightweight version of the SQL Server Express database engine that's targeted for program development. LocalDB starts on demand and runs in user mode, so there's no complex configuration. By default, LocalDB database creates `*.mdf` files in the `C:\Users\<user>\` directory.

1. From the **View** menu, open **SQL Server Object Explorer** (SSOX).



2. Right-click on the `Movie` table and select **View Designer**:

Note the key icon next to `ID`. By default, EF creates a property named `ID` for the primary key.

3. Right-click on the `Movie` table and select **View Data**:

Seed the database

Create a new class named `SeedData` in the *Models* folder with the following code:

C#

```
using Microsoft.EntityFrameworkCore;
using RazorPagesMovie.Data;

namespace RazorPagesMovie.Models;

public static class SeedData
```

```
{
    public static void Initialize(IServiceProvider serviceProvider)
    {
        using (var context = new RazorPagesMovieContext(
            serviceProvider.GetRequiredService<
                DbContextOptions<RazorPagesMovieContext>>()))
        {
            if (context == null || context.Movie == null)
            {
                throw new ArgumentNullException("Null
RazorPagesMovieContext");
            }

            // Look for any movies.
            if (context.Movie.Any())
            {
                return;   // DB has been seeded
            }

            context.Movie.AddRange(
                new Movie
                {
                    Title = "When Harry Met Sally",
                    ReleaseDate = DateTime.Parse("1989-2-12"),
                    Genre = "Romantic Comedy",
                    Price = 7.99M
                },

                new Movie
                {
                    Title = "Ghostbusters ",
                    ReleaseDate = DateTime.Parse("1984-3-13"),
                    Genre = "Comedy",
                    Price = 8.99M
                },

                new Movie
                {
                    Title = "Ghostbusters 2",
                    ReleaseDate = DateTime.Parse("1986-2-23"),
                    Genre = "Comedy",
                    Price = 9.99M
                },

                new Movie
                {
                    Title = "Rio Bravo",
                    ReleaseDate = DateTime.Parse("1959-4-15"),
                    Genre = "Western",
                    Price = 3.99M
                }
            );
            context.SaveChanges();
        }
```

```
    }
}
```

If there are any movies in the database, the seed initializer returns and no movies are added.

C#

```
if (context.Movie.Any())
{
    return;
}
```

Add the seed initializer

Update the `Program.cs` with the following highlighted code:

Visual Studio

C#

```
using Microsoft.EntityFrameworkCore;
using RazorPagesMovie.Data;
using RazorPagesMovie.Models;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();
builder.Services.AddDbContext<RazorPagesMovieContext>(options =>

options.UseSqlServer(builder.Configuration.GetConnectionString("RazorPag
esMovieContext") ?? throw new InvalidOperationException("Connection
string 'RazorPagesMovieContext' not found.")));

var app = builder.Build();

using (var scope = app.Services.CreateScope())
{
    var services = scope.ServiceProvider;

    SeedData.Initialize(services);
}

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}
```

```
app.UseHttpsRedirection();

app.UseRouting();

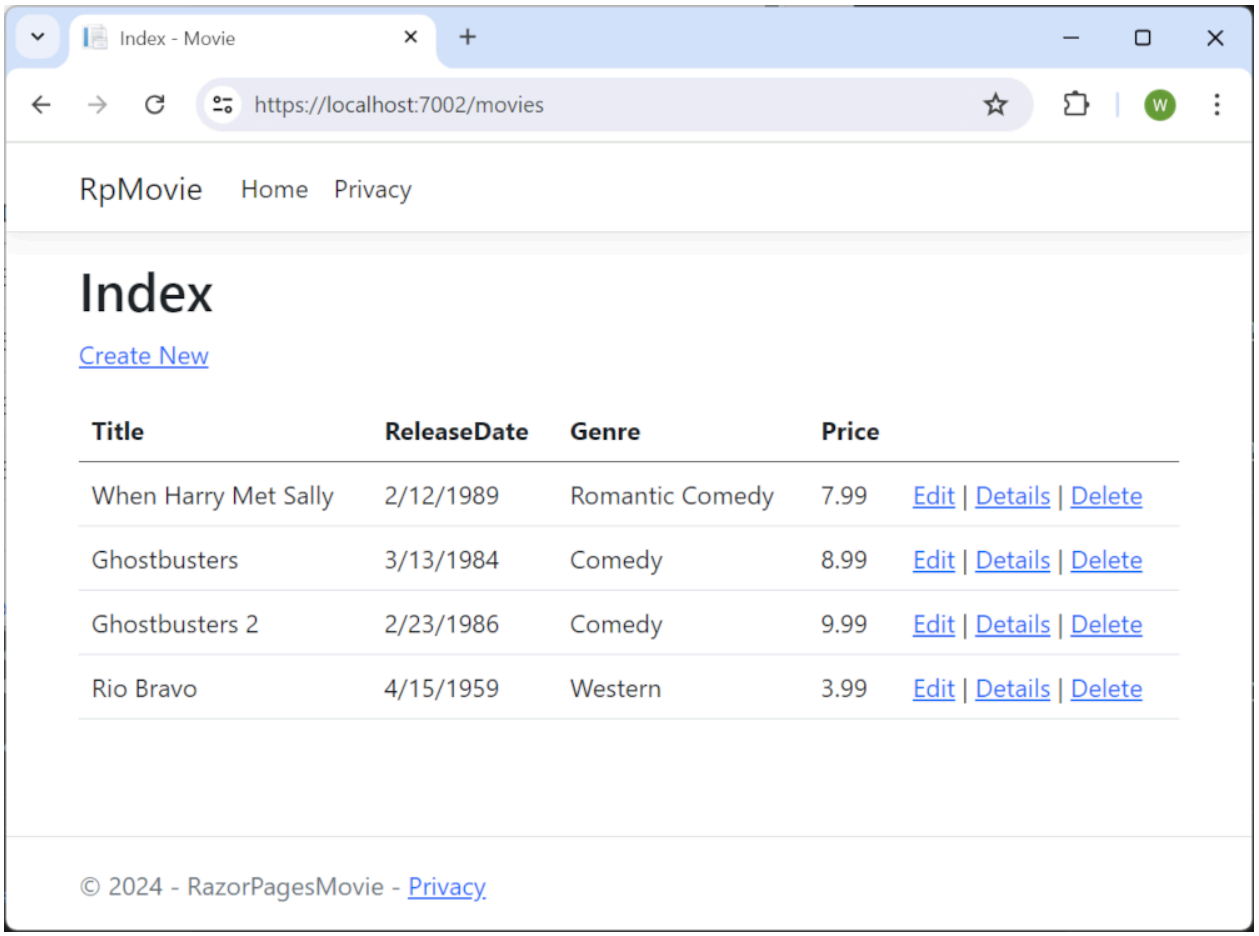
app.UseAuthorization();

app.MapStaticAssets();
app.MapRazorPages();

app.Run();
```

In the previous code, `Program.cs` has been modified to do the following:

- Get a database context instance from the dependency injection (DI) container.
- Call the `seedData.Initialize` method, passing to it the database context instance.
- Dispose the context when the seed method completes. The using statement ensures the context is disposed.



The following exception occurs when `Update-Database` has not been run:

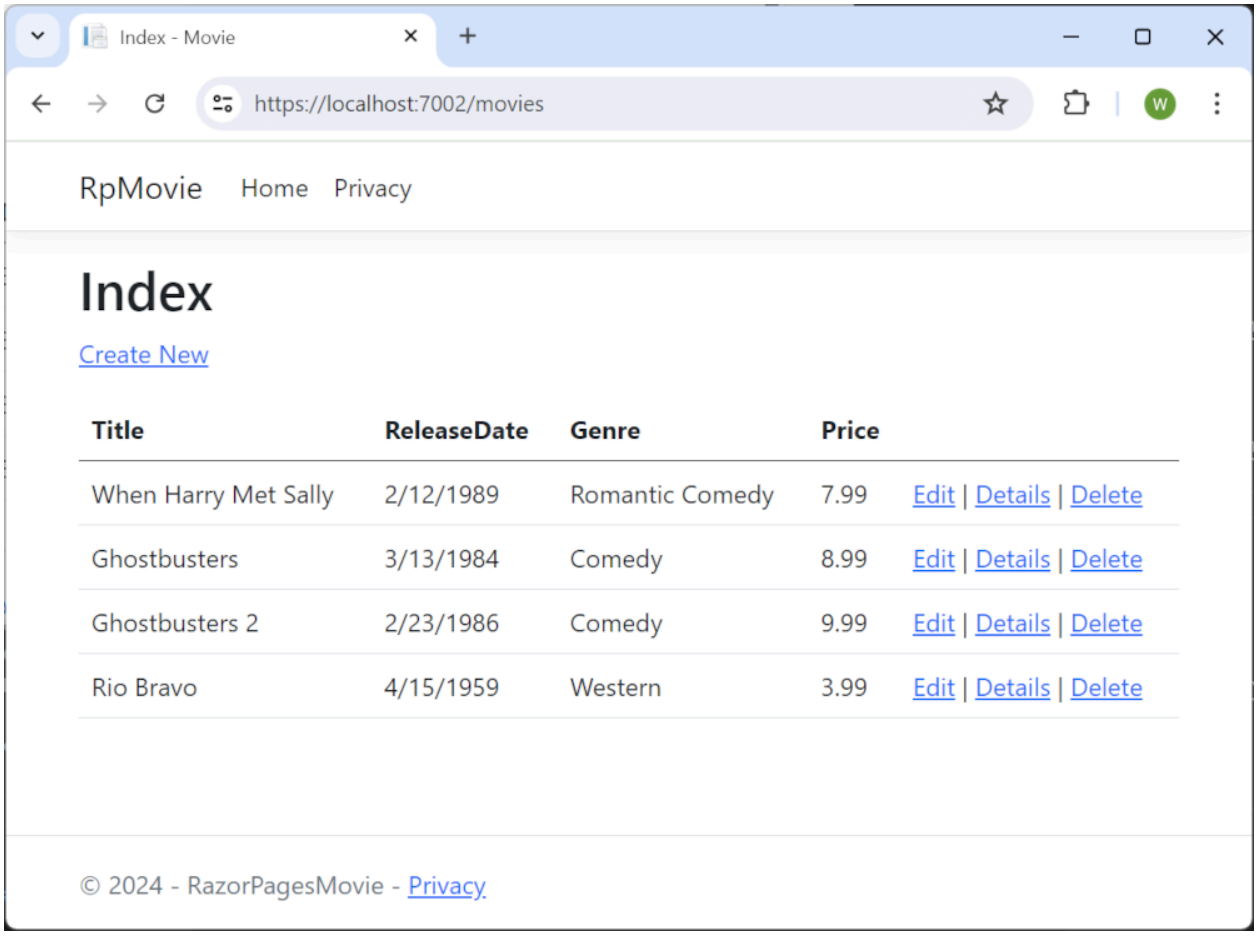
> `SqlException: Cannot open database "RazorPagesMovieContext-" requested by the login. The login failed.` `Login failed for user 'user name'.`

Test the app

Delete all the records in the database so the seed method will run. Stop and start the app to seed the database. If the database isn't seeded, put a breakpoint on `if (context.Movie.Any())` and step through the code.

The app shows the seeded data:

Next steps



Previous: Scaffolded Razor Pages
Next: Update the pages

Part 5, update the generated pages in an ASP.NET Core app

Article • 06/23/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

The scaffolded movie app has a good start, but the presentation isn't ideal. **ReleaseDate** should be two words, **Release Date**.

Update the model

Update `Models/Movie.cs` with the following highlighted code:

C#

```
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace RazorPagesMovie.Models;

public class Movie
{
    public int Id { get; set; }
    public string Title { get; set; } = string.Empty;

    [Display(Name = "Release Date")]
    [DataType(DataType.Date)]
    public DateTime ReleaseDate { get; set; }
    public string Genre { get; set; } = string.Empty;

    [Column(TypeName = "decimal(18, 2)")]
    public decimal Price { get; set; }
}
```

In the previous code:

- The `[Column(TypeName = "decimal(18, 2)")]` data annotation enables Entity Framework Core to correctly map `Price` to currency in the database. For more information, see Data Types.
- The [Display] attribute specifies the display name of a field. In the preceding code, `Release Date` instead of `ReleaseDate`.
- The [DataType] attribute specifies the type of the data (`Date`). The time information stored in the field isn't displayed.

DataAnnotations is covered in the next tutorial.

Browse to *Pages/Movies* and hover over an **Edit** link to see the target URL.

The **Edit**, **Details**, and **Delete** links are generated by the Anchor Tag Helper in the `Pages/Movies/Index.cshtml` file.

CSHTML

```
@foreach (var item in Model.Movie) {
        <tr>
            <td>
                @Html.DisplayFor(modelItem => item.Title)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.ReleaseDate)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Genre)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Price)
            </td>
            <td>
                <a asp-page="./Edit" asp-route-id="@item.Id">Edit</a> |
                <a asp-page="./Details" asp-route-id="@item.Id">Details</a>
|
                <a asp-page="./Delete" asp-route-id="@item.Id">Delete</a>
            </td>
        </tr>
}
    </tbody>
</table>
```

Tag Helpers enable server-side code to participate in creating and rendering HTML elements in Razor files.

In the preceding code, the Anchor Tag Helper dynamically generates the HTML `href` attribute value from the Razor Page (the route is relative), the `asp-page`, and the route identifier (`asp-route-id`). For more information, see URL generation for Pages.

Use **View Source** from a browser to examine the generated markup. A portion of the generated HTML is shown below:

HTML

```
<td>
  <a href="/Movies/Edit?id=1">Edit</a> |
  <a href="/Movies/Details?id=1">Details</a> |
  <a href="/Movies/Delete?id=1">Delete</a>
</td>
```

The dynamically generated links pass the movie ID with a query string. For example, the `?id=1` in `https://localhost:5001/Movies/Details?id=1`.

Add route template

Update the Edit, Details, and Delete Razor Pages to use the `{id:int}` route template. Change the page directive for each of these pages from `@page` to `@page "{id:int}"`. Run the app and then view source.

The generated HTML adds the ID to the path portion of the URL:

HTML

```
<td>
  <a href="/Movies/Edit/1">Edit</a> |
  <a href="/Movies/Details/1">Details</a> |
  <a href="/Movies/Delete/1">Delete</a>
</td>
```

A request to the page with the `{id:int}` route template that does **not** include the integer returns an HTTP 404 (not found) error. For example, `https://localhost:5001/Movies/Details` returns a 404 error. To make the ID optional, append `?` to the route constraint:

CSHTML

```
@page "{id:int?}"
```

Test the behavior of `@page "{id:int?}"`:

1. Set the page directive in `Pages/Movies/Details.cshtml` to `@page "{id:int?}"`.
2. Set a break point in `public async Task<IActionResult> OnGetAsync(int? id)`, in `Pages/Movies/Details.cshtml.cs`.
3. Navigate to `https://localhost:5001/Movies/Details/`.

With the `@page "{id:int}"` directive, the break point is never hit. The routing engine returns HTTP 404. Using `@page "{id:int?}"`, the `OnGetAsync` method returns `NotFound` (HTTP 404):

C#

```
public async Task<IActionResult> OnGetAsync(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    var movie = await _context.Movie.FirstOrDefaultAsync(m => m.Id == id);
    if (movie == null)
    {
        return NotFound();
    }
    else
    {
        Movie = movie;
    }
    return Page();
}
```

Review concurrency exception handling

Review the `OnPostAsync` method in the `Pages/Movies/Edit.cshtml.cs` file:

C#

```
public async Task<IActionResult> OnPostAsync()
{
    if (!ModelState.IsValid)
    {
        return Page();
    }
```

```
    _context.Attach(Movie).State = EntityState.Modified;

    try
    {
        await _context.SaveChangesAsync();
    }
    catch (DbUpdateConcurrencyException)
    {
        if (!MovieExists(Movie.Id))
        {
            return NotFound();
        }
        else
        {
            throw;
        }
    }

    return RedirectToPage("./Index");
}

private bool MovieExists(int id)
{
    return _context.Movie.Any(e => e.Id == id);
}
```

The previous code detects concurrency exceptions when one client deletes the movie and the other client posts changes to the movie.

To test the `catch` block:

1. Set a breakpoint on `catch (DbUpdateConcurrencyException)`.
2. Select **Edit** for a movie, make changes, but don't enter **Save**.
3. In another browser window, select the **Delete** link for the same movie, and then delete the movie.
4. In the previous browser window, post changes to the movie.

Production code may want to detect concurrency conflicts. See Handle concurrency conflicts for more information.

Posting and binding review

Examine the `Pages/Movies/Edit.cshtml.cs` file:

C#

```
public class EditModel : PageModel
{
```

```
    private readonly RazorPagesMovie.Data.RazorPagesMovieContext _context;

    public EditModel(RazorPagesMovie.Data.RazorPagesMovieContext context)
    {
        _context = context;
    }

    [BindProperty]
    public Movie Movie { get; set; } = default!;

    public async Task<IActionResult> OnGetAsync(int? id)
    {
        if (id == null)
        {
            return NotFound();
        }

        var movie =  await _context.Movie.FirstOrDefaultAsync(m => m.Id ==
id);
        if (movie == null)
        {
            return NotFound();
        }
        Movie = movie;
        return Page();
    }

    // To protect from overposting attacks, enable the specific properties
you want to bind to.
    // For more details, see https://aka.ms/RazorPagesCRUD.
    public async Task<IActionResult> OnPostAsync()
    {
        if (!ModelState.IsValid)
        {
            return Page();
        }

        _context.Attach(Movie).State = EntityState.Modified;

        try
        {
            await _context.SaveChangesAsync();
        }
        catch (DbUpdateConcurrencyException)
        {
            if (!MovieExists(Movie.Id))
            {
                return NotFound();
            }
            else
            {
                throw;
            }
        }
```

```
            return RedirectToPage("./Index");
        }

        private bool MovieExists(int id)
        {
            return _context.Movie.Any(e => e.Id == id);
        }
```

When an HTTP GET request is made to the Movies/Edit page, for example, `https://localhost:5001/Movies/Edit/3`:

- The `OnGetAsync` method fetches the movie from the database and returns the `Page` method.
- The `Page` method renders the `Pages/Movies/Edit.cshtml` Razor Page. The `Pages/Movies/Edit.cshtml` file contains the model directive `@model RazorPagesMovie.Pages.Movies.EditModel`, which makes the movie model available on the page.
- The Edit form is displayed with the values from the movie.

When the Movies/Edit page is posted:

- The form values on the page are bound to the `Movie` property. The `[BindProperty]` attribute enables Model binding.

  C#

  ```
  [BindProperty]
  public Movie Movie { get; set; }
  ```

- If there are errors in the model state, for example, `ReleaseDate` cannot be converted to a date, the form is redisplayed with the submitted values.
- If there are no model errors, the movie is saved.

The HTTP GET methods in the Index, Create, and Delete Razor pages follow a similar pattern. The HTTP POST `OnPostAsync` method in the Create Razor Page follows a similar pattern to the `OnPostAsync` method in the Edit Razor Page.

Part 6, add search to ASP.NET Core Razor Pages

Article • 06/23/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

By Rick Anderson

In the following sections, searching movies by *genre* or *name* is added.

Add the following highlighted code to `Pages/Movies/Index.cshtml.cs`:

C#

```
public class IndexModel : PageModel
{
    private readonly RazorPagesMovie.Data.RazorPagesMovieContext _context;

    public IndexModel(RazorPagesMovie.Data.RazorPagesMovieContext context)
    {
        _context = context;
    }

    public IList<Movie> Movie { get;set; }  = default!;

    [BindProperty(SupportsGet = true)]
    public string? SearchString { get; set; }

    public SelectList? Genres { get; set; }

    [BindProperty(SupportsGet = true)]
    public string? MovieGenre { get; set; }
```

In the previous code:

- `SearchString`: Contains the text users enter in the search text box. `SearchString` has the [BindProperty] attribute. `[BindProperty]` binds form values and query

strings with the same name as the property. `[BindProperty(SupportsGet = true)]` is required for binding on HTTP GET requests.

- `Genres`: Contains the list of genres. `Genres` allows the user to select a genre from the list. `SelectList` requires `using Microsoft.AspNetCore.Mvc.Rendering;`
- `MovieGenre`: Contains the specific genre the user selects. For example, "Western".
- `Genres` and `MovieGenre` are used later in this tutorial.

> ⚠ **Warning**
>
> For security reasons, you must opt in to binding `GET` request data to page model properties. Verify user input before mapping it to properties. Opting into `GET` binding is useful when addressing scenarios that rely on query string or route values.
>
> To bind a property on `GET` requests, set the [BindProperty] attribute's `SupportsGet` property to `true`:
>
> C#
>
> ```
> [BindProperty(SupportsGet = true)]
> ```
>
> For more information, see ASP.NET Core Community Standup: Bind on GET discussion (YouTube).

Update the `Movies/Index` page's `OnGetAsync` method with the following code:

C#

```
public async Task OnGetAsync()
{
    var movies = from m in _context.Movie
                 select m;
    if (!string.IsNullOrEmpty(SearchString))
    {
        movies = movies.Where(s => s.Title.Contains(SearchString));
    }

    Movie = await movies.ToListAsync();
}
```

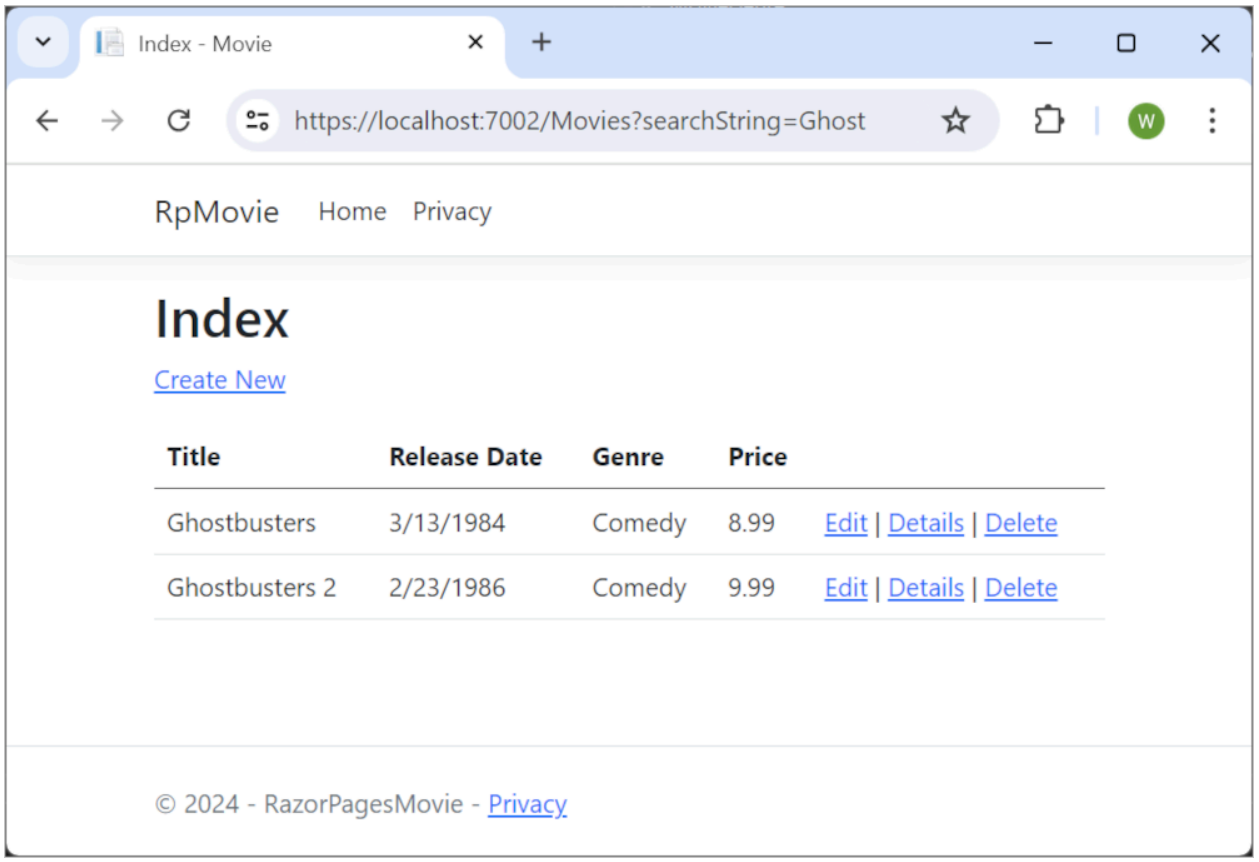
The first line of the `OnGetAsync` method creates a LINQ query to select the movies:

C#

```
var movies = from m in _context.Movie
             select m;
```

The query is only ***defined*** at this point, it has ***not*** been run against the database.

If the `SearchString` property is not `null` or empty, the movies query is modified to filter on the search string:



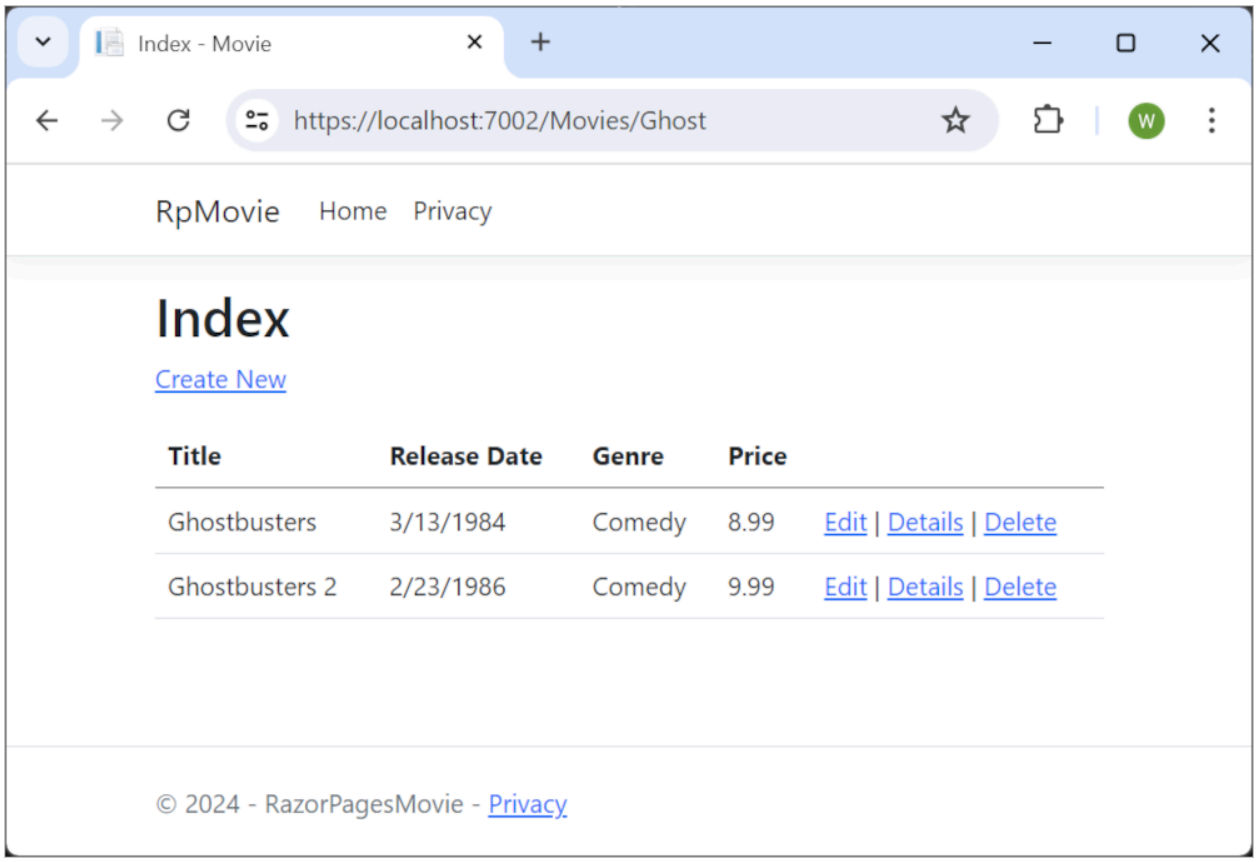
C#

```
if (!string.IsNullOrEmpty(SearchString))
{
    movies = movies.Where(s => s.Title.Contains(SearchString));
}
```

The `s => s.Title.Contains()` code is a Lambda Expression. Lambdas are used in method-based LINQ queries as arguments to standard query operator methods such as the Where method or `Contains`. LINQ queries are not executed when they're defined or when they're modified by calling a method, such as `Where`, `Contains`, or `OrderBy`. Rather, query execution is deferred. The evaluation of an expression is delayed until its realized value is iterated over or the `ToListAsync` method is called. See Query Execution for more information.

> ⓘ Note
>
> The Contains method is run on the database, not in the C# code. The case sensitivity on the query depends on the database and the collation. On SQL Server, `Contains` maps to SQL LIKE, which is case insensitive. SQLite with the default collation is a mixture of case sensitive and case ***IN***sensitive, depending on the query. For information on making case insensitive SQLite queries, see the following:
>
> - How to use case-insensitive query with Sqlite provider? (dotnet/efcore #11414)
> - How to make a SQLite column case insensitive (dotnet/AspNetCore.Docs #22314)
> - Collations and Case Sensitivity

Navigate to the Movies page and append a query string such as `?searchString=Ghost` to the URL. For example, `https://localhost:5001/Movies?searchString=Ghost`. The filtered movies are displayed.



If the following route template is added to the Index page, the search string can be passed as a URL segment. For example, `https://localhost:5001/Movies/Ghost`.

CSHTML

```
@page "{searchString?}"
```

The preceding route constraint allows searching the title as route data (a URL segment) instead of as a query string value. The `?` in `"{searchString?}"` means this is an optional route parameter.

The ASP.NET Core runtime uses model binding to set the value of the `SearchString` property from the query string (`?searchString=Ghost`) or route data (`https://localhost:5001/Movies/Ghost`). Model binding is ***not*** case sensitive.

However, users cannot be expected to modify the URL to search for a movie. In this step, UI is added to filter movies. If you added the route constraint `"{searchString?}"`, remove it.

Open the `Pages/Movies/Index.cshtml` file, and add the markup highlighted in the following code:

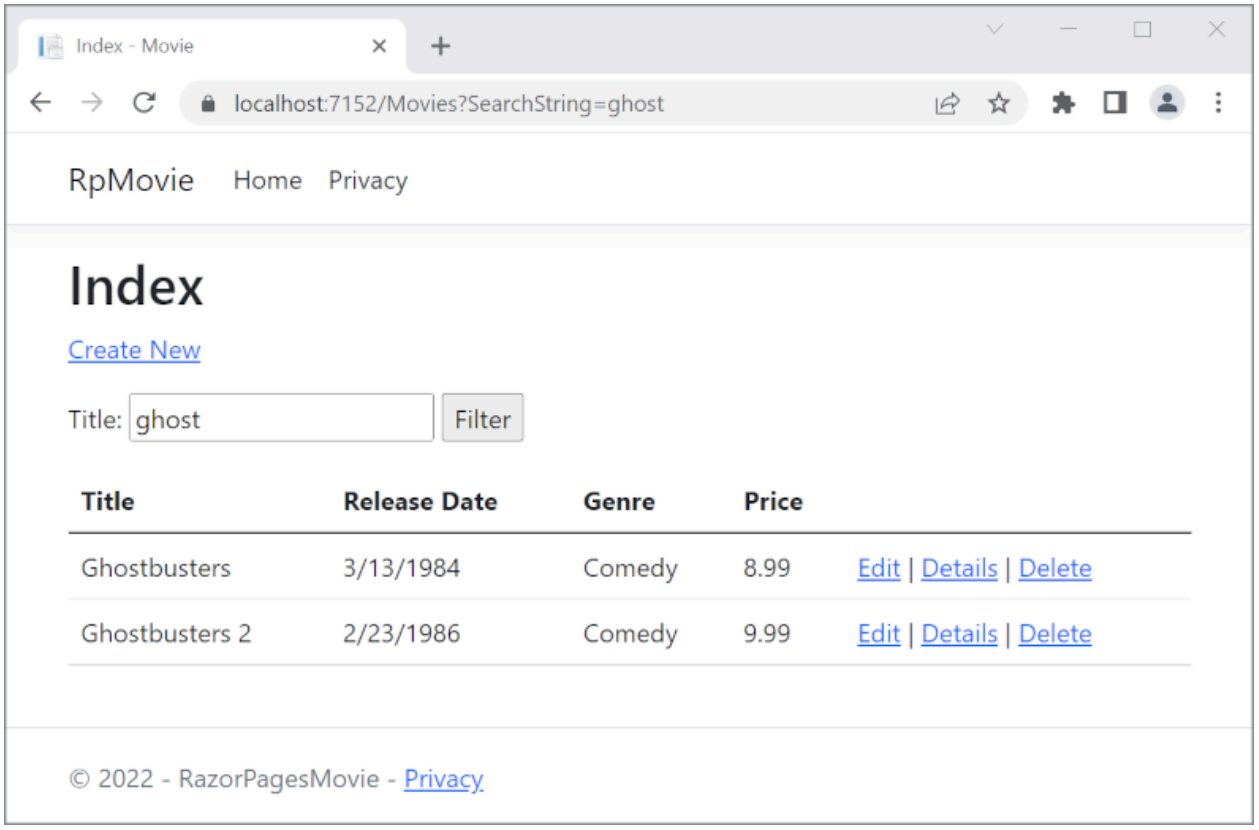
CSHTML

```
@page
@model RazorPagesMovie.Pages.Movies.IndexModel

@{
    ViewData["Title"] = "Index";
}

<h1>Index</h1>

<p>
    <a asp-page="Create">Create New</a>
</p>
```



```
<form>
    <p>
        Title: <input type="text" asp-for="SearchString" />
        <input type="submit" value="Filter" />
    </p>
</form>
```

```
<table class="table">
    <thead>
```

The HTML `<form>` tag uses the following Tag Helpers:

- Form Tag Helper. When the form is submitted, the filter string is sent to the *Pages/Movies/Index* page via query string.
- Input Tag Helper

Save the changes and test the filter.

Search by genre

Update the `Movies/Index.cshtml.cs` page `OnGetAsync` method with the following code:

C#

```
public async Task OnGetAsync()
{
    // <snippet_search_linqQuery>
```

```
    IQueryable<string> genreQuery = from m in _context.Movie
                                    orderby m.Genre
                                    select m.Genre;
    // </snippet_search_linqQuery>

    var movies = from m in _context.Movie
                 select m;

    if (!string.IsNullOrEmpty(SearchString))
    {
        movies = movies.Where(s => s.Title.Contains(SearchString));
    }

    if (!string.IsNullOrEmpty(MovieGenre))
    {
        movies = movies.Where(x => x.Genre == MovieGenre);
    }

    // <snippet_search_selectList>
    Genres = new SelectList(await genreQuery.Distinct().ToListAsync());
    // </snippet_search_selectList>
    Movie = await movies.ToListAsync();
}
```

The following code is a LINQ query that retrieves all the genres from the database.

C#

```
IQueryable<string> genreQuery = from m in _context.Movie
                                orderby m.Genre
                                select m.Genre;
```

The `SelectList` of genres is created by projecting the distinct genres:

C#

```
Genres = new SelectList(await genreQuery.Distinct().ToListAsync());
```

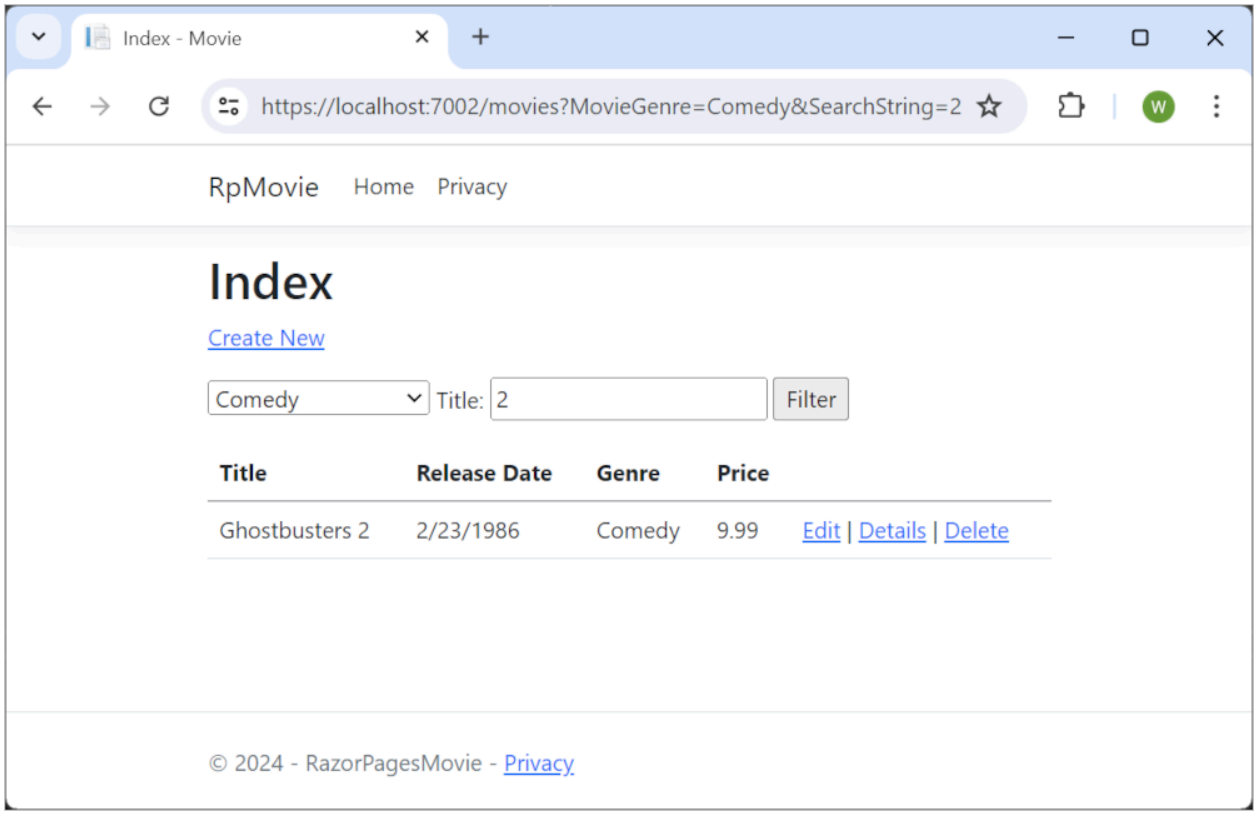
Add search by genre to the Razor Page

Update the `Index.cshtml` <form> element as highlighted in the following markup:

CSHTML

```
@page
@model RazorPagesMovie.Pages.Movies.IndexModel

@{
    ViewData["Title"] = "Index";
```



```
}

<h1>Index</h1>

<p>
    <a asp-page="Create">Create New</a>
</p>

<form>
    <p>
        <select asp-for="MovieGenre" asp-items="Model.Genres">
            <option value="">All</option>
        </select>
        Title: <input type="text" asp-for="SearchString" />
        <input type="submit" value="Filter" />
    </p>
</form>
```

Test the app by searching by genre, by movie title, and by both:

Part 7, add a new field to a Razor Page in ASP.NET Core

Article • 06/23/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

By Rick Anderson

In this section Entity Framework Core (EF Core) is used to define the database schema based on the app's model class:

- Add a new field to the model.
- Migrate the new field schema change to the database.

The EF Core approach allows for a more agile development process. The developer works on the app's data model directly while the database schema is created and then syncronized, all without the developer having to switch contexts to and from a datbase management tool. For an overview of Entity Framework Core and its benefits, see Entity Framework Core.

Using EF Code to automatically create and track a database:

- Adds an __EFMigrationsHistory table to the database to track whether the schema of the database is in sync with the model classes it was generated from.
- Throws an exception if the model classes aren't in sync with the database.

Automatic verification that the schema and model are in sync makes it easier to find inconsistent database code issues.

Adding a Rating Property to the Movie Model

1. Open the `Models/Movie.cs` file and add a `Rating` property:

```
C#
```

```
public class Movie
{
    public int Id { get; set; }
    public string Title { get; set; } = string.Empty;

    [Display(Name = "Release Date")]
    [DataType(DataType.Date)]
    public DateTime ReleaseDate { get; set; }
    public string Genre { get; set; } = string.Empty;

    [Column(TypeName = "decimal(18, 2)")]
    public decimal Price { get; set; }
    public string Rating { get; set; } = string.Empty;
}
```

2. Edit `Pages/Movies/Index.cshtml`, and add a `Rating` field:

CSHTML

```
@page
@model RazorPagesMovie.Pages.Movies.IndexModel

@{
    ViewData["Title"] = "Index";
}

<h1>Index</h1>

<p>
    <a asp-page="Create">Create New</a>
</p>

<form>
    <p>
        <select asp-for="MovieGenre" asp-items="Model.Genres">
            <option value="">All</option>
        </select>
        Title: <input type="text" asp-for="SearchString" />
        <input type="submit" value="Filter" />
    </p>
</form>

<table class="table">

    <thead>
        <tr>
            <th>
                @Html.DisplayNameFor(model => model.Movie[0].Title)
            </th>
            <th>
                @Html.DisplayNameFor(model =>
model.Movie[0].ReleaseDate)
```

```
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Movie[0].Genre)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Movie[0].Price)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Movie[0].Rating)
            </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
        @foreach (var item in Model.Movie)
        {
            <tr>
                <td>
                    @Html.DisplayFor(modelItem => item.Title)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.ReleaseDate)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Genre)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Price)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Rating)
                </td>
                <td>
                    <a asp-page="./Edit" asp-route-
id="@item.Id">Edit</a> |
                    <a asp-page="./Details" asp-route-
id="@item.Id">Details</a> |
                    <a asp-page="./Delete" asp-route-
id="@item.Id">Delete</a>
                </td>
            </tr>
        }
    </tbody>
</table>
```

3. Update the following pages with a `Rating` field:

- *Pages/Movies/Create.cshtml*.
- *Pages/Movies/Delete.cshtml*.
- *Pages/Movies/Details.cshtml*.
- *Pages/Movies/Edit.cshtml*.

The app won't work until the database is updated to include the new field. Running the app without an update to the database throws a `SqlException`:

```
SqlException: Invalid column name 'Rating'.
```

The `SqlException` exception is caused by the updated Movie model class being different than the schema of the Movie table of the database. There's no `Rating` column in the database table.

There are a few approaches to resolving the error:

1. Have the Entity Framework automatically drop and re-create the database using the new model class schema. This approach is convenient early in the development cycle, it allows developers to quickly evolve the model and database schema together. The downside is that existing data in the database is lost. Don't use this approach on a production database! Dropping the database on schema changes and using an initializer to automatically seed the database with test data is often a productive way to develop an app.
2. Explicitly modify the schema of the existing database so that it matches the model classes. The advantage of this approach is to keep the data. Make this change either manually or by creating a database change script.
3. Use EF Core Migrations to update the database schema.

For this tutorial, use EF Core Migrations.

Update the `SeedData` class so that it provides a value for the new column. A sample change is shown below, but make this change for each `new Movie` block.

C#

```
context.Movie.AddRange(
    new Movie
    {
        Title = "When Harry Met Sally",
        ReleaseDate = DateTime.Parse("1989-2-12"),
        Genre = "Romantic Comedy",
        Price = 7.99M,
        Rating = "R"
    },
```

See the completed SeedData.cs file.

Build the app

Visual Studio

Press `Ctrl`+`Shift`+`B`

Visual Studio

Add a migration for the rating field

1. From the **Tools** menu, select **NuGet Package Manager** > **Package Manager Console**.

2. In the Package Manager Console (PMC), enter the following command:

```
PowerShell

Add-Migration Rating
```

The `Add-Migration` command tells the framework to:

- Compare the `Movie` model with the `Movie` database schema.
- Create code to migrate the database schema to the new model.

The name "Rating" is arbitrary and is used to name the migration file. It's helpful to use a meaningful name for the migration file.

2. In the PMC, enter the following command:

```
PowerShell

Update-Database
```

The `Update-Database` command tells the framework to apply the schema changes to the database and to preserve existing data.

Delete all the records in the database, the initializer will seed the database and include the `Rating` field. Deleting can be done with the delete links in the browser or from Sql Server Object Explorer (SSOX).

Another option is to delete the database and use migrations to re-create the database. To delete the database in SSOX:

1. Select the database in SSOX.

2. Right-click on the database, and select **Delete**.

3. Check **Close existing connections**.

4. Select **OK**.

5. In the PMC, update the database:

```
PowerShell

Update-Database
```

Run the app and verify you can create, edit, and display movies with a `Rating` field. If the database isn't seeded, set a break point in the `SeedData.Initialize` method.

Part 8 of tutorial series on Razor Pages

Article • 06/23/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

By Rick Anderson

In this section, validation logic is added to the `Movie` model. The validation rules are enforced any time a user creates or edits a movie.

Validation

A key tenet of software development is called DRY ("**D**on't **R**epeat **Y**ourself"). Razor Pages encourages development where functionality is specified once, and it's reflected throughout the app. DRY can help:

- Reduce the amount of code in an app.
- Make the code less error prone, and easier to test and maintain.

The validation support provided by Razor Pages and Entity Framework is a good example of the DRY principle:

- Validation rules are declaratively specified in one place, in the model class.
- Rules are enforced everywhere in the app.

Add validation rules to the movie model

The System.ComponentModel.DataAnnotations namespace provides:

- A set of built-in validation attributes that are applied declaratively to a class or property.
- Formatting attributes like `[DataType]` that help with formatting and don't provide any validation.

Update the `Movie` class to take advantage of the built-in `[Required]`, `[StringLength]`, `[RegularExpression]`, and `[Range]` validation attributes.

C#

```
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace RazorPagesMovie.Models;

public class Movie
{
    public int Id { get; set; }

    [StringLength(60, MinimumLength = 3)]
    [Required]
    public string Title { get; set; } = string.Empty;

    [DataType(DataType.Date)]
    public DateTime ReleaseDate { get; set; }

    [Range(1, 100)]
    [DataType(DataType.Currency)]
    [Column(TypeName = "decimal(18, 2)")]
    public decimal Price { get; set; }

    [RegularExpression(@"^[A-Z]+[a-zA-Z\s]*$")]
    [Required]
    [StringLength(30)]
    public string Genre { get; set; } = string.Empty;

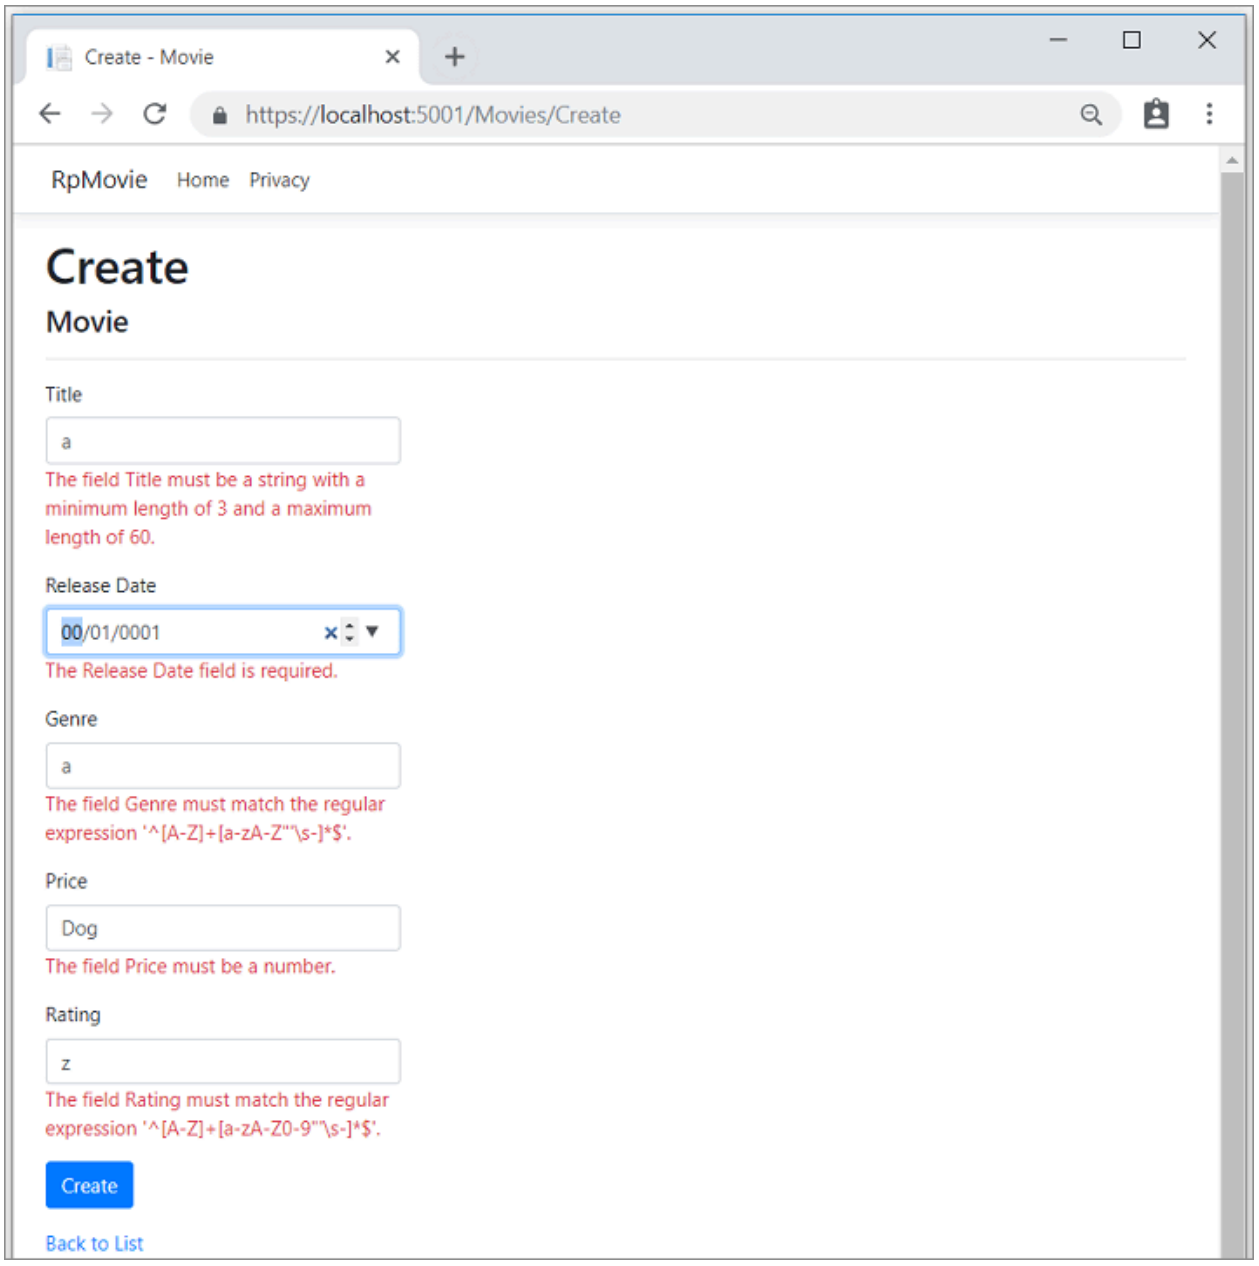
    [RegularExpression(@"^[A-Z]+[a-zA-Z0-9""'\s-]*$")]
    [StringLength(5)]
    [Required]
    public string Rating { get; set; } = string.Empty;
}
```

The validation attributes specify behavior to enforce on the model properties they're applied to:

- The `[Required]` and `[MinimumLength]` attributes indicate that a property must have a value. Nothing prevents a user from entering white space to satisfy this validation.
- The `[RegularExpression]` attribute is used to limit what characters can be input. In the preceding code, `Genre`:
  - Must only use letters.
  - The first letter must be uppercase. White spaces are allowed, while numbers and special characters aren't allowed.

- The `RegularExpression` `Rating`:
  - Requires that the first character be an uppercase letter.
  - Allows special characters and numbers in subsequent spaces. "PG-13" is valid for a rating, but fails for a `Genre`.
- The `[Range]` attribute constrains a value to within a specified range.
- The `[StringLength]` attribute can set a maximum length of a string property, and optionally its minimum length.
- Value types, such as `decimal`, `int`, `float`, `DateTime`, are inherently required and don't need the `[Required]` attribute.

The preceding validation rules are used for demonstration, they are not optimal for a production system. For example, the preceding prevents entering a movie with only two chars and doesn't allow special characters in `Genre`.



Having validation rules automatically enforced by ASP.NET Core helps:

- Make the app more robust.
- Reduce chances of saving invalid data to the database.

Validation Error UI in Razor Pages

Run the app and navigate to Pages/Movies.

Select the **Create New** link. Complete the form with some invalid values. When jQuery client-side validation detects the error, it displays an error message.

> **Note**
>
> You may not be able to enter decimal commas in decimal fields. To support jQuery validation for non-English locales that use a comma (",") for a decimal point, and non US-English date formats, you must take steps to globalize your app. See this GitHub comment 4076 for instructions on adding decimal comma.

Notice how the form has automatically rendered a validation error message in each field containing an invalid value. The errors are enforced both client-side, using JavaScript and jQuery, and server-side, when a user has JavaScript disabled.

A significant benefit is that **no** code changes were necessary in the Create or Edit pages. Once data annotations were applied to the model, the validation UI was enabled. The Razor Pages created in this tutorial automatically picked up the validation rules, using

validation attributes on the properties of the `Movie` model class. Test validation using the Edit page, the same validation is applied.

The form data isn't posted to the server until there are no client-side validation errors. Verify form data isn't posted by one or more of the following approaches:

- Put a break point in the `OnPostAsync` method. Submit the form by selecting **Create** or **Save**. The break point is never hit.
- Use the Fiddler tool.
- Use the browser developer tools to monitor network traffic.

Server-side validation

When JavaScript is disabled in the browser, submitting the form with errors will post to the server.

Optional, test server-side validation:

1. Disable JavaScript in the browser. JavaScript can be disabled using browser's developer tools. If JavaScript cannot be disabled in the browser, try another browser.
2. Set a break point in the `OnPostAsync` method of the Create or Edit page.
3. Submit a form with invalid data.
4. Verify the model state is invalid:

```
C#
```

```
if (!ModelState.IsValid)
{
    return Page();
}
```

Alternatively, Disable client-side validation on the server.

The following code shows a portion of the `Create.cshtml` page scaffolded earlier in the tutorial. It's used by the Create and Edit pages to:

- Display the initial form.
- Redisplay the form in the event of an error.

```
CSHTML
```

```
<form method="post">
    <div asp-validation-summary="ModelOnly" class="text-danger"></div>
    <div class="form-group">
        <label asp-for="Movie.Title" class="control-label"></label>
        <input asp-for="Movie.Title" class="form-control" />
        <span asp-validation-for="Movie.Title" class="text-danger"></span>
    </div>
```

The Input Tag Helper uses the DataAnnotations attributes and produces HTML attributes needed for jQuery Validation on the client-side. The Validation Tag Helper displays validation errors. See Validation for more information.

The Create and Edit pages have no validation rules in them. The validation rules and the error strings are specified only in the `Movie` class. These validation rules are automatically applied to Razor Pages that edit the `Movie` model.

When validation logic needs to change, it's done only in the model. Validation is applied consistently throughout the app, validation logic is defined in one place. Validation in one place helps keep the code clean, and makes it easier to maintain and update.

Use DataType Attributes

Examine the `Movie` class. The `System.ComponentModel.DataAnnotations` namespace provides formatting attributes in addition to the built-in set of validation attributes. The `[DataType]` attribute is applied to the `ReleaseDate` and `Price` properties.

C#

```
[DataType(DataType.Date)]
public DateTime ReleaseDate { get; set; }

[Range(1, 100)]
[DataType(DataType.Currency)]
[Column(TypeName = "decimal(18, 2)")]
public decimal Price { get; set; }
```

The `[DataType]` attributes provide:

- Hints for the view engine to format the data.
- Supplies attributes such as `<a>` for URL's and `<a href="mailto:EmailAddress.com">` for email.

Use the `[RegularExpression]` attribute to validate the format of the data. The `[DataType]` attribute is used to specify a data type that's more specific than the

database intrinsic type. `[DataType]` attributes aren't validation attributes. In the sample app, only the date is displayed, without time.

The `DataType` enumeration provides many data types, such as `Date`, `Time`, `PhoneNumber`, `Currency`, `EmailAddress`, and more.

The `[DataType]` attributes:

- Can enable the app to automatically provide type-specific features. For example, a `mailto:` link can be created for `DataType.EmailAddress`.
- Can provide a date selector `DataType.Date` in browsers that support HTML5.
- Emit HTML 5 `data-`, pronounced "data dash", attributes that HTML 5 browsers consume.
- Do **not** provide any validation.

`DataType.Date` doesn't specify the format of the date that's displayed. By default, the data field is displayed according to the default formats based on the server's `CultureInfo`.

The `[Column(TypeName = "decimal(18, 2)")]` data annotation is required so Entity Framework Core can correctly map `Price` to currency in the database. For more information, see Data Types.

The `[DisplayFormat]` attribute is used to explicitly specify the date format:

```
C#

[DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode =
true)]
public DateTime ReleaseDate { get; set; }
```

The `ApplyFormatInEditMode` setting specifies that the formatting will be applied when the value is displayed for editing. That behavior may not be wanted for some fields. For example, in currency values, the currency symbol is usually not wanted in the edit UI.

The `[DisplayFormat]` attribute can be used by itself, but it's generally a good idea to use the `[DataType]` attribute. The `[DataType]` attribute conveys the semantics of the data as opposed to how to render it on a screen. The `[DataType]` attribute provides the following benefits that aren't available with `[DisplayFormat]`:

- The browser can enable HTML5 features, for example to show a calendar control, the locale-appropriate currency symbol, email links, etc.
- By default, the browser renders data using the correct format based on its locale.

- The `[DataType]` attribute can enable the ASP.NET Core framework to choose the right field template to render the data. The `DisplayFormat`, if used by itself, uses the string template.

Note: jQuery validation doesn't work with the `[Range]` attribute and `DateTime`. For example, the following code will always display a client-side validation error, even when the date is in the specified range:

C#

```
[Range(typeof(DateTime), "1/1/1966", "1/1/2020")]
```

It's a best practice to avoid compiling hard dates in models, so using the `[Range]` attribute and `DateTime` is discouraged. Use Configuration for date ranges and other values that are subject to frequent change rather than specifying it in code.

The following code shows combining attributes on one line:

C#

```
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace RazorPagesMovie.Models;

public class Movie
{
    public int Id { get; set; }

    [StringLength(60, MinimumLength = 3)]
    public string Title { get; set; } = string.Empty;

    [Display(Name = "Release Date"), DataType(DataType.Date)]
    public DateTime ReleaseDate { get; set; }

    [RegularExpression(@"^[A-Z]+[a-zA-Z\s]*$"), Required, StringLength(30)]
    public string Genre { get; set; } = string.Empty;

    [Range(1, 100), DataType(DataType.Currency)]
    [Column(TypeName = "decimal(18, 2)")]
    public decimal Price { get; set; }

    [RegularExpression(@"^[A-Z]+[a-zA-Z0-9""'\s-]*$"), StringLength(5)]
    public string Rating { get; set; } = string.Empty;
}
```

Get started with Razor Pages and EF Core shows advanced EF Core operations with Razor Pages.

Apply migrations

The DataAnnotations applied to the class changes the schema. For example, the DataAnnotations applied to the `Title` field:

C#

```
[StringLength(60, MinimumLength = 3)]
[Required]
public string Title { get; set; } = string.Empty;
```

- Limits the characters to 60.
- Doesn't allow a `null` value.

The `Movie` table currently has the following schema:

SQL

```
CREATE TABLE [dbo].[Movie] (
    [ID]          INT             IDENTITY (1, 1) NOT NULL,
    [Title]       NVARCHAR (MAX)  NULL,
    [ReleaseDate] DATETIME2 (7)   NOT NULL,
    [Genre]       NVARCHAR (MAX)  NULL,
    [Price]       DECIMAL (18, 2) NOT NULL,
    [Rating]      NVARCHAR (MAX)  NULL,
    CONSTRAINT [PK_Movie] PRIMARY KEY CLUSTERED ([ID] ASC)
);
```

The preceding schema changes don't cause EF to throw an exception. However, create a migration so the schema is consistent with the model.

Visual Studio

From the **Tools** menu, select **NuGet Package Manager** > **Package Manager Console**. In the PMC, enter the following commands:

PowerShell

```
Add-Migration New_DataAnnotations
Update-Database
```

`Update-Database` runs the `Up` method of the `New_DataAnnotations` class.

Examine the `Up` method:

C#

```
public partial class New_DataAnnotations : Migration
{
    /// <inheritdoc />
    protected override void Up(MigrationBuilder migrationBuilder)
    {
        migrationBuilder.AlterColumn<string>(
            name: "Title",
            table: "Movie",
            type: "nvarchar(60)",
            maxLength: 60,
            nullable: false,
            oldClrType: typeof(string),
            oldType: "nvarchar(max)");

        migrationBuilder.AlterColumn<string>(
            name: "Rating",
            table: "Movie",
            type: "nvarchar(5)",
            maxLength: 5,
            nullable: false,
            oldClrType: typeof(string),
            oldType: "nvarchar(max)");

        migrationBuilder.AlterColumn<string>(
            name: "Genre",
            table: "Movie",
            type: "nvarchar(30)",
            maxLength: 30,
            nullable: false,
            oldClrType: typeof(string),
            oldType: "nvarchar(max)");
    }
```

The updated `Movie` table has the following schema:

SQL

```
CREATE TABLE [dbo].[Movie] (
    [ID]          INT             IDENTITY (1, 1) NOT NULL,
    [Title]       NVARCHAR (60)   NOT NULL,
    [ReleaseDate] DATETIME2 (7)   NOT NULL,
    [Genre]       NVARCHAR (30)   NOT NULL,
    [Price]       DECIMAL (18, 2) NOT NULL,
    [Rating]      NVARCHAR (5)    NOT NULL,
    CONSTRAINT [PK_Movie] PRIMARY KEY CLUSTERED ([ID] ASC)
);
```

Publish to Azure

For information on deploying to Azure, see Tutorial: Build an ASP.NET Core app in Azure with SQL Database.

Thanks for completing this introduction to Razor Pages. Get started with Razor Pages and EF Core is an excellent follow up to this tutorial.

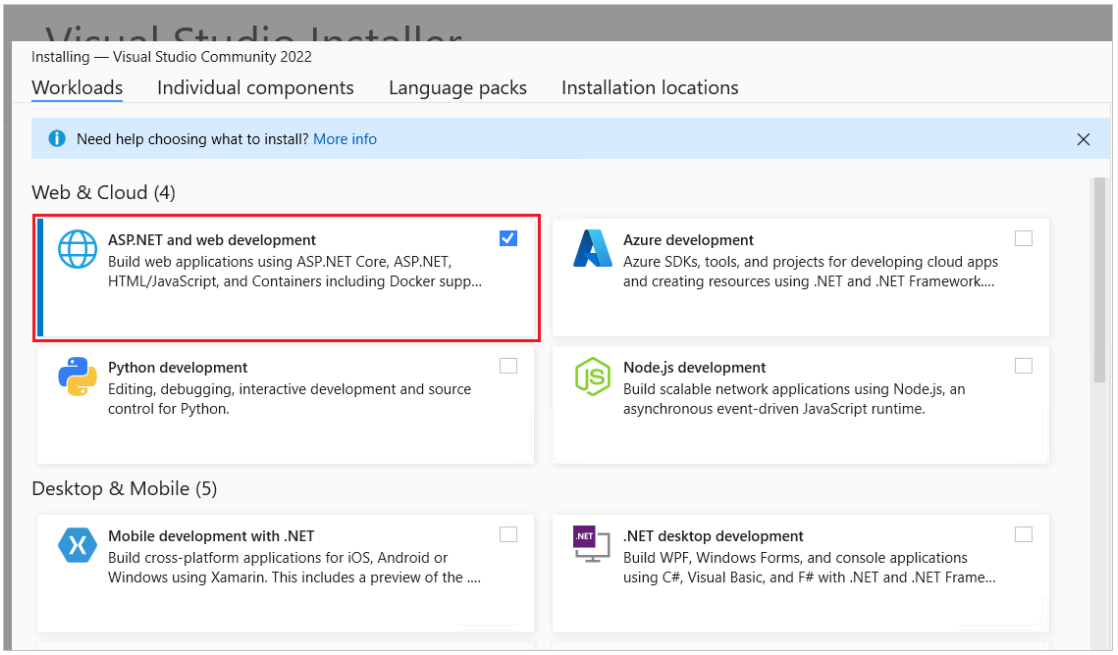
By Rick Anderson

This tutorial teaches ASP.NET Core MVC web development with controllers and views. If you're new to ASP.NET Core web development, consider the Razor Pages version of this tutorial, which provides an easier starting point. See Choose an ASP.NET Core UI, which compares Razor Pages, MVC, and Blazor for UI development.

This is the first tutorial of a series that teaches ASP.NET Core MVC web development with controllers and views.

At the end of the series, you'll have an app that manages, validates, and displays movie data. You learn how to:

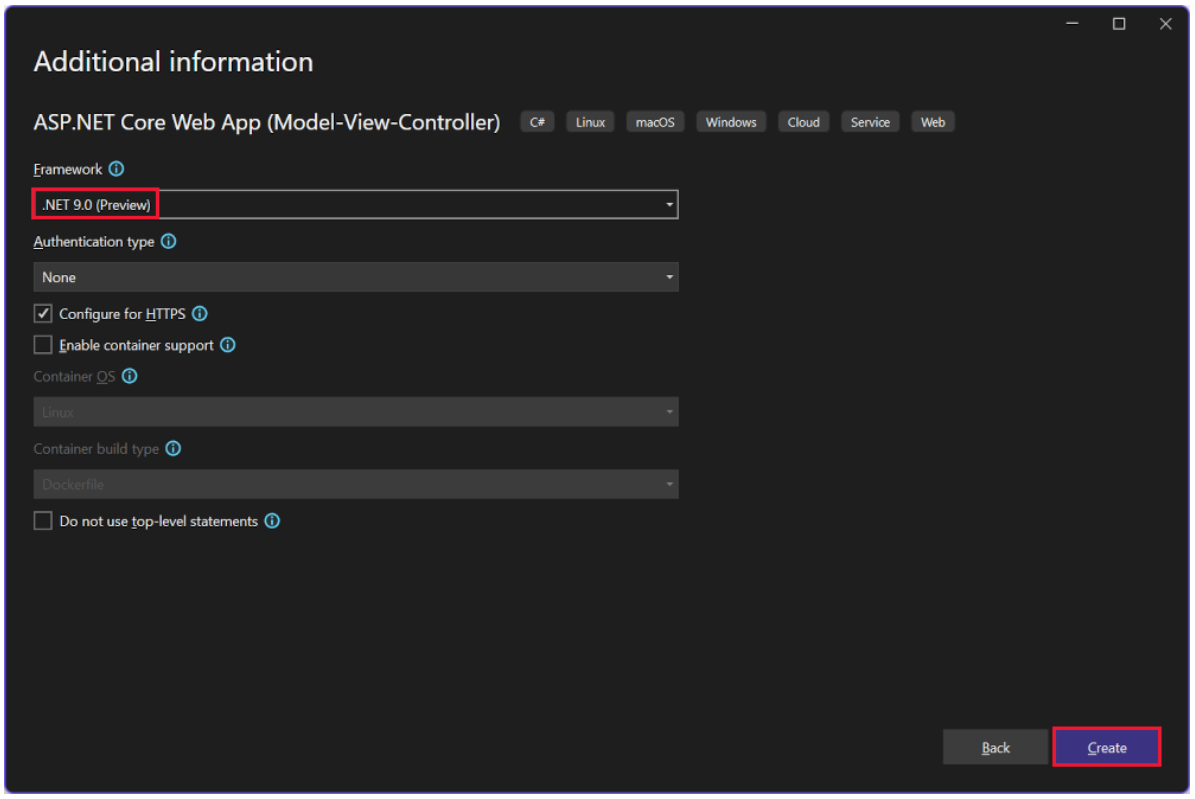


- ✓ Create a web app.
- ✓ Add and scaffold a model.
- ✓ Work with a database.
- ✓ Add search and validation.

View or download sample code (how to download).

Prerequisites

Visual Studio



- Visual Studio 2022 Preview with the **ASP.NET and web development** workload.

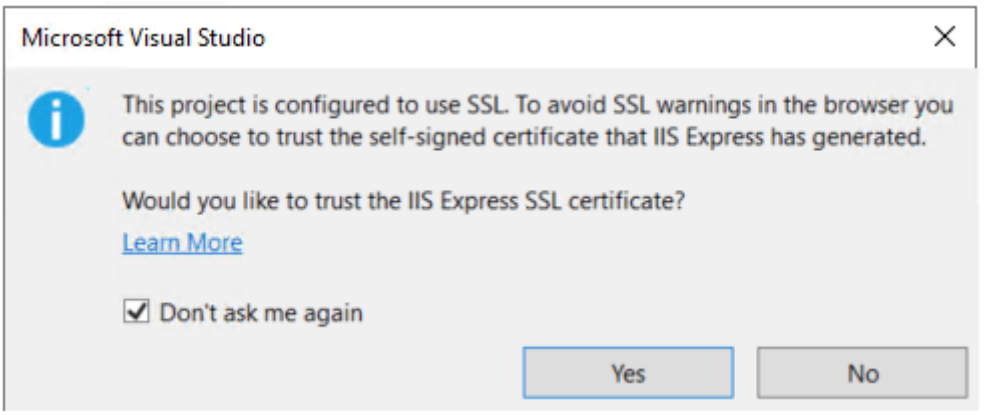
Create a web app

Visual Studio

- Start Visual Studio and select **Create a new project**.
- In the **Create a new project** dialog, select **ASP.NET Core Web App (Model-View-Controller)** > **Next**.
- In the **Configure your new project** dialog:
  - Enter `MvcMovie` for **Project name**. It's important to name the project *MvcMovie*. Capitalization needs to match each `namespace` when code is copied.
  - The **Location** for the project can be set to anywhere.
- Select **Next**.
- In the **Additional information** dialog:
  - Select **.NET 9.0 (Preview)**.
  - Verify that **Do not use top-level statements** is unchecked.
- Select **Create**.

For more information, including alternative approaches to create the project, see Create a new project in Visual Studio.

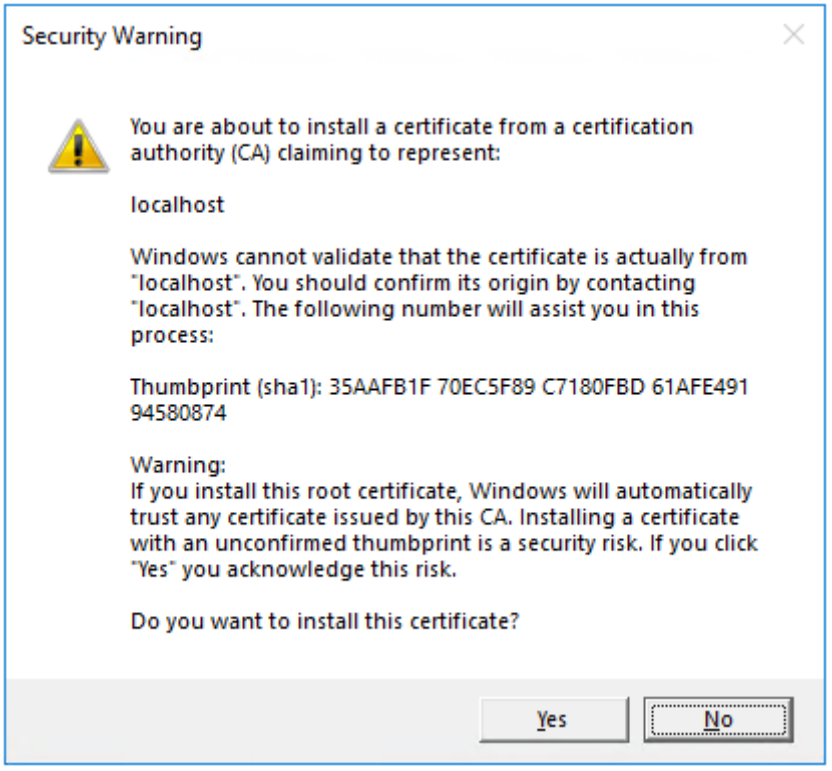
Visual Studio uses the default project template for the created MVC project. The created project:



- Is a working app.
- Is a basic starter project.

Run the app

Visual Studio



- Press `Ctrl`+`F5` to run the app without the debugger.

  Visual Studio displays the following dialog when a project is not yet configured to use SSL:

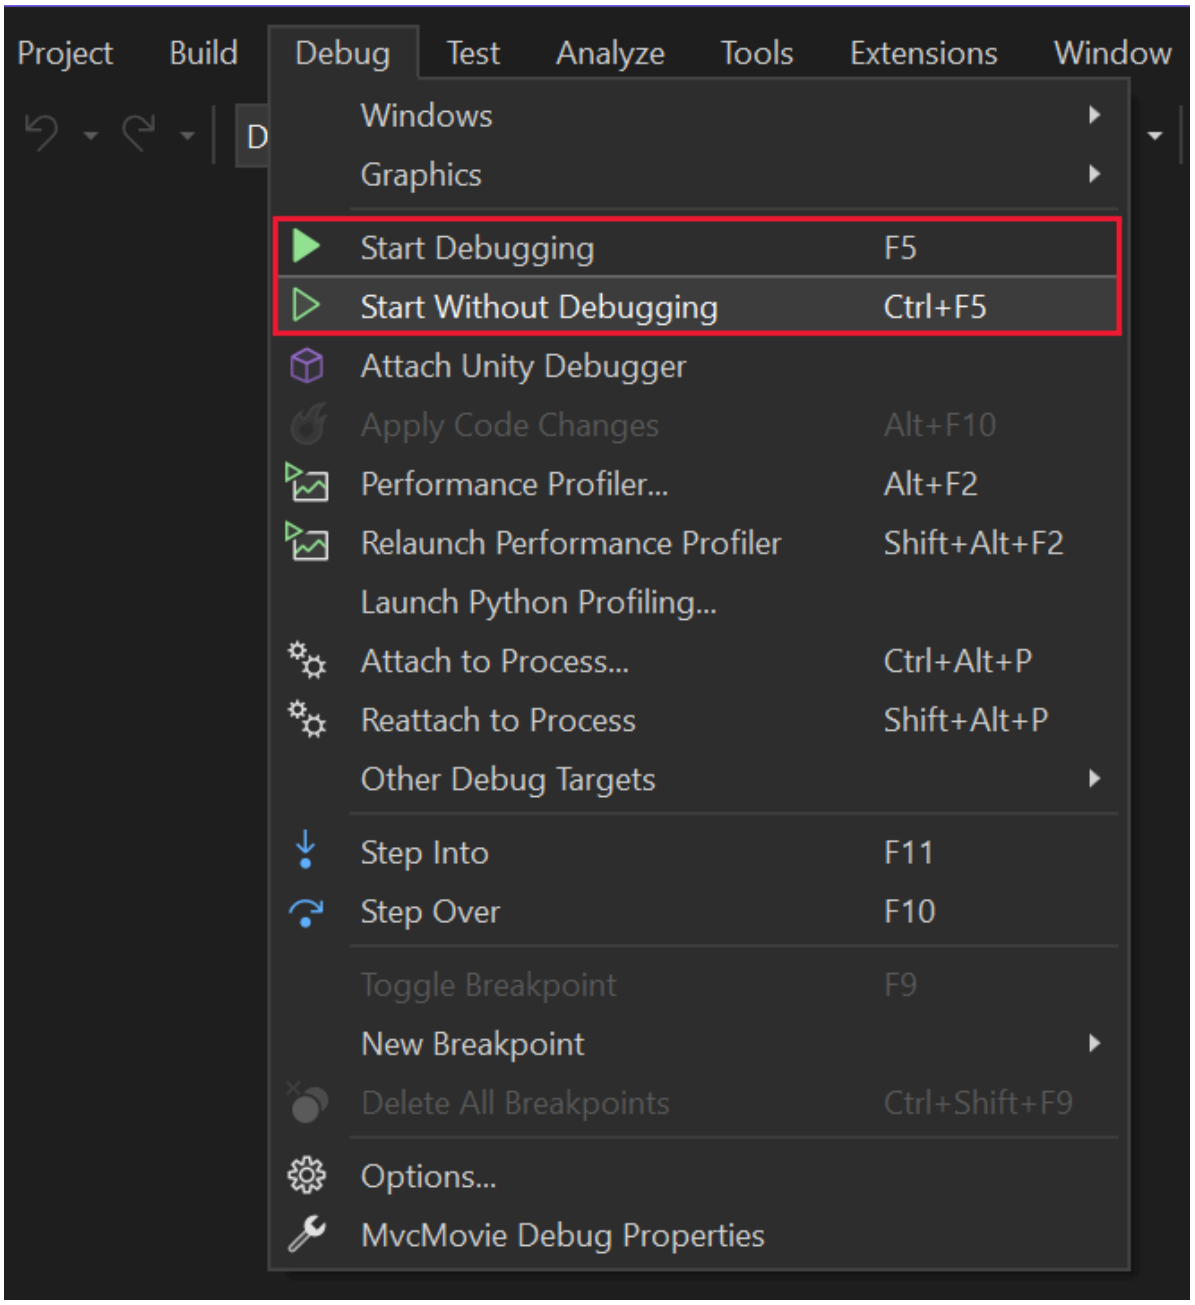
Select **Yes** if you trust the IIS Express SSL certificate.

The following dialog is displayed:

Select **Yes** if you agree to trust the development certificate.

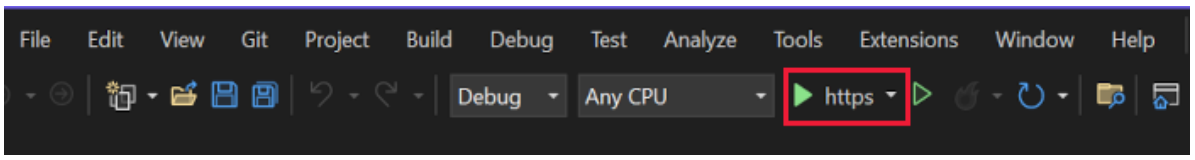
For information on trusting the Firefox browser, see Firefox SEC_ERROR_INADEQUATE_KEY_USAGE certificate error.

Visual Studio runs the app and opens the default browser.



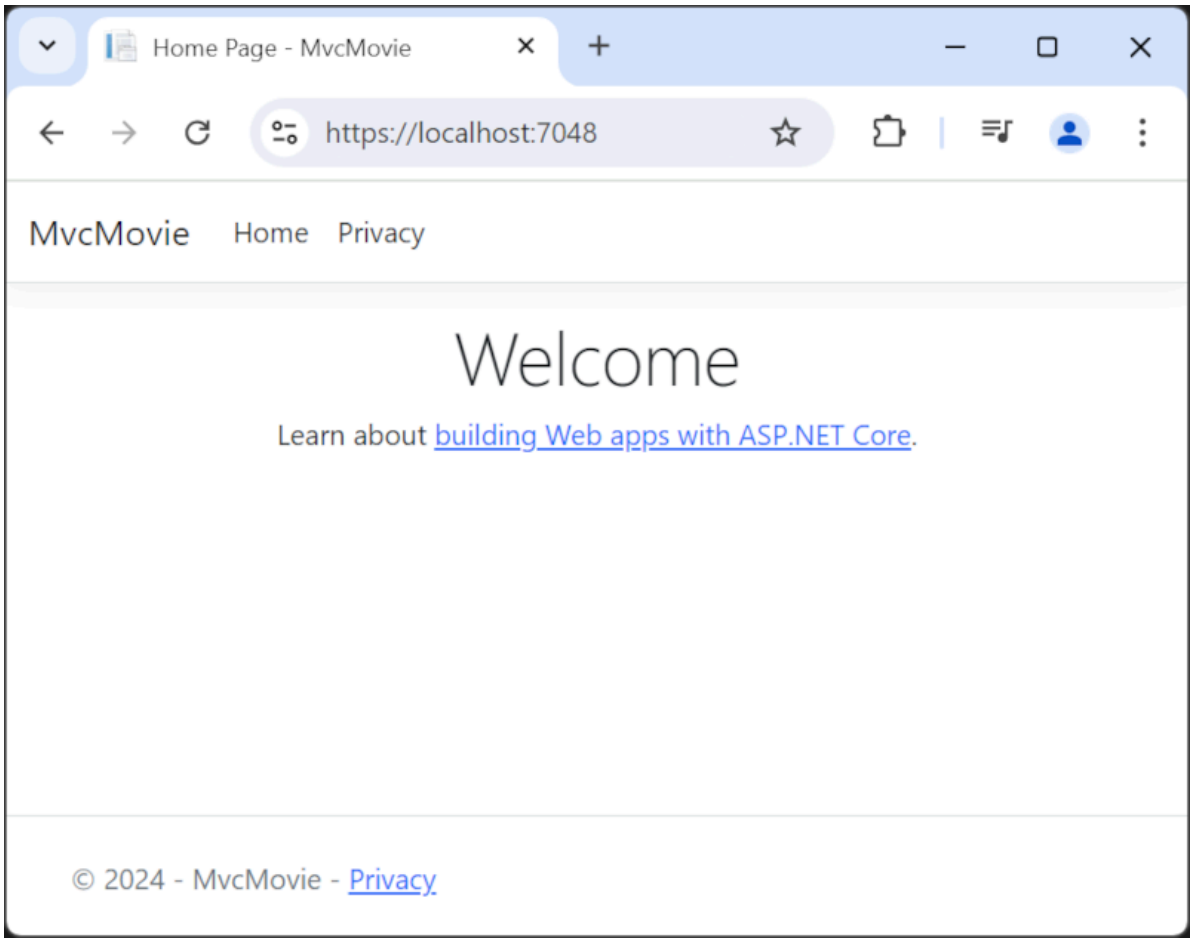
The address bar shows `localhost:<port#>` and not something like `example.com`. The standard hostname for your local computer is `localhost`. When Visual Studio creates a web project, a random port is used for the web server.

Launching the app without debugging by pressing `Ctrl`+`F5` allows you to:



- Make code changes.

- Save the file.
- Quickly refresh the browser and see the code changes.



You can launch the app in debug or non-debug mode from the **Debug** menu:

You can debug the app by selecting the **https** button in the toolbar:

The following image shows the app:

- Close the browser window. Visual Studio will stop the application.

Visual Studio

Visual Studio help

- Learn to debug C# code using Visual Studio
- Introduction to the Visual Studio IDE

In the next tutorial in this series, you learn about MVC and start writing some code.

Next: Add a controller

Part 2, add a controller to an ASP.NET Core MVC app

Article • 07/26/2024

By Rick Anderson

The Model-View-Controller (MVC) architectural pattern separates an app into three main components: **M**odel, **V**iew, and **C**ontroller. The MVC pattern helps you create apps that are more testable and easier to update than traditional monolithic apps.

MVC-based apps contain:

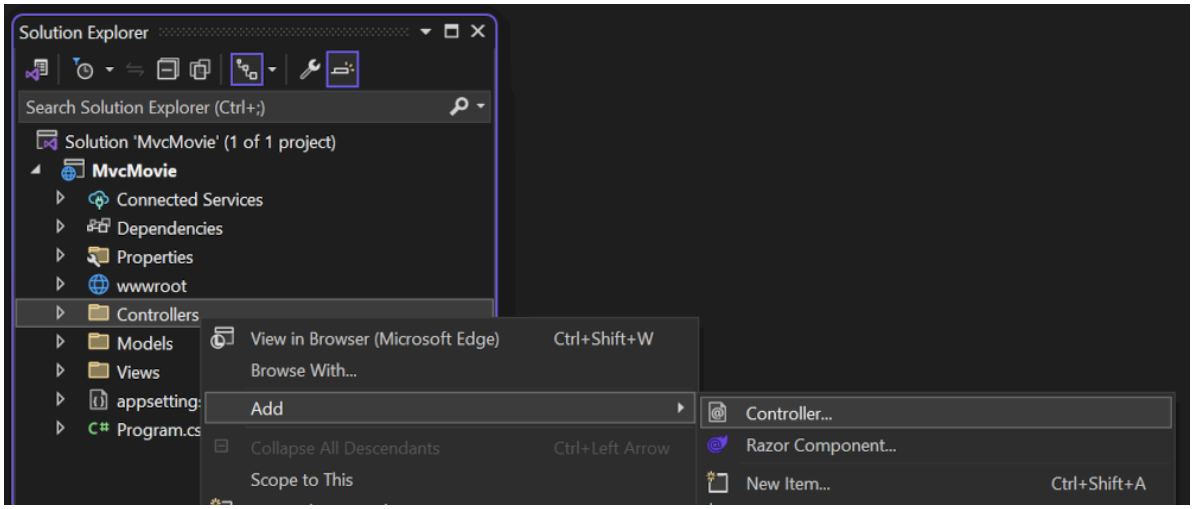
- **M**odels: Classes that represent the data of the app. The model classes use validation logic to enforce business rules for that data. Typically, model objects retrieve and store model state in a database. In this tutorial, a `Movie` model retrieves movie data from a database, provides it to the view or updates it. Updated data is written to a database.
- **V**iews: Views are the components that display the app's user interface (UI). Generally, this UI displays the model data.
- **C**ontrollers: Classes that:
  - Handle browser requests.
  - Retrieve model data.
  - Call view templates that return a response.

In an MVC app, the view only displays information. The controller handles and responds to user input and interaction. For example, the controller handles URL segments and query-string values, and passes these values to the model. The model might use these values to query the database. For example:

- `https://localhost:5001/Home/Privacy`: specifies the `Home` controller and the `Privacy` action.

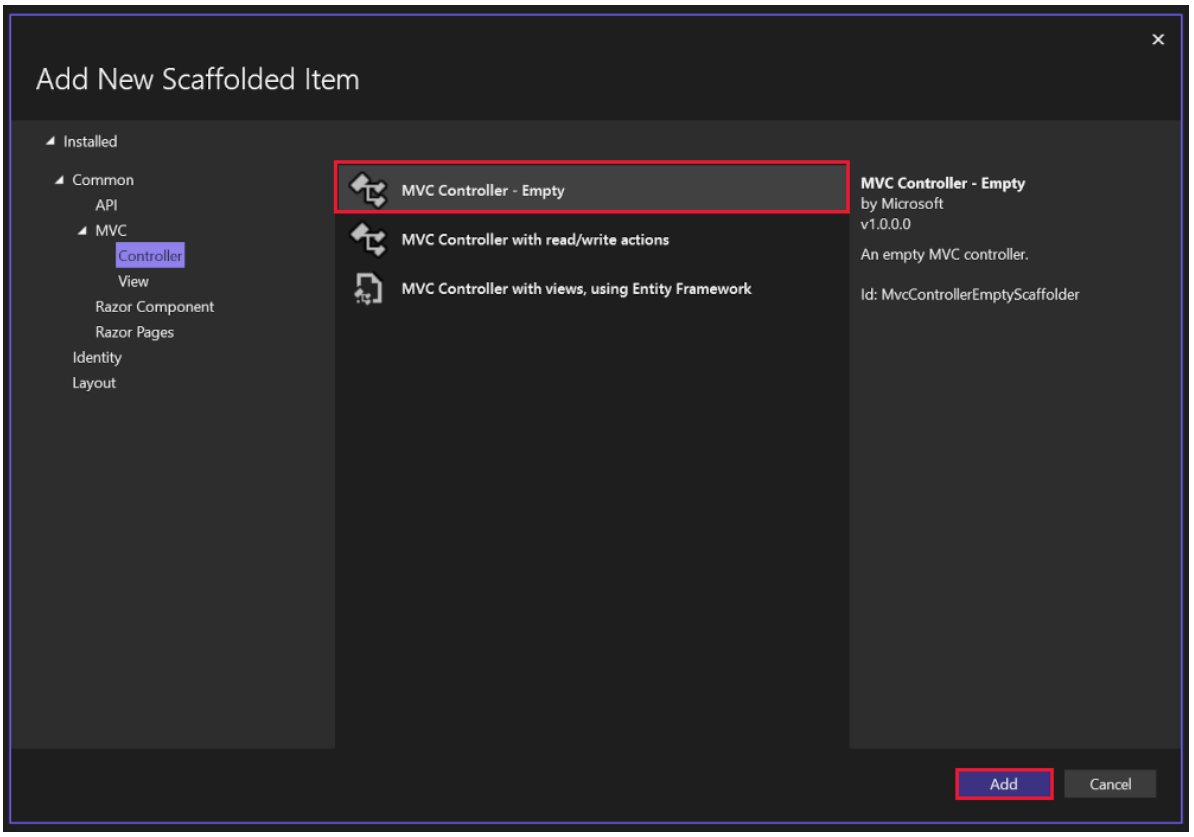
- `https://localhost:5001/Movies/Edit/5`: is a request to edit the movie with ID=5 using the `Movies` controller and the `Edit` action, which are detailed later in the tutorial.

Route data is explained later in the tutorial.



The MVC architectural pattern separates an app into three main groups of components: Models, Views, and Controllers. This pattern helps to achieve separation of concerns: The UI logic belongs in the view. Input logic belongs in the controller. Business logic belongs in the model. This separation helps manage complexity when building an app, because it enables work on one aspect of the implementation at a time without impacting the code of another. For example, you can work on the view code without depending on the business logic code.

These concepts are introduced and demonstrated in this tutorial series while building a movie app. The MVC project contains folders for the *Controllers* and *Views*.



Add a controller

Visual Studio

In **Solution Explorer**, right-click **Controllers** > **Add** > **Controller**.

In the **Add New Scaffolded Item** dialog box, select **MVC Controller - Empty** > **Add**.

In the **Add New Item - MvcMovie** dialog, enter `HelloWorldController.cs` and select **Add**.

Replace the contents of `Controllers/HelloWorldController.cs` with the following code:

C#

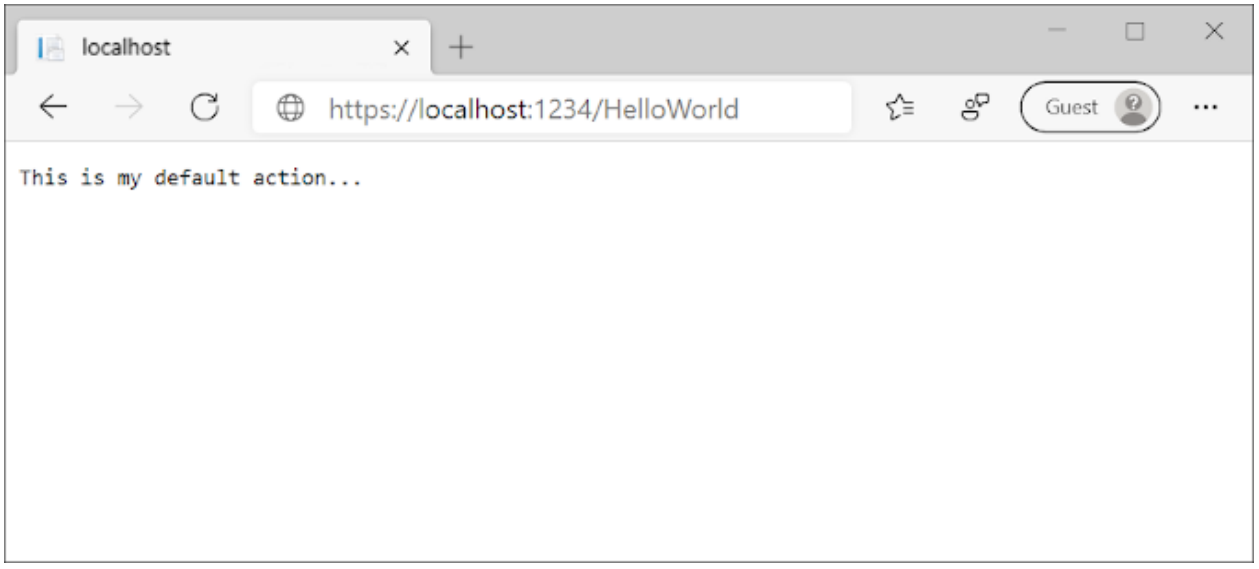
```
using Microsoft.AspNetCore.Mvc;
using System.Text.Encodings.Web;

namespace MvcMovie.Controllers;

public class HelloWorldController : Controller
{
    //
    // GET: /HelloWorld/
    public string Index()
    {
        return "This is my default action...";
    }
    //
    // GET: /HelloWorld/Welcome/
    public string Welcome()
    {
        return "This is the Welcome action method...";
    }
}
```

Every `public` method in a controller is callable as an HTTP endpoint. In the sample above, both methods return a string. Note the comments preceding each method.

An HTTP endpoint:



- Is a targetable URL in the web application, such as `https://localhost:5001/HelloWorld`.
- Combines:
  - The protocol used: `HTTPS`.
  - The network location of the web server, including the TCP port: `localhost:5001`.
  - The target URI: `HelloWorld`.

The first comment states this is an HTTP GET method that's invoked by appending `/HelloWorld/` to the base URL.

The second comment specifies an HTTP GET method that's invoked by appending `/HelloWorld/Welcome/` to the URL. Later on in the tutorial, the scaffolding engine is used to generate `HTTP POST` methods, which update data.

Run the app without the debugger by pressing `Ctrl`+`F5` (Windows) or `⌘`+`F5` (macOS).

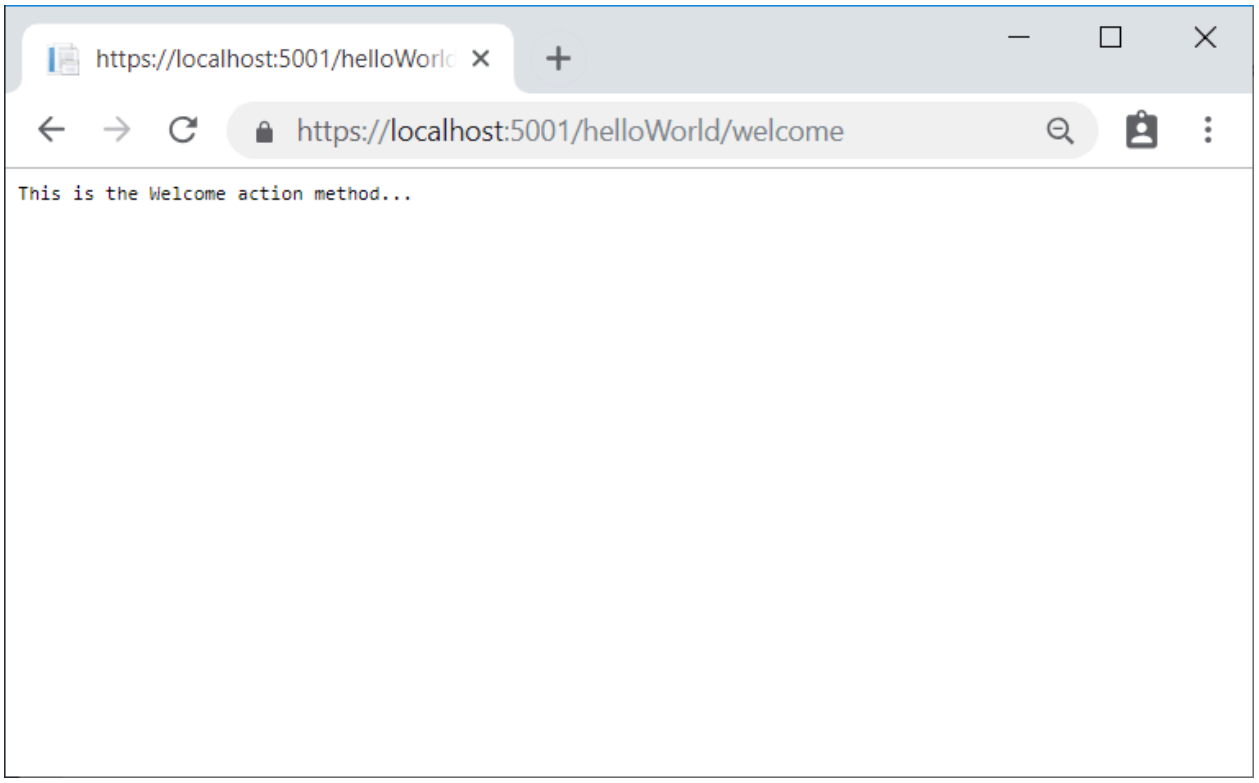
Append `/HelloWorld` to the path in the address bar. The `Index` method returns a string.

MVC invokes controller classes, and the action methods within them, depending on the incoming URL. The default URL routing logic used by MVC, uses a format like this to determine what code to invoke:

`/[Controller]/[ActionName]/[Parameters]`

The routing format is set in the `Program.cs` file.

C#



```
app.MapControllerRoute(
    name: "default",
    pattern: "{controller=Home}/{action=Index}/{id?}");
```

When you browse to the app and don't supply any URL segments, it defaults to the "Home" controller and the "Index" method specified in the template line highlighted above. In the preceding URL segments:

- The first URL segment determines the controller class to run. So `localhost:5001/HelloWorld` maps to the **HelloWorld** Controller class.
- The second part of the URL segment determines the action method on the class. So `localhost:5001/HelloWorld/Index` causes the `Index` method of the `HelloWorldController` class to run. Notice that you only had to browse to `localhost:5001/HelloWorld` and the `Index` method was called by default. `Index` is the default method that will be called on a controller if a method name isn't explicitly specified.
- The third part of the URL segment (`id`) is for route data. Route data is explained later in the tutorial.

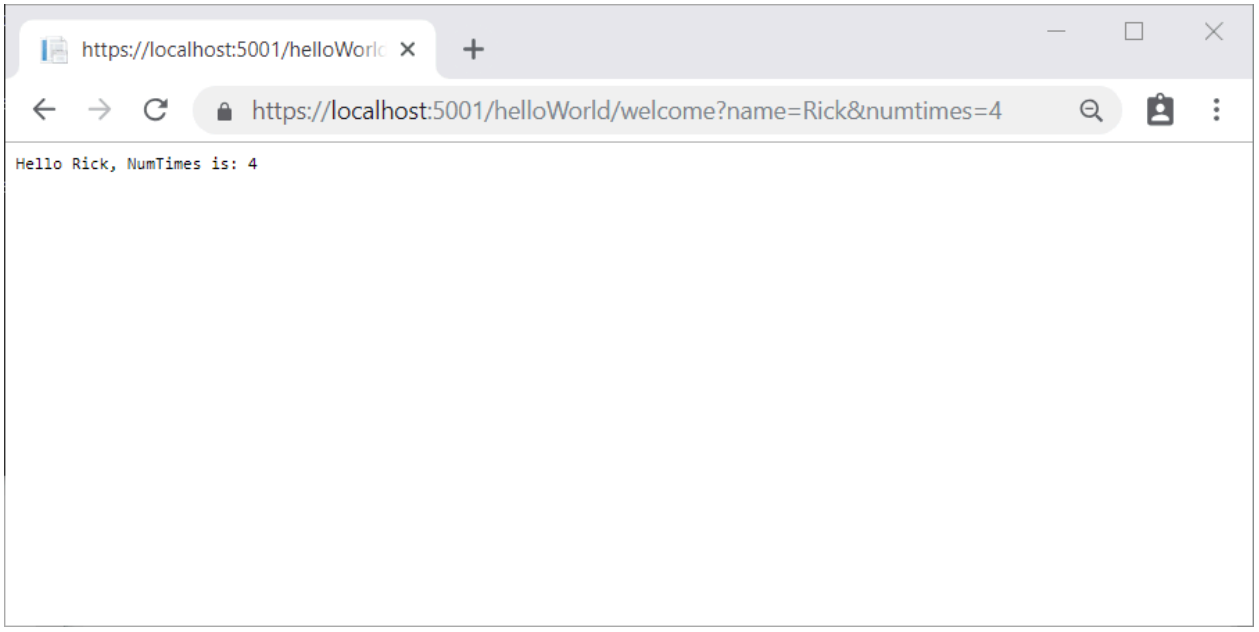
Browse to: `https://localhost:{PORT}/HelloWorld/Welcome`. Replace `{PORT}` with your port number.

The `Welcome` method runs and returns the string `This is the Welcome action method...`. For this URL, the controller is `HelloWorld` and `Welcome` is the action method. You haven't used the `[Parameters]` part of the URL yet.

Modify the code to pass some parameter information from the URL to the controller. For example, `/HelloWorld/Welcome?name=Rick&numtimes=4`.

Change the `Welcome` method to include two parameters as shown in the following code.

C#



```
// GET: /HelloWorld/Welcome/
// Requires using System.Text.Encodings.Web;
public string Welcome(string name, int numTimes = 1)
{
    return HtmlEncoder.Default.Encode($"Hello {name}, NumTimes is:
{numTimes}");
}
```

The preceding code:

- Uses the C# optional-parameter feature to indicate that the `numTimes` parameter defaults to 1 if no value is passed for that parameter.
- Uses `HtmlEncoder.Default.Encode` to protect the app from malicious input, such as through JavaScript.
- Uses Interpolated Strings in `$"Hello {name}, NumTimes is: {numTimes}"`.

Run the app and browse to: `https://localhost:{PORT}/HelloWorld/Welcome?name=Rick&numtimes=4`. Replace `{PORT}` with your port number.

Try different values for `name` and `numtimes` in the URL. The MVC model binding system automatically maps the named parameters from the query string to parameters in the method. See Model Binding for more information.

In the previous image:

- The URL segment `Parameters` isn't used.
- The `name` and `numTimes` parameters are passed in the query string.
- The `?` (question mark) in the above URL is a separator, and the query string follows.
- The `&` character separates field-value pairs.

Replace the `Welcome` method with the following code:

C#

```
public string Welcome(string name, int ID = 1)
{
    return HtmlEncoder.Default.Encode($"Hello {name}, ID: {ID}");
}
```

Run the app and enter the following URL: `https://localhost:{PORT}/HelloWorld/Welcome/3?name=Rick`

In the preceding URL:

- The third URL segment matched the route parameter `id`.
- The `Welcome` method contains a parameter `id` that matched the URL template in the `MapControllerRoute` method.
- The trailing `?` starts the query string.

C#

```
app.MapControllerRoute(
    name: "default",
    pattern: "{controller=Home}/{action=Index}/{id?}");
```

In the preceding example:

- The third URL segment matched the route parameter `id`.
- The `Welcome` method contains a parameter `id` that matched the URL template in the `MapControllerRoute` method.
- The trailing `?` (in `id?`) indicates the `id` parameter is optional.

Part 3, add a view to an ASP.NET Core MVC app

Article • 07/26/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

By Rick Anderson

In this section, you modify the `HelloWorldController` class to use Razor view files. This cleanly encapsulates the process of generating HTML responses to a client.

View templates are created using Razor. Razor-based view templates:

- Have a `.cshtml` file extension.
- Provide an elegant way to create HTML output with C#.

Currently the `Index` method returns a string with a message in the controller class. In the `HelloWorldController` class, replace the `Index` method with the following code:

C#

```
public IActionResult Index()
{
    return View();
}
```

The preceding code:

- Calls the controller's View method.
- Uses a view template to generate an HTML response.

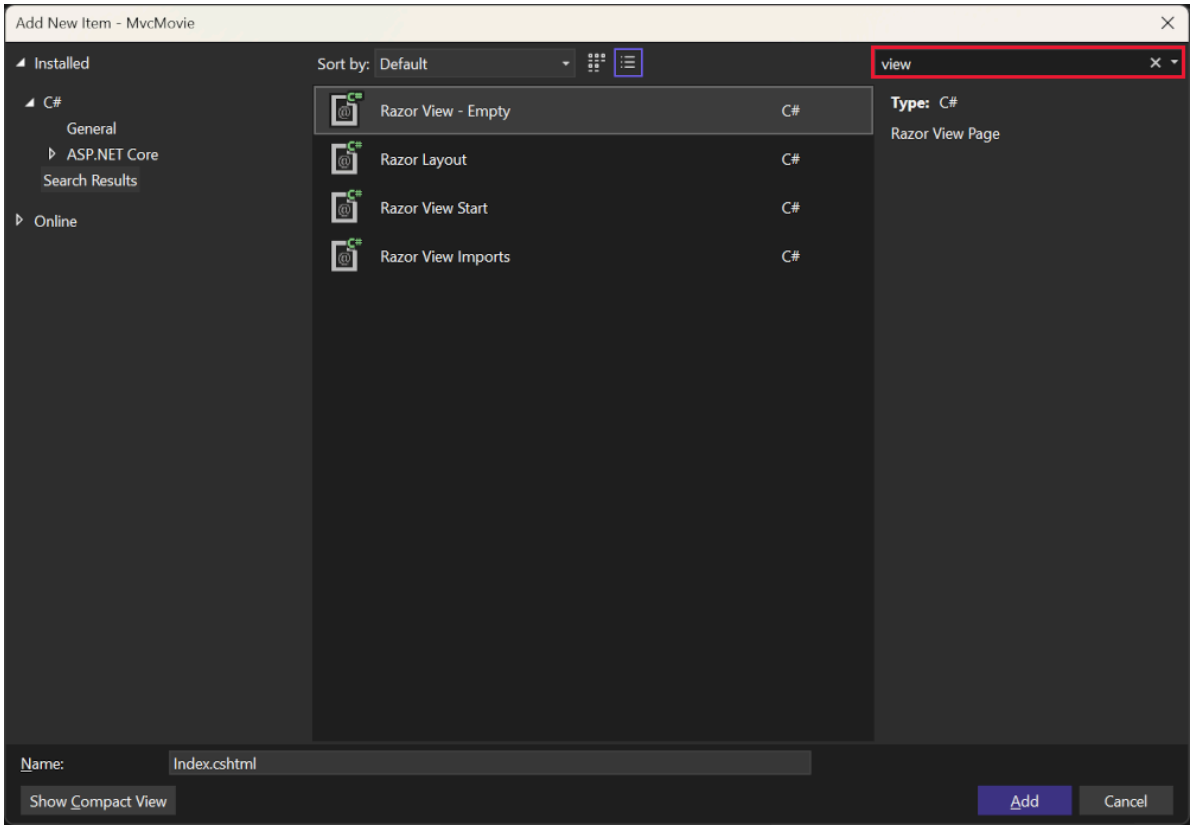
Controller methods:

- Are referred to as *action methods*. For example, the `Index` action method in the preceding code.

- Generally return an IActionResult or a class derived from ActionResult, not a type like `string`.

Add a view

Visual Studio



Right-click on the *Views* folder, and then **Add** > **New Folder** and name the folder *HelloWorld*.

Right-click on the *Views/HelloWorld* folder, and then **Add** > **New Item**.

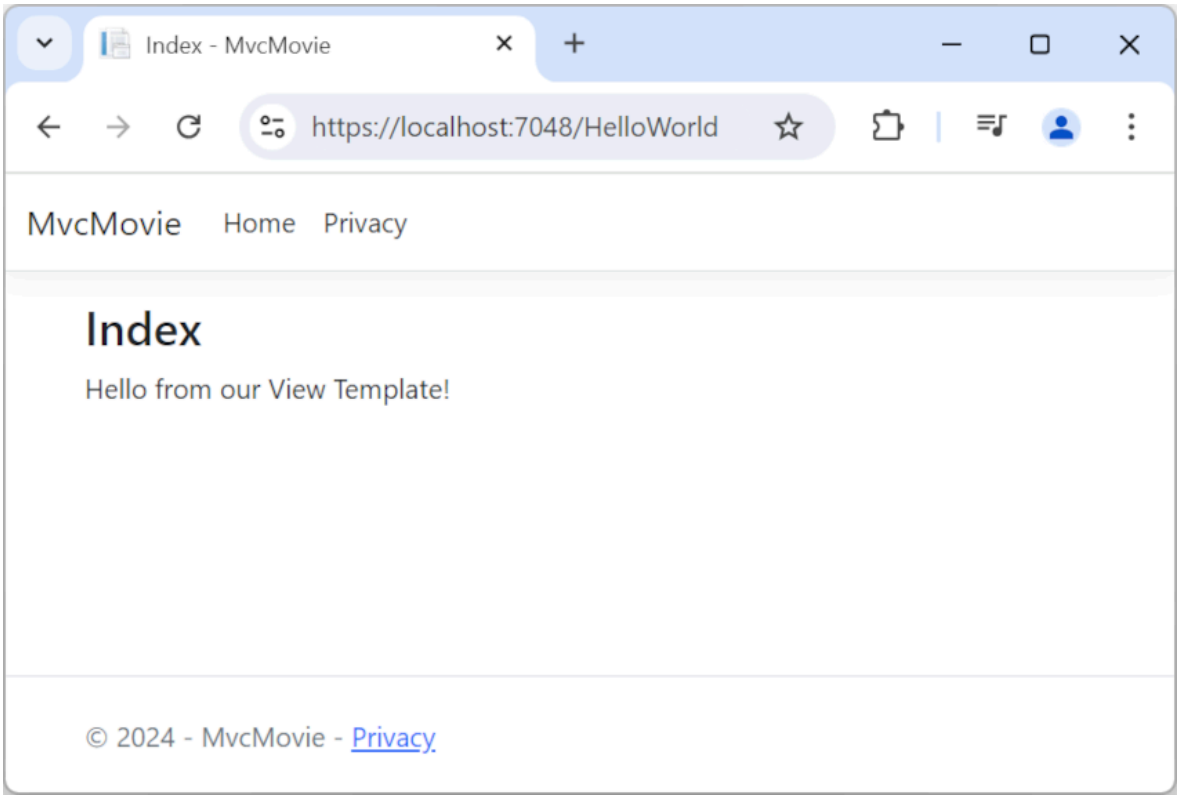
In the **Add New Item** dialog select **Show All Templates**.

In the **Add New Item - MvcMovie** dialog:

- In the search box in the upper-right, enter *view*
- Select **Razor View - Empty**
- Keep the **Name** box value, `Index.cshtml`.
- Select **Add**

Replace the contents of the `Views/HelloWorld/Index.cshtml` Razor view file with the following:

CSHTML



```
@{
    ViewData["Title"] = "Index";
}

<h2>Index</h2>

<p>Hello from our View Template!</p>
```

Navigate to `https://localhost:{PORT}/HelloWorld`:

- The `Index` method in the `HelloWorldController` ran the statement `return View();`, which specified that the method should use a view template file to render a response to the browser.
- A view template file name wasn't specified, so MVC defaulted to using the default view file. When the view file name isn't specified, the default view is returned. The default view has the same name as the action method, `Index` in this example. The view template `/Views/HelloWorld/Index.cshtml` is used.
- The following image shows the string "Hello from our View Template!" hard-coded in the view:

Change views and layout pages

Select the menu links **MvcMovie**, **Home**, and **Privacy**. Each page shows the same menu layout. The menu layout is implemented in the `Views/Shared/_Layout.cshtml` file.

Open the `Views/Shared/_Layout.cshtml` file.

Layout templates allow:

- Specifying the HTML container layout of a site in one place.
- Applying the HTML container layout across multiple pages in the site.

Find the `@RenderBody()` line. `RenderBody` is a placeholder where all the view-specific pages you create show up, *wrapped* in the layout page. For example, if you select the **Privacy** link, the `Views/Home/Privacy.cshtml` view is rendered inside the `RenderBody` method.

Change the title, footer, and menu link in the layout file

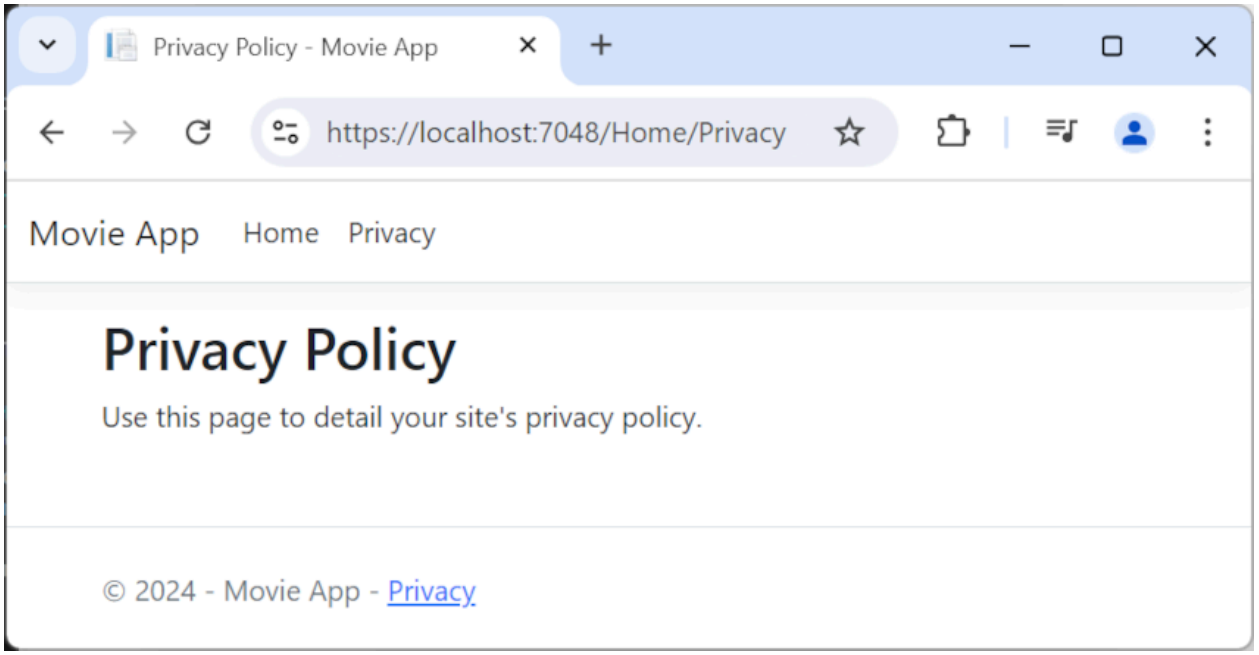
Replace the content of the `Views/Shared/_Layout.cshtml` file with the following markup. The changes are highlighted:

CSHTML

```
<!DOCTYPE html>
<html lang="en">
<head>
    <meta charset="utf-8" />
    <meta name="viewport" content="width=device-width, initial-scale=1.0" />
    <title>@ViewData["Title"] - Movie App</title>
    <link rel="stylesheet" href="~/lib/bootstrap/dist/css/bootstrap.css" />
    <link rel="stylesheet" href="~/css/site.css" asp-append-version="true"
/>
    <link rel="stylesheet" href="~/MvcMovie.styles.css" asp-append-
version="true" />
</head>
<body>
    <header>
        <nav class="navbar navbar-expand-sm navbar-toggleable-sm navbar-
light bg-white border-bottom box-shadow mb-3">
            <div class="container-fluid">
                <a class="navbar-brand" asp-area="" asp-controller="Movies"
asp-action="Index">Movie App</a>
                <button class="navbar-toggler" type="button" data-bs-
toggle="collapse" data-bs-target=".navbar-collapse" aria-
controls="navbarSupportedContent"
                        aria-expanded="false" aria-label="Toggle
navigation">
                    <span class="navbar-toggler-icon"></span>
```

```
                </button>
                <div class="navbar-collapse collapse d-sm-inline-flex
justify-content-between">
                    <ul class="navbar-nav flex-grow-1">
                        <li class="nav-item">
                            <a class="nav-link text-dark" asp-area="" asp-
controller="Home" asp-action="Index">Home</a>
                        </li>
                        <li class="nav-item">
                            <a class="nav-link text-dark" asp-area="" asp-
controller="Home" asp-action="Privacy">Privacy</a>
                        </li>
                    </ul>
                </div>
            </div>
        </nav>
    </header>
    <div class="container">
        <main role="main" class="pb-3">
            @RenderBody()
        </main>
    </div>

    <footer class="border-top footer text-muted">
        <div class="container">
            &copy; 2024 - Movie App - <a asp-area="" asp-controller="Home"
asp-action="Privacy">Privacy</a>
        </div>
    </footer>
    <script src="~/lib/jquery/dist/jquery.js"></script>
    <script src="~/lib/bootstrap/dist/js/bootstrap.js"></script>
    <script src="~/js/site.js" asp-append-version="true"></script>
    @await RenderSectionAsync("Scripts", required: false)
</body>
</html>
```



The preceding markup made the following changes:

- Three occurrences of `MvcMovie` to `Movie App`.
- The anchor element `<a class="navbar-brand" asp-area="" asp-controller="Home" asp-action="Index">MvcMovie</a>` to `<a class="navbar-brand" asp-controller="Movies" asp-action="Index">Movie App</a>`.

In the preceding markup, the `asp-area=""` anchor Tag Helper attribute and attribute value was omitted because this app isn't using Areas.

Note: The `Movies` controller hasn't been implemented. At this point, the `Movie App` link isn't functional.

Save the changes and select the **Privacy** link. Notice how the title on the browser tab displays **Privacy Policy - Movie App** instead of **Privacy Policy - MvcMovie**

Select the **Home** link.

Notice that the title and anchor text display **Movie App**. The changes were made once in the layout template and all pages on the site reflect the new link text and new title.

Examine the `Views/_ViewStart.cshtml` file:

CSHTML

```
@{
    Layout = "_Layout";
}
```

The `Views/_ViewStart.cshtml` file brings in the `Views/Shared/_Layout.cshtml` file to each view. The `Layout` property can be used to set a different layout view, or set it to `null` so no layout file will be used.

Open the `Views/HelloWorld/Index.cshtml` view file.

Change the title and `<h2>` element as highlighted in the following:

CSHTML

```
@{
    ViewData["Title"] = "Movie List";
}

<h2>My Movie List</h2>
```

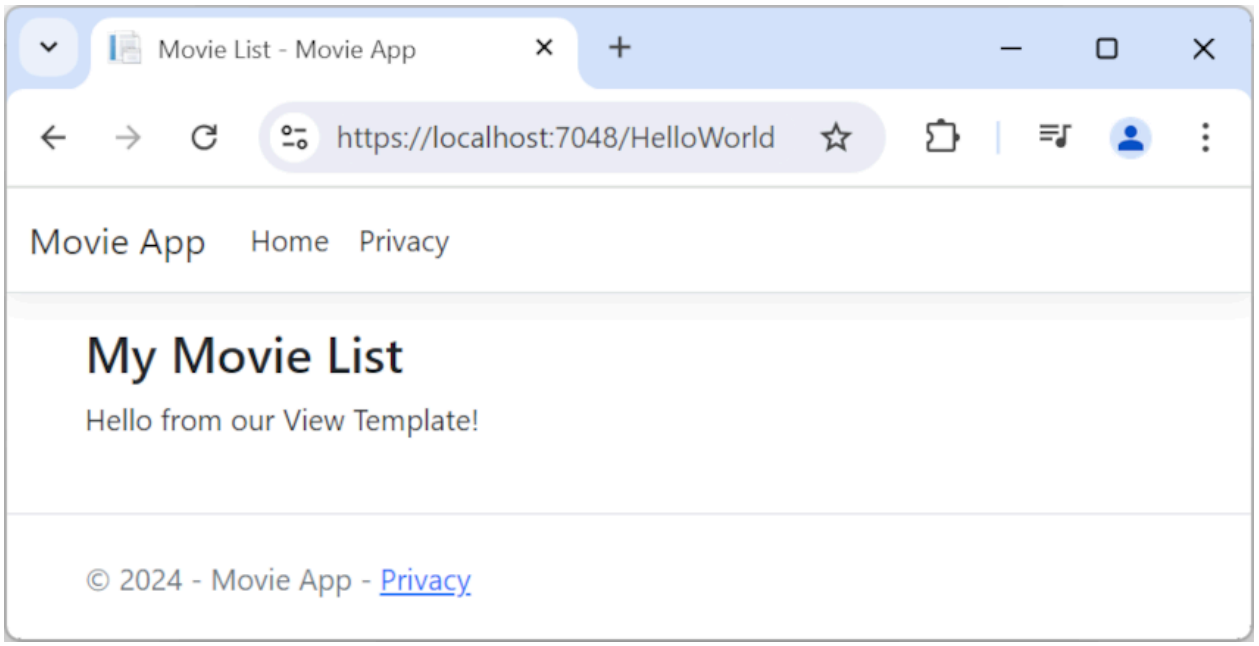
```
<p>Hello from our View Template!</p>
```

The title and `<h2>` element are slightly different so it's clear which part of the code changes the display.

`ViewData["Title"] = "Movie List";` in the code above sets the `Title` property of the `ViewData` dictionary to "Movie List". The `Title` property is used in the `<title>` HTML element in the layout page:

CSHTML

```
<title>@ViewData["Title"] - Movie App</title>
```



Save the change and navigate to `https://localhost:{PORT}/HelloWorld`.

Notice that the following have changed:

- Browser title.
- Primary heading.
- Secondary headings.

If there are no changes in the browser, it could be cached content that is being viewed. Press Ctrl+F5 in the browser to force the response from the server to be loaded. The browser title is created with `ViewData["Title"]` we set in the `Index.cshtml` view template and the additional "- Movie App" added in the layout file.

The content in the `Index.cshtml` view template is merged with the `Views/Shared/_Layout.cshtml` view template. A single HTML response is sent to the browser. Layout templates make it easy to make changes that apply across all of the pages in an app. To learn more, see Layout.

The small bit of "data", the "Hello from our View Template!" message, is hard-coded however. The MVC application has a "V" (view), a "C" (controller), but no "M" (model) yet.

Passing Data from the Controller to the View

Controller actions are invoked in response to an incoming URL request. A controller class is where the code is written that handles the incoming browser requests. The controller retrieves data from a data source and decides what type of response to send back to the browser. View templates can be used from a controller to generate and format an HTML response to the browser.

Controllers are responsible for providing the data required in order for a view template to render a response.

View templates should **not**:

- Do business logic
- Interact with a database directly.

A view template should work only with the data that's provided to it by the controller. Maintaining this "separation of concerns" helps keep the code:

- Clean.
- Testable.
- Maintainable.

Currently, the `Welcome` method in the `HelloWorldController` class takes a `name` and an `ID` parameter and then outputs the values directly to the browser.

Rather than have the controller render this response as a string, change the controller to use a view template instead. The view template generates a dynamic response, which means that appropriate data must be passed from the controller to the view to generate the response. Do this by having the controller put the dynamic data (parameters) that the view template needs in a `ViewData` dictionary. The view template can then access the dynamic data.

In `HelloWorldController.cs`, change the `Welcome` method to add a `Message` and `NumTimes` value to the `ViewData` dictionary.

The `ViewData` dictionary is a dynamic object, which means any type can be used. The `ViewData` object has no defined properties until something is added. The MVC model binding system automatically maps the named parameters `name` and `numTimes` from the query string to parameters in the method. The complete `HelloWorldController`:

C#

```
using Microsoft.AspNetCore.Mvc;
using System.Text.Encodings.Web;

namespace MvcMovie.Controllers;

public class HelloWorldController : Controller
{
    public IActionResult Index()
    {
        return View();
    }
    public IActionResult Welcome(string name, int numTimes = 1)
    {
        ViewData["Message"] = "Hello " + name;
        ViewData["NumTimes"] = numTimes;
        return View();
    }
}
```

The `ViewData` dictionary object contains data that will be passed to the view.

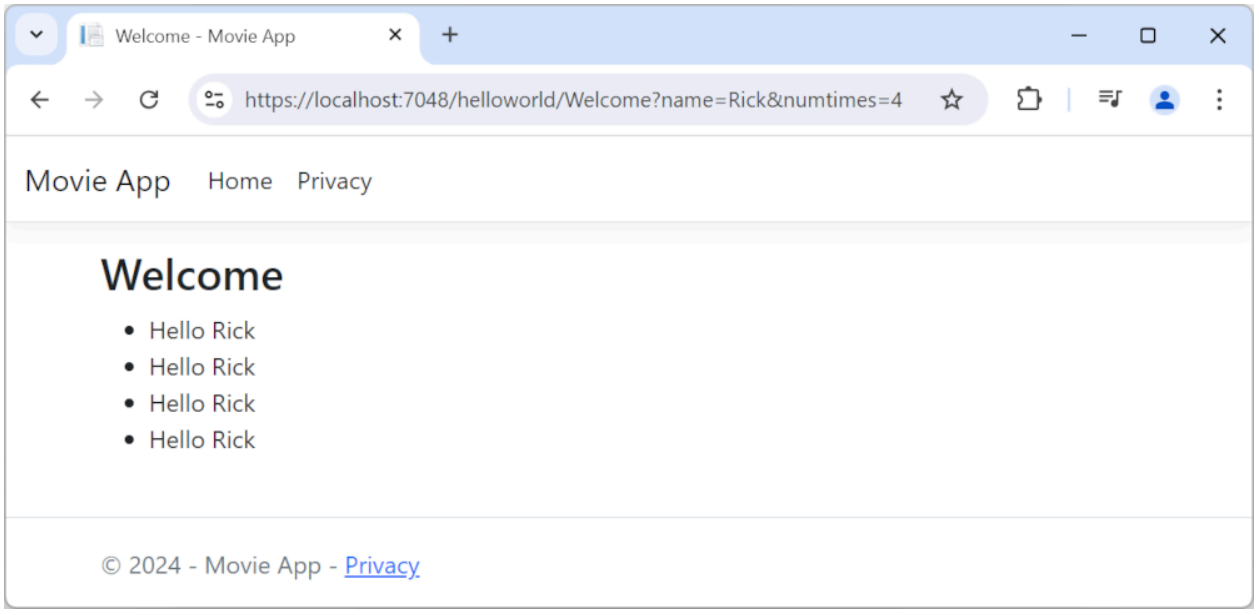
Create a Welcome view template named `Views/HelloWorld/Welcome.cshtml`.

You'll create a loop in the `Welcome.cshtml` view template that displays "Hello" `NumTimes`. Replace the contents of `Views/HelloWorld/Welcome.cshtml` with the following:

CSHTML

```
@{
    ViewData["Title"] = "Welcome";
```

```
}



<h2>Welcome</h2>

<ul>
    @for (int i = 0; i < (int)ViewData["NumTimes"]!; i++)
    {
        <li>@ViewData["Message"]</li>
    }
</ul>
```

Save your changes and browse to the following URL:

`https://localhost:{PORT}/HelloWorld/Welcome?name=Rick&numtimes=4`

Data is taken from the URL and passed to the controller using the MVC model binder. The controller packages the data into a `ViewData` dictionary and passes that object to the view. The view then renders the data as HTML to the browser.

In the preceding sample, the `ViewData` dictionary was used to pass data from the controller to a view. Later in the tutorial, a view model is used to pass data from a controller to a view. The view model approach to passing data is preferred over the `ViewData` dictionary approach.

In the next tutorial, a database of movies is created.

Part 4, add a model to an ASP.NET Core MVC app

Article • 07/26/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

By Rick Anderson and Jon P Smith.

In this tutorial, classes are added for managing movies in a database. These classes are the "**M**odel" part of the **M**VC app.

These model classes are used with Entity Framework Core (EF Core) to work with a database. EF Core is an object-relational mapping (ORM) framework that simplifies the data access code that you have to write.

The model classes created are known as ***POCO*** classes, from **P**lain **O**ld **C**LR **O**bjects. POCO classes don't have any dependency on EF Core. They only define the properties of the data to be stored in the database.

In this tutorial, model classes are created first, and EF Core creates the database.

Add a data model class

Visual Studio

Right-click the *Models* folder > **Add** > **Class**. Name the file `Movie.cs`.

Update the `Models/Movie.cs` file with the following code:

C#

```
using System.ComponentModel.DataAnnotations;

namespace MvcMovie.Models;
```

```
public class Movie
{
    public int Id { get; set; }
    public string? Title { get; set; }
    [DataType(DataType.Date)]
    public DateTime ReleaseDate { get; set; }
    public string? Genre { get; set; }
    public decimal Price { get; set; }
}
```

The `Movie` class contains an `Id` field, which is required by the database for the primary key.

The DataType attribute on `ReleaseDate` specifies the type of the data (`Date`). With this attribute:

- The user isn't required to enter time information in the date field.
- Only the date is displayed, not time information.

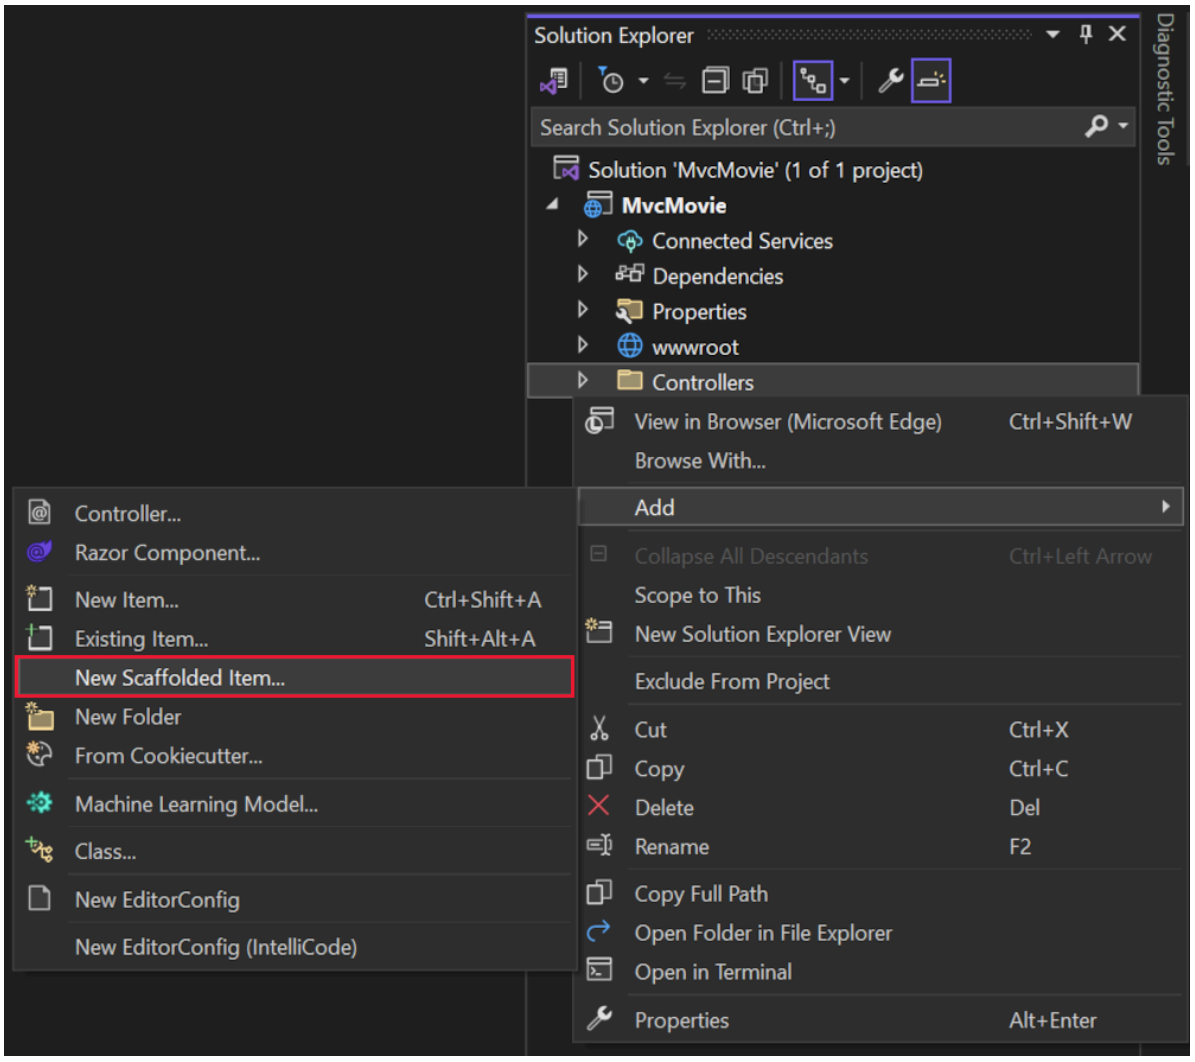
DataAnnotations are covered in a later tutorial.

The question mark after `string` indicates that the property is nullable. For more information, see Nullable reference types.

Add NuGet packages

Visual Studio

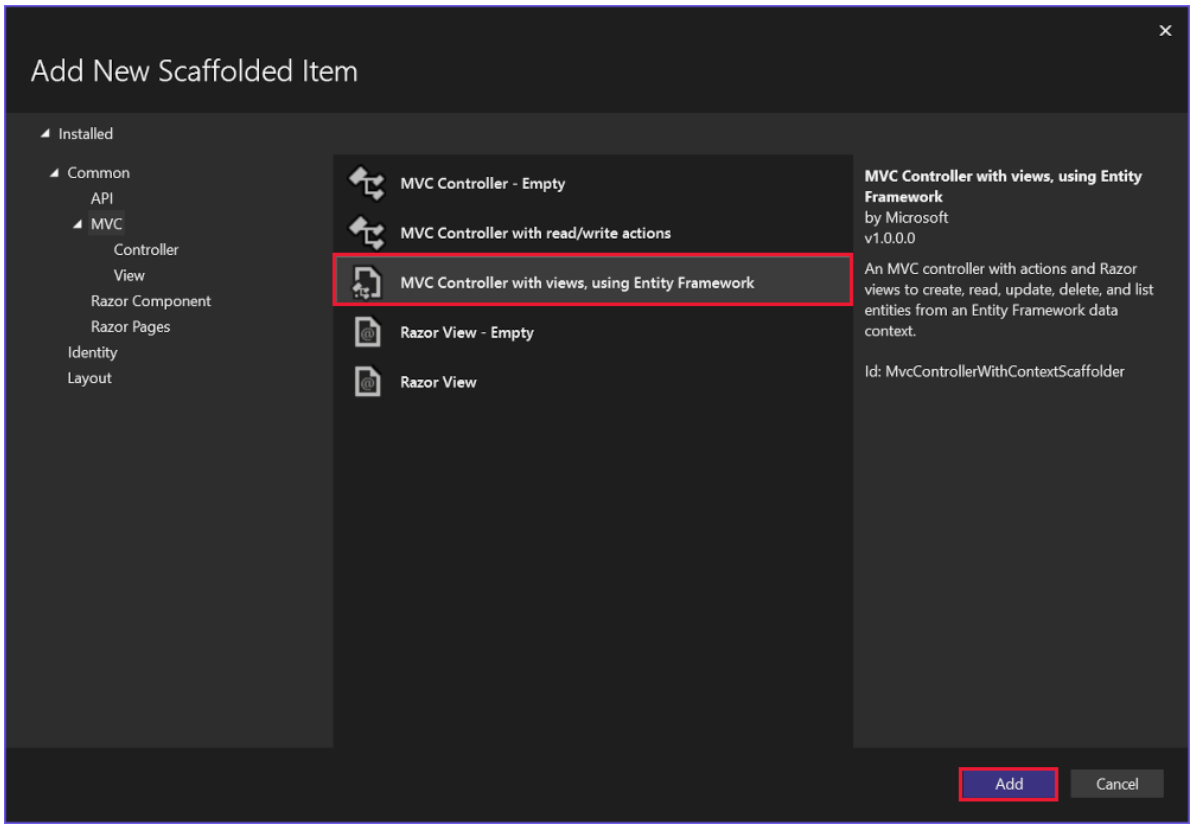
Visual Studio automatically installs the required packages.



Build the project as a check for compiler errors.

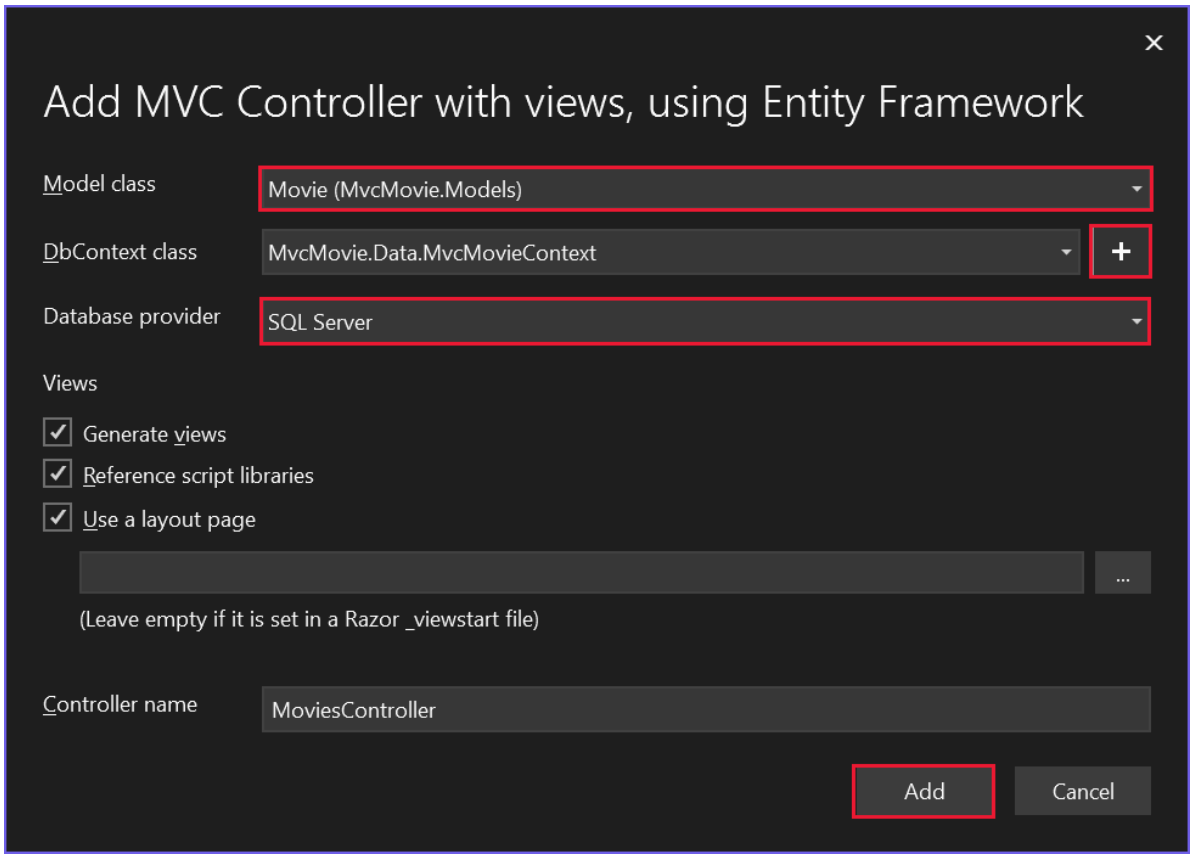
Scaffold movie pages

Use the scaffolding tool to produce `Create`, `Read`, `Update`, and `Delete` (CRUD) pages for the movie model.



Visual Studio

In **Solution Explorer**, right-click the *Controllers* folder and select **Add** > **New Scaffolded Item**.



In the **Add New Scaffolded Item** dialog:

- In the left pane, select **Installed** > **Common** > **MVC**.
- Select **MVC Controller with views, using Entity Framework**.
- Select **Add**.

Complete the **Add MVC Controller with views, using Entity Framework** dialog:

- In the **Model class** drop down, select **Movie (MvcMovie.Models)**.
- In the **Data context class** row, select the + (plus) sign.
  - In the **Add Data Context** dialog, the class name *MvcMovie.Data.MvcMovieContext* is generated.
  - Select **Add**.
- In the **Database provider** drop down, select **SQL Server**.
- **Views** and **Controller name**: Keep the default.
- Select **Add**.

If you get an error message, select **Add** a second time to try it again.

Scaffolding adds the following packages:

- `Microsoft.EntityFrameworkCore.SqlServer`
- `Microsoft.EntityFrameworkCore.Tools`
- `Microsoft.VisualStudio.Web.CodeGeneration.Design`

Scaffolding creates the following:

- A movies controller: `Controllers/MoviesController.cs`
- Razor view files for **Create**, **Delete**, **Details**, **Edit**, and **Index** pages: `Views/Movies/*.cshtml`
- A database context class: `Data/MvcMovieContext.cs`

Scaffolding updates the following:

- Inserts required package references in the `MvcMovie.csproj` project file.
- Registers the database context in the `Program.cs` file.
- Adds a database connection string to the `appsettings.json` file.

The automatic creation of these files and file updates is known as *scaffolding*.

The scaffolded pages can't be used yet because the database doesn't exist. Running the app and selecting the **Movie App** link results in a *Cannot open database* or *no*

such table: Movie error message.

Build the app to verify that there are no errors.

Initial migration

Use the EF Core Migrations feature to create the database. *Migrations* is a set of tools that create and update a database to match the data model.

Visual Studio

From the **Tools** menu, select **NuGet Package Manager** > **Package Manager Console** .

In the Package Manager Console (PMC), enter the following command:

```
PowerShell

Add-Migration InitialCreate
```

- `Add-Migration InitialCreate`: Generates a `Migrations/{timestamp}_InitialCreate.cs` migration file. The `InitialCreate` argument is the migration name. Any name can be used, but by convention, a name is selected that describes the migration. Because this is the first migration, the generated class contains code to create the database schema. The database schema is based on the model specified in the `MvcMovieContext` class.

The following warning is displayed, which is addressed in a later step:

> No store type was specified for the decimal property 'Price' on entity type 'Movie'. This will cause values to be silently truncated if they do not fit in the default precision and scale. Explicitly specify the SQL server column type that can accommodate all the values in 'OnModelCreating' using 'HasColumnType', specify precision and scale using 'HasPrecision', or configure a value converter using 'HasConversion'.

In the PMC, enter the following command:

```
PowerShell
```

```
Update-Database
```

- `Update-Database`: Updates the database to the latest migration, which the previous command created. This command runs the `Up` method in the `Migrations/{time-stamp}_InitialCreate.cs` file, which creates the database.

For more information on the PMC tools for EF Core, see EF Core tools reference - PMC in Visual Studio.

Test the app

Visual Studio

Run the app and select the **Movie App** link.

If you get an exception similar to the following, you may have missed the `Update-Database` command in the migrations step:

Console

```
SqlException: Cannot open database "MvcMovieContext-1" requested by the
login. The login failed.
```

Note

You may not be able to enter decimal commas in the `Price` field. To support jQuery validation for non-English locales that use a comma (",") for a decimal point and for non US-English date formats, the app must be globalized. For globalization instructions, see this GitHub issue.

Examine the generated database context class and registration

With EF Core, data access is performed using a model. A model is made up of entity classes and a context object that represents a session with the database. The context object allows querying and saving data. The database context is derived from

Microsoft.EntityFrameworkCore.DbContext and specifies the entities to include in the data model.

Scaffolding creates the `Data/MvcMovieContext.cs` database context class:

C#

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;
using Microsoft.EntityFrameworkCore;
using MvcMovie.Models;

namespace MvcMovie.Data
{
    public class MvcMovieContext : DbContext
    {
        public MvcMovieContext (DbContextOptions<MvcMovieContext> options)
            : base(options)
        {
        }

        public DbSet<MvcMovie.Models.Movie> Movie { get; set; } = default!;
    }
}
```

The preceding code creates a DbSet<Movie> property that represents the movies in the database.

Dependency injection

ASP.NET Core is built with dependency injection (DI). Services, such as the database context, are registered with DI in `Program.cs`. These services are provided to components that require them via constructor parameters.

In the `Controllers/MoviesController.cs` file, the constructor uses Dependency Injection to inject the `MvcMovieContext` database context into the controller. The database context is used in each of the CRUD methods in the controller.

Scaffolding generated the following highlighted code in `Program.cs`:

Visual Studio

C#

```
var builder = WebApplication.CreateBuilder(args);
builder.Services.AddDbContext<MvcMovieContext>(options =>

options.UseSqlServer(builder.Configuration.GetConnectionString("MvcMovie
Context") ?? throw new InvalidOperationException("Connection string
'MvcMovieContext' not found.")));
```

The ASP.NET Core configuration system reads the "MvcMovieContext" database connection string.

Examine the generated database connection string

Scaffolding added a connection string to the `appsettings.json` file:

Visual Studio

JSON

```
{
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "Microsoft.AspNetCore": "Warning"
    }
  },
  "AllowedHosts": "*",
  "ConnectionStrings": {
    "MvcMovieContext": "Server=
(localdb)\\mssqllocaldb;Database=MvcMovieContext-4ebefa10-de29-4dea-
b2ad-8a8dc6bcf374;Trusted_Connection=True;MultipleActiveResultSets=true"
  }
}
```

For local development, the ASP.NET Core configuration system reads the `ConnectionString` key from the `appsettings.json` file.

The `InitialCreate` class

Examine the `Migrations/{timestamp}_InitialCreate.cs` migration file:

C#

```
using System;
using Microsoft.EntityFrameworkCore.Migrations;
```

```
#nullable disable

namespace MvcMovie.Migrations
{
    /// <inheritdoc />
    public partial class InitialCreate : Migration
    {
        /// <inheritdoc />
        protected override void Up(MigrationBuilder migrationBuilder)
        {
            migrationBuilder.CreateTable(
                name: "Movie",
                columns: table => new
                {
                    Id = table.Column<int>(type: "int", nullable: false)
                        .Annotation("SqlServer:Identity", "1, 1"),
                    Title = table.Column<string>(type: "nvarchar(max)",
nullable: true),
                    ReleaseDate = table.Column<DateTime>(type: "datetime2",
nullable: false),
                    Genre = table.Column<string>(type: "nvarchar(max)",
nullable: true),
                    Price = table.Column<decimal>(type: "decimal(18,2)",
nullable: false)
                },
                constraints: table =>
                {
                    table.PrimaryKey("PK_Movie", x => x.Id);
                });
        }

        /// <inheritdoc />
        protected override void Down(MigrationBuilder migrationBuilder)
        {
            migrationBuilder.DropTable(
                name: "Movie");
        }
    }
}
```

In the preceding code:

- `InitialCreate.Up` creates the Movie table and configures `Id` as the primary key.
- `InitialCreate.Down` reverts the schema changes made by the `Up` migration.

Dependency injection in the controller

Open the `Controllers/MoviesController.cs` file and examine the constructor:

```
C#
```

```
public class MoviesController : Controller
{
    private readonly MvcMovieContext _context;

    public MoviesController(MvcMovieContext context)
    {
        _context = context;
    }
```

The constructor uses Dependency Injection to inject the database context (`MvcMovieContext`) into the controller. The database context is used in each of the CRUD methods in the controller.

Test the **Create** page. Enter and submit data.

Test the **Edit**, **Details**, and **Delete** pages.

Strongly typed models and the `@model` directive

Earlier in this tutorial, you saw how a controller can pass data or objects to a view using the `ViewData` dictionary. The `ViewData` dictionary is a dynamic object that provides a convenient late-bound way to pass information to a view.

MVC provides the ability to pass strongly typed model objects to a view. This strongly typed approach enables compile time code checking. The scaffolding mechanism passed a strongly typed model in the `MoviesController` class and views.

Examine the generated `Details` method in the `Controllers/MoviesController.cs` file:

C#

```
// GET: Movies/Details/5
public async Task<IActionResult> Details(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    var movie = await _context.Movie
        .FirstOrDefaultAsync(m => m.Id == id);
    if (movie == null)
    {
        return NotFound();
    }
```

```
    return View(movie);
}
```

The `id` parameter is generally passed as route data. For example, `https://localhost:5001/movies/details/1` sets:

- The controller to the `movies` controller, the first URL segment.
- The action to `details`, the second URL segment.
- The `id` to 1, the last URL segment.

The `id` can be passed in with a query string, as in the following example:

`https://localhost:5001/movies/details?id=1`

The `id` parameter is defined as a nullable type (`int?`) in cases when the `id` value isn't provided.

A lambda expression is passed in to the FirstOrDefaultAsync method to select movie entities that match the route data or query string value.

C#

```
var movie = await _context.Movie
    .FirstOrDefaultAsync(m => m.Id == id);
```

If a movie is found, an instance of the `Movie` model is passed to the `Details` view:

C#

```
return View(movie);
```

Examine the contents of the `Views/Movies/Details.cshtml` file:

CSHTML

```
@model MvcMovie.Models.Movie

@{
    ViewData["Title"] = "Details";
}

<h1>Details</h1>

<div>
    <h4>Movie</h4>
    <hr />
```

```
    <dl class="row">
        <dt class = "col-sm-2">
            @Html.DisplayNameFor(model => model.Title)
        </dt>
        <dd class = "col-sm-10">
            @Html.DisplayFor(model => model.Title)
        </dd>
        <dt class = "col-sm-2">
            @Html.DisplayNameFor(model => model.ReleaseDate)
        </dt>
        <dd class = "col-sm-10">
            @Html.DisplayFor(model => model.ReleaseDate)
        </dd>
        <dt class = "col-sm-2">
            @Html.DisplayNameFor(model => model.Genre)
        </dt>
        <dd class = "col-sm-10">
            @Html.DisplayFor(model => model.Genre)
        </dd>
        <dt class = "col-sm-2">
            @Html.DisplayNameFor(model => model.Price)
        </dt>
        <dd class = "col-sm-10">
            @Html.DisplayFor(model => model.Price)
        </dd>
    </dl>
</div>
<div>
    <a asp-action="Edit" asp-route-id="@Model.Id">Edit</a> |
    <a asp-action="Index">Back to List</a>
</div>
```

The `@model` statement at the top of the view file specifies the type of object that the view expects. When the movie controller was created, the following `@model` statement was included:

CSHTML

```
@model MvcMovie.Models.Movie
```

This `@model` directive allows access to the movie that the controller passed to the view. The `Model` object is strongly typed. For example, in the `Details.cshtml` view, the code passes each movie field to the `DisplayNameFor` and `DisplayFor` HTML Helpers with the strongly typed `Model` object. The `Create` and `Edit` methods and views also pass a `Movie` model object.

Examine the `Index.cshtml` view and the `Index` method in the Movies controller. Notice how the code creates a `List` object when it calls the `View` method. The code passes this

`Movies` list from the `Index` action method to the view:

C#

```
// GET: Movies
public async Task<IActionResult> Index()
{
    return View(await _context.Movie.ToListAsync());
}
```

The code returns problem details if the `Movie` property of the data context is null.

When the movies controller was created, scaffolding included the following `@model` statement at the top of the `Index.cshtml` file:

CSHTML

```
@model IEnumerable<MvcMovie.Models.Movie>
```

The `@model` directive allows access to the list of movies that the controller passed to the view by using a `Model` object that's strongly typed. For example, in the `Index.cshtml` view, the code loops through the movies with a `foreach` statement over the strongly typed `Model` object:

CSHTML

```
@model IEnumerable<MvcMovie.Models.Movie>

@{
    ViewData["Title"] = "Index";
}

<h1>Index</h1>

<p>
    <a asp-action="Create">Create New</a>
</p>
<table class="table">
    <thead>
        <tr>
            <th>
                @Html.DisplayNameFor(model => model.Title)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.ReleaseDate)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Genre)
```

```
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Price)
            </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
@foreach (var item in Model) {
        <tr>
            <td>
                @Html.DisplayFor(modelItem => item.Title)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.ReleaseDate)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Genre)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Price)
            </td>
            <td>
                <a asp-action="Edit" asp-route-id="@item.Id">Edit</a> |
                <a asp-action="Details" asp-route-id="@item.Id">Details</a>
|
                <a asp-action="Delete" asp-route-id="@item.Id">Delete</a>
            </td>
        </tr>
}
    </tbody>
</table>
```

Because the `Model` object is strongly typed as an `IEnumerable<Movie>` object, each item in the loop is typed as `Movie`. Among other benefits, the compiler validates the types used in the code.

Part 5, work with a database in an ASP.NET Core MVC app

Article • 09/10/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

By Rick Anderson and Jon P Smith.

The `MvcMovieContext` object handles the task of connecting to the database and mapping `Movie` objects to database records. The database context is registered with the Dependency Injection container in the `Program.cs` file:

Visual Studio

C#

```
var builder = WebApplication.CreateBuilder(args);
builder.Services.AddDbContext<MvcMovieContext>(options =>

options.UseSqlServer(builder.Configuration.GetConnectionString("MvcMovie
Context") ?? throw new InvalidOperationException("Connection string
'MvcMovieContext' not found.")));
```

The ASP.NET Core Configuration system reads the `ConnectionString` key. For local development, it gets the connection string from the `appsettings.json` file:

JSON

```
"ConnectionStrings": {
  "MvcMovieContext": "Server=

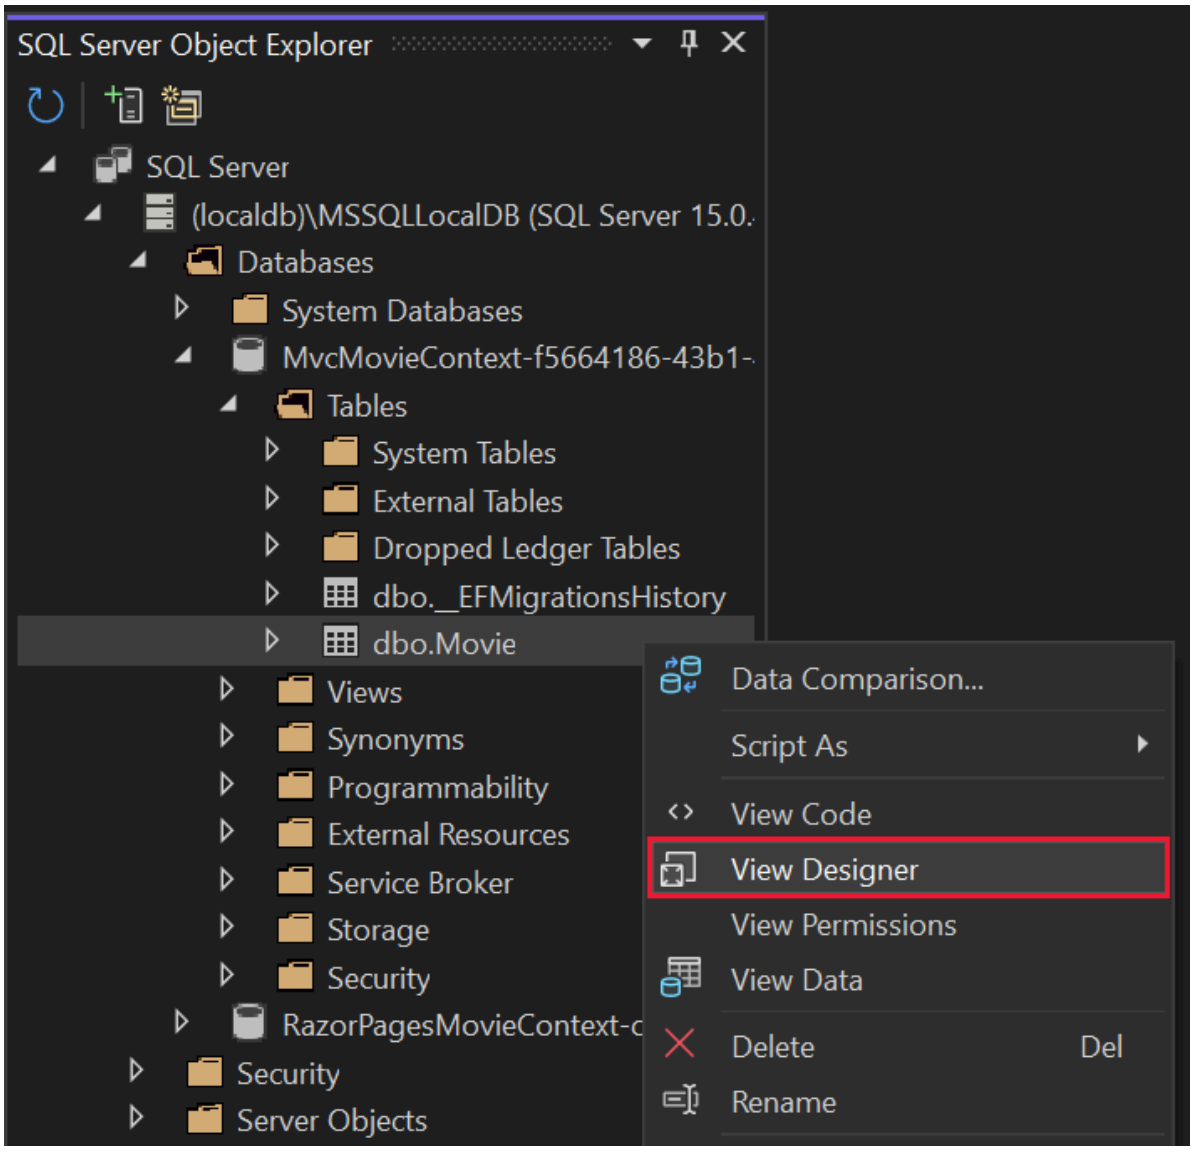
}
```

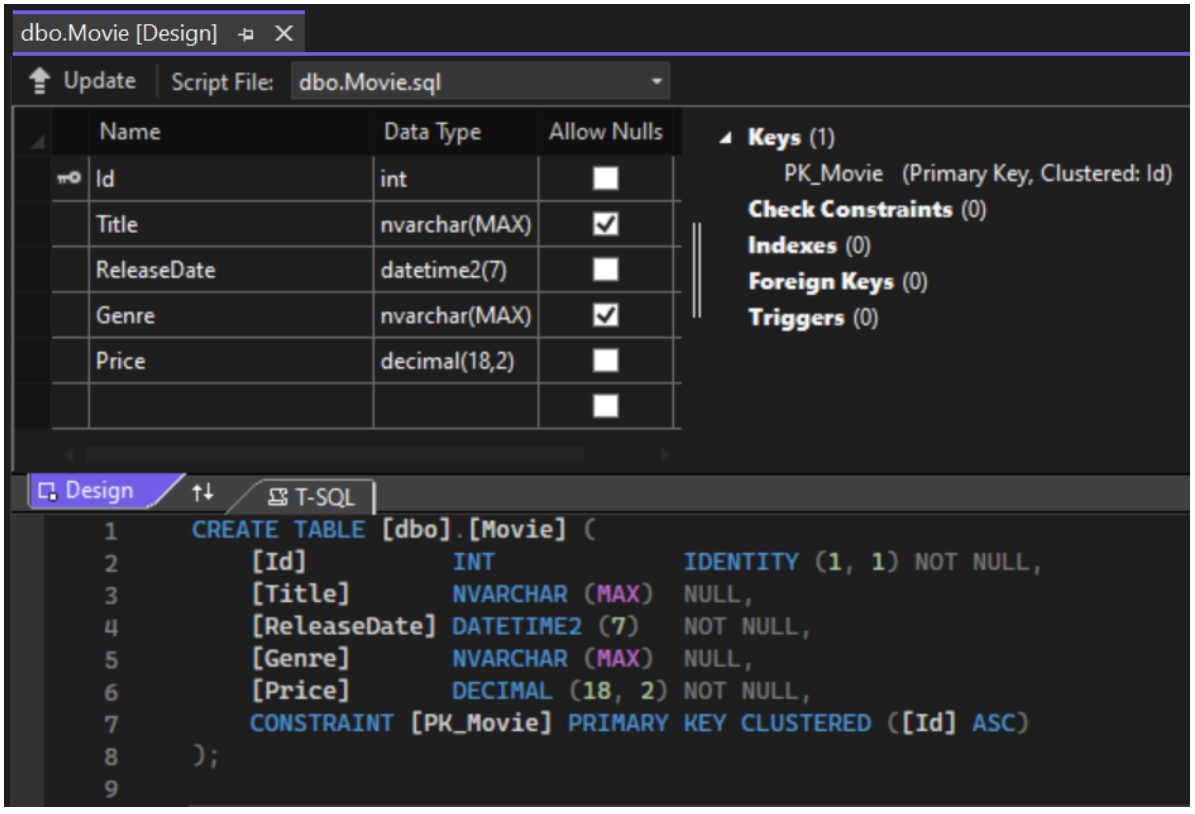
> **Note**
>
> This article uses a local database that doesn't require the user to be authenticated. Production apps should use the most secure authentication flow available. For more information on authentication for deployed test and production apps, see Secure authentication flows.

Visual Studio

SQL Server Express LocalDB



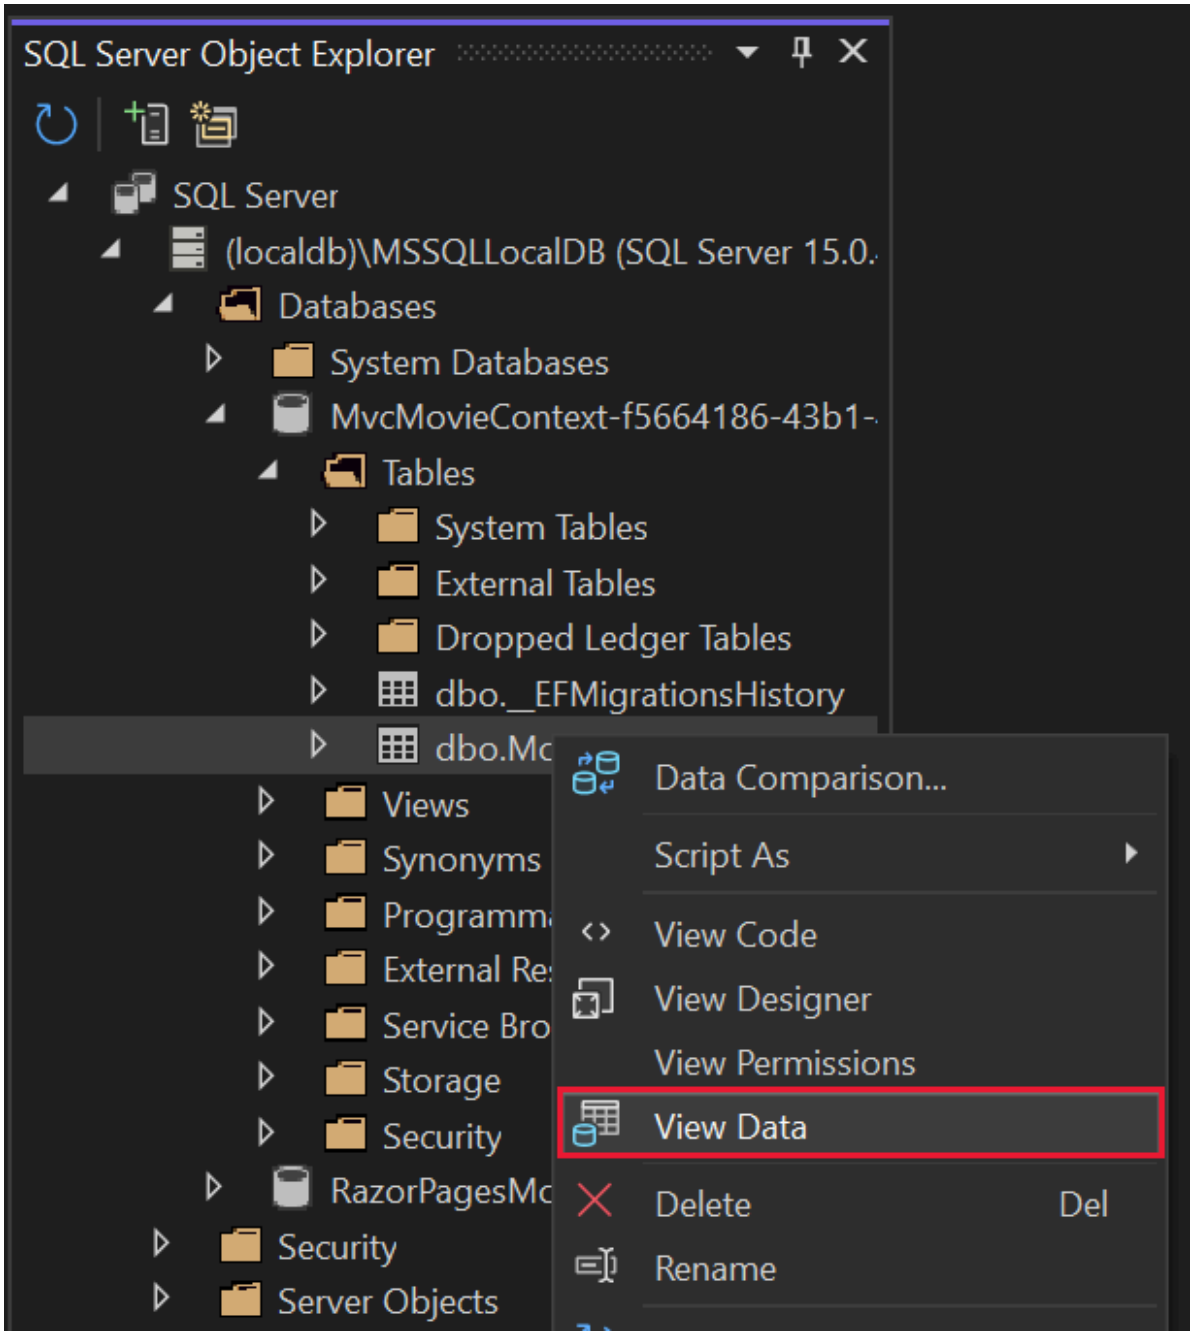
LocalDB:



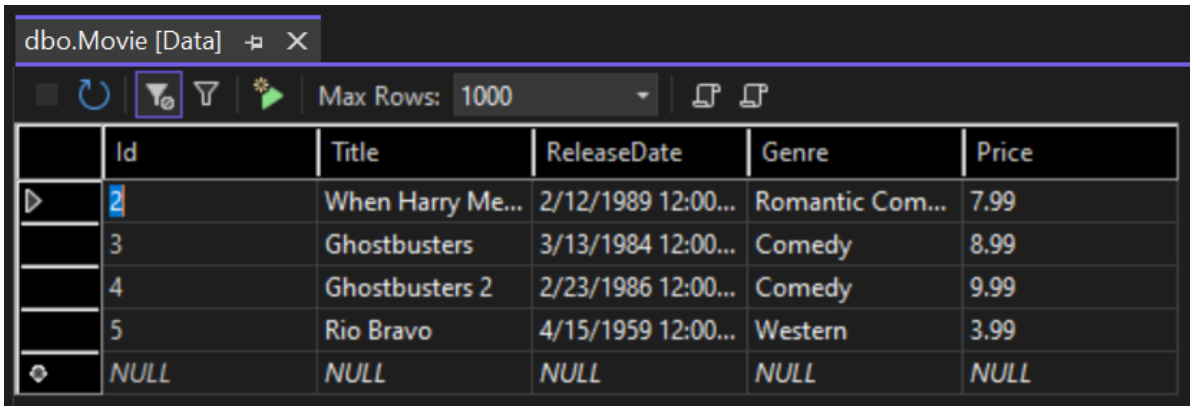
- Is a lightweight version of the SQL Server Express Database Engine, installed by default with Visual Studio.
- Starts on demand by using a connection string.
- Is targeted for program development. It runs in user mode, so there's no complex configuration.
- By default creates *.mdf* files in the *C:/Users/{user}* directory.

Examine the database

From the **View** menu, open **SQL Server Object Explorer** (SSOX).



Right-click on the `Movie` table (`dbo.Movie`) > **View Designer**



SQL Server Object Explorer
SQL Server
(localdb)\MSSQLLocalDB (SQL Server 15.0.

int
Title
nvarchar(MAX)
ReleaseDate
datetime2(7)
Genre
nvarchar(MAX)
Price
decimal(18,2)
Keys (1)
PK_Movie (Primary Key, Clustered: Id)
Check Constraints (0)
Indexes (0)
Foreign Keys (0)
Triggers (0)
Design
T-SQL
CREATE TABLE [dbo].[Movie] (
[Id] INT IDENTITY (1, 1) NOT NULL,
[Title] NVARCHAR (MAX) NULL,
[ReleaseDate] DATETIME2 (7) NOT NULL,
[Genre] NVARCHAR (MAX) NULL,
[Price] DECIMAL (18, 2) NOT NULL,
CONSTRAINT [PK_Movie] PRIMARY KEY CLUSTERED ([Id] ASC)
);

Note the key icon next to `ID`. By default, EF makes a property named `ID` the primary key.

Right-click on the `Movie` table > **View Data**

Seed the database

Create a new class named `SeedData` in the *Models* folder. Replace the generated code with the following:

C#

```
using Microsoft.EntityFrameworkCore;
using Microsoft.Extensions.DependencyInjection;
using MvcMovie.Data;
using System;
using System.Linq;

namespace MvcMovie.Models;

public static class SeedData
{
    public static void Initialize(IServiceProvider serviceProvider)
    {
        using (var context = new MvcMovieContext(
            serviceProvider.GetRequiredService<
                DbContextOptions<MvcMovieContext>>()))
        {
            // Look for any movies.
            if (context.Movie.Any())
            {
                return;   // DB has been seeded
            }
            context.Movie.AddRange(
                new Movie
                {
                    Title = "When Harry Met Sally",
                    ReleaseDate = DateTime.Parse("1989-2-12"),
                    Genre = "Romantic Comedy",
                    Price = 7.99M
                },
                new Movie
                {
                    Title = "Ghostbusters ",
```

```
                    ReleaseDate = DateTime.Parse("1984-3-13"),
                    Genre = "Comedy",
                    Price = 8.99M
                },
                new Movie
                {
                    Title = "Ghostbusters 2",
                    ReleaseDate = DateTime.Parse("1986-2-23"),
                    Genre = "Comedy",
                    Price = 9.99M
                },
                new Movie
                {
                    Title = "Rio Bravo",
                    ReleaseDate = DateTime.Parse("1959-4-15"),
                    Genre = "Western",
                    Price = 3.99M
                }
            );
            context.SaveChanges();
        }
    }
}
```

If there are any movies in the database, the seed initializer returns and no movies are added.

C#

```
if (context.Movie.Any())
{
    return;  // DB has been seeded.
}
```

Add the seed initializer

Visual Studio

Replace the contents of `Program.cs` with the following code. The new code is highlighted.

C#

```
using Microsoft.EntityFrameworkCore;
using Microsoft.Extensions.DependencyInjection;
using MvcMovie.Data;
using MvcMovie.Models;
var builder = WebApplication.CreateBuilder(args);
```

```
builder.Services.AddDbContext<MvcMovieContext>(options =>

options.UseSqlServer(builder.Configuration.GetConnectionString("MvcMovie
Context") ?? throw new InvalidOperationException("Connection string
'MvcMovieContext' not found.")));

// Add services to the container.
builder.Services.AddControllersWithViews();

var app = builder.Build();

using (var scope = app.Services.CreateScope())
{
    var services = scope.ServiceProvider;

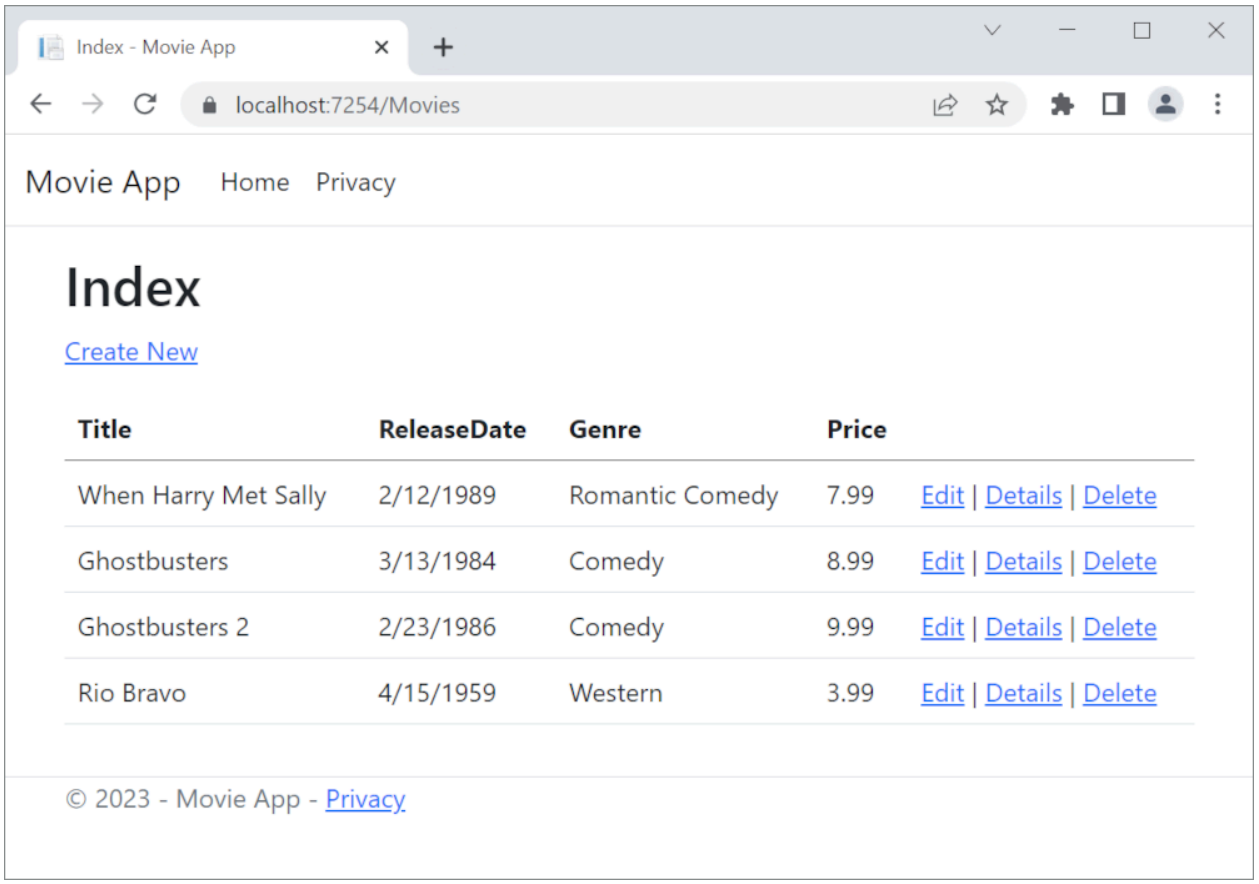
    SeedData.Initialize(services);
}
// Configure the HTTP request pipeline.
if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Home/Error");
    // The default HSTS value is 30 days. You may want to change this
for production scenarios, see https://aka.ms/aspnetcore-hsts.
    app.UseHsts();
}

app.UseHttpsRedirection();

app.UseRouting();

app.UseAuthorization();

app.MapStaticAssets();



app.MapControllerRoute(
    name: "default",
    pattern: "{controller=Home}/{action=Index}/{id?}");

app.Run();
```

Delete all the records in the database. You can do this with the delete links in the browser or from SSOX.

Test the app. Force the app to initialize, calling the code in the `Program.cs` file, so the seed method runs. To force initialization, close the command prompt window that Visual Studio opened, and restart by pressing Ctrl+F5.

The app shows the seeded data.

By Rick Anderson

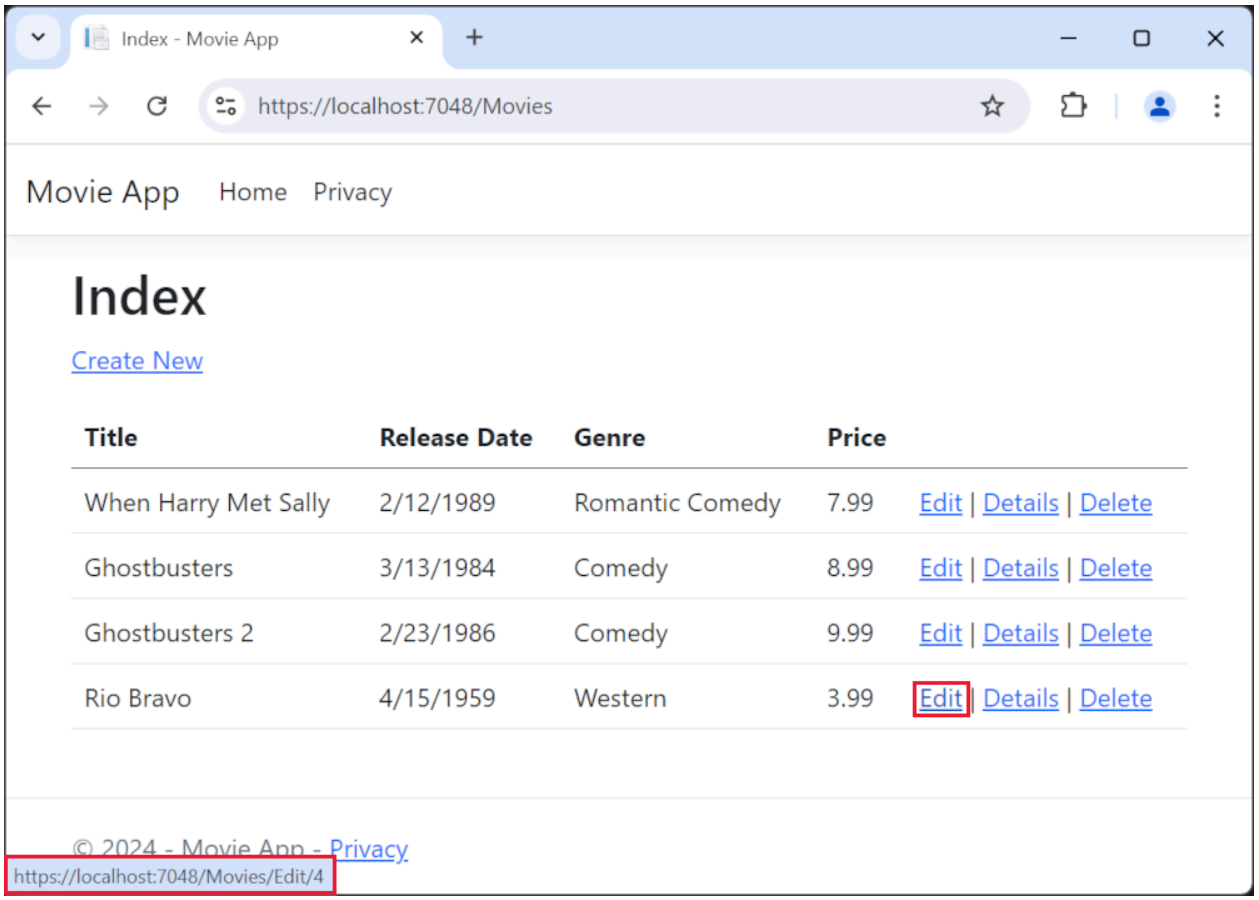
We have a good start to the movie app, but the presentation isn't ideal, for example, **ReleaseDate** should be two words.

Open the `Models/Movie.cs` file and add the highlighted lines shown below:

```
C#
```

```
using System;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace MvcMovie.Models;



public class Movie
{
    public int Id { get; set; }
    public string? Title { get; set; }

    [Display(Name = "Release Date")]
    [DataType(DataType.Date)]
    public DateTime ReleaseDate { get; set; }
    public string? Genre { get; set; }
    [Column(TypeName = "decimal(18, 2)")]
    public decimal Price { get; set; }
}
```

`DataAnnotations` are explained in the next tutorial. The Display attribute specifies what to display for the name of a field (in this case "Release Date" instead of "ReleaseDate"). The DataType attribute specifies the type of the data (Date), so the time information stored in the field isn't displayed.

The `[Column(TypeName = "decimal(18, 2)")]` data annotation is required so Entity Framework Core can correctly map `Price` to currency in the database. For more information, see Data Types.

Browse to the `Movies` controller and hold the mouse pointer over an **Edit** link to see the target URL.

The **Edit**, **Details**, and **Delete** links are generated by the Core MVC Anchor Tag Helper in the `Views/Movies/Index.cshtml` file.

CSHTML

```
            <a asp-action="Edit" asp-route-id="@item.Id">Edit</a> |
            <a asp-action="Details" asp-route-id="@item.Id">Details</a> |
            <a asp-action="Delete" asp-route-id="@item.Id">Delete</a>
        </td>
    </tr>
```

Tag Helpers enable server-side code to participate in creating and rendering HTML elements in Razor files. In the code above, the `AnchorTagHelper` dynamically generates the HTML `href` attribute value from the controller action method and route id. You use **View Source** from your favorite browser or use the developer tools to examine the generated markup. A portion of the generated HTML is shown below:

HTML

```
 <td>
    <a href="/Movies/Edit/4"> Edit </a> |
    <a href="/Movies/Details/4"> Details </a> |
    <a href="/Movies/Delete/4"> Delete </a>
</td>
```

Recall the format for routing set in the `Program.cs` file:

C#

```
app.MapControllerRoute(
    name: "default",
    pattern: "{controller=Home}/{action=Index}/{id?}");
```

ASP.NET Core translates `https://localhost:5001/Movies/Edit/4` into a request to the `Edit` action method of the `Movies` controller with the parameter `Id` of 4. (Controller methods are also known as action methods.)

Tag Helpers are one of the most popular new features in ASP.NET Core. For more information, see Additional resources.

Open the `Movies` controller and examine the two `Edit` action methods. The following code shows the `HTTP GET Edit` method, which fetches the movie and populates the edit form generated by the `Edit.cshtml` Razor file.

C#

```
// GET: Movies/Edit/5
public async Task<IActionResult> Edit(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    var movie = await _context.Movie.FindAsync(id);
    if (movie == null)
    {
        return NotFound();
    }
    return View(movie);
}
```

The following code shows the `HTTP POST Edit` method, which processes the posted movie values:

C#

```
// POST: Movies/Edit/5
// To protect from overposting attacks, enable the specific properties you
want to bind to.
// For more details, see http://go.microsoft.com/fwlink/?LinkId=317598.
[HttpPost]
[ValidateAntiForgeryToken]
```

```
public async Task<IActionResult> Edit(int id,
[Bind("Id,Title,ReleaseDate,Genre,Price,Rating")] Movie movie)
{
    if (id != movie.Id)
    {
        return NotFound();
    }

    if (ModelState.IsValid)
    {
        try
        {
            _context.Update(movie);
            await _context.SaveChangesAsync();
        }
        catch (DbUpdateConcurrencyException)
        {
            if (!MovieExists(movie.Id))
            {
                return NotFound();
            }
            else
            {
                throw;
            }
        }
        return RedirectToAction(nameof(Index));
    }
    return View(movie);
}
```

The `[Bind]` attribute is one way to protect against over-posting. You should only include properties in the `[Bind]` attribute that you want to change. For more information, see Protect your controller from over-posting. ViewModels provide an alternative approach to prevent over-posting.

Notice the second `Edit` action method is preceded by the `[HttpPost]` attribute.

C#

```
// POST: Movies/Edit/5
// To protect from overposting attacks, enable the specific properties you
want to bind to.
// For more details, see http://go.microsoft.com/fwlink/?LinkId=317598.
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<IActionResult> Edit(int id,
[Bind("Id,Title,ReleaseDate,Genre,Price,Rating")] Movie movie)
{
    if (id != movie.Id)
    {
        return NotFound();
```

```
    }

    if (ModelState.IsValid)
    {
        try
        {
            _context.Update(movie);
            await _context.SaveChangesAsync();
        }
        catch (DbUpdateConcurrencyException)
        {
            if (!MovieExists(movie.Id))
            {
                return NotFound();
            }
            else
            {
                throw;
            }
        }
        return RedirectToAction(nameof(Index));
    }
    return View(movie);
}
```

The `HttpPost` attribute specifies that this `Edit` method can be invoked *only* for `POST` requests. You could apply the `[HttpGet]` attribute to the first edit method, but that's not necessary because `[HttpGet]` is the default.

The `ValidateAntiForgeryToken` attribute is used to prevent forgery of a request and is paired up with an antiforgery token generated in the edit view file (`Views/Movies/Edit.cshtml`). The edit view file generates the antiforgery token with the Form Tag Helper.

CSHTML

```
<form asp-action="Edit">
```

The Form Tag Helper generates a hidden antiforgery token that must match the `[ValidateAntiForgeryToken]` generated antiforgery token in the `Edit` method of the Movies controller. For more information, see Prevent Cross-Site Request Forgery (XSRF/CSRF) attacks in ASP.NET Core.

The `HttpGet Edit` method takes the movie `ID` parameter, looks up the movie using the Entity Framework `FindAsync` method, and returns the selected movie to the Edit view. If a movie cannot be found, `NotFound` (HTTP 404) is returned.

C#

```
// GET: Movies/Edit/5
public async Task<IActionResult> Edit(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    var movie = await _context.Movie.FindAsync(id);
    if (movie == null)
    {
        return NotFound();
    }
    return View(movie);
}
```

When the scaffolding system created the Edit view, it examined the `Movie` class and created code to render `<label>` and `<input>` elements for each property of the class. The following example shows the Edit view that was generated by the Visual Studio scaffolding system:

CSHTML

```
@model MvcMovie.Models.Movie

@{
    ViewData["Title"] = "Edit";
}

<h1>Edit</h1>

<h4>Movie</h4>
<hr />
<div class="row">
    <div class="col-md-4">
        <form asp-action="Edit">
            <div asp-validation-summary="ModelOnly" class="text-danger">
</div>
            <input type="hidden" asp-for="Id" />
            <div class="form-group">
                <label asp-for="Title" class="control-label"></label>
                <input asp-for="Title" class="form-control" />
                <span asp-validation-for="Title" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="ReleaseDate" class="control-label"></label>
                <input asp-for="ReleaseDate" class="form-control" />
                <span asp-validation-for="ReleaseDate" class="text-danger">
</span>
            </div>
```

```
            <div class="form-group">
                <label asp-for="Genre" class="control-label"></label>
                <input asp-for="Genre" class="form-control" />
                <span asp-validation-for="Genre" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Price" class="control-label"></label>
                <input asp-for="Price" class="form-control" />
                <span asp-validation-for="Price" class="text-danger"></span>
            </div>
            <div class="form-group">
                <input type="submit" value="Save" class="btn btn-primary" />
            </div>
        </form>
    </div>
</div>

<div>
    <a asp-action="Index">Back to List</a>
</div>

@section Scripts {
    @{await Html.RenderPartialAsync("_ValidationScriptsPartial");}
}
```

Notice how the view template has a `@model MvcMovie.Models.Movie` statement at the top of the file. `@model MvcMovie.Models.Movie` specifies that the view expects the model for the view template to be of type `Movie`.

The scaffolded code uses several Tag Helper methods to streamline the HTML markup. The Label Tag Helper displays the name of the field ("Title", "ReleaseDate", "Genre", or "Price"). The Input Tag Helper renders an HTML `<input>` element. The Validation Tag Helper displays any validation messages associated with that property.

Run the application and navigate to the `/Movies` URL. Click an **Edit** link. In the browser, view the source for the page. The generated HTML for the `<form>` element is shown below.

HTML

```
<form action="/Movies/Edit/7" method="post">
    <div class="form-horizontal">
        <h4>Movie</h4>
        <hr />
        <div class="text-danger" />
        <input type="hidden" data-val="true" data-val-required="The ID field
is required." id="ID" name="ID" value="7" />
        <div class="form-group">
            <label class="control-label col-md-2" for="Genre" />
            <div class="col-md-10">
```

```
                <input class="form-control" type="text" id="Genre"
name="Genre" value="Western" />
                <span class="text-danger field-validation-valid" data-
valmsg-for="Genre" data-valmsg-replace="true"></span>
            </div>
        </div>
        <div class="form-group">
            <label class="control-label col-md-2" for="Price" />
            <div class="col-md-10">
                <input class="form-control" type="text" data-val="true"
data-val-number="The field Price must be a number." data-val-required="The
Price field is required." id="Price" name="Price" value="3.99" />
                <span class="text-danger field-validation-valid" data-
valmsg-for="Price" data-valmsg-replace="true"></span>
            </div>
        </div>
        <!-- Markup removed for brevity -->
        <div class="form-group">
            <div class="col-md-offset-2 col-md-10">
                <input type="submit" value="Save" class="btn btn-default" />
            </div>
        </div>
    </div>
    <input name="__RequestVerificationToken" type="hidden"
value="CfDJ8Inyxgp63fRFqUePGvuI5jGZsloJu1L7X9le1gy7NCIlSduCRx9jDQClrV9pOTTmq
UyXnJBXhmrjcUVDJyDUMm7-
MF_9rK8aAZdRdlOri7FmKVkRe_2v5LIHGKFcTjPrWPYnc9AdSbomkiOSaTEg7RU" />
</form>
```

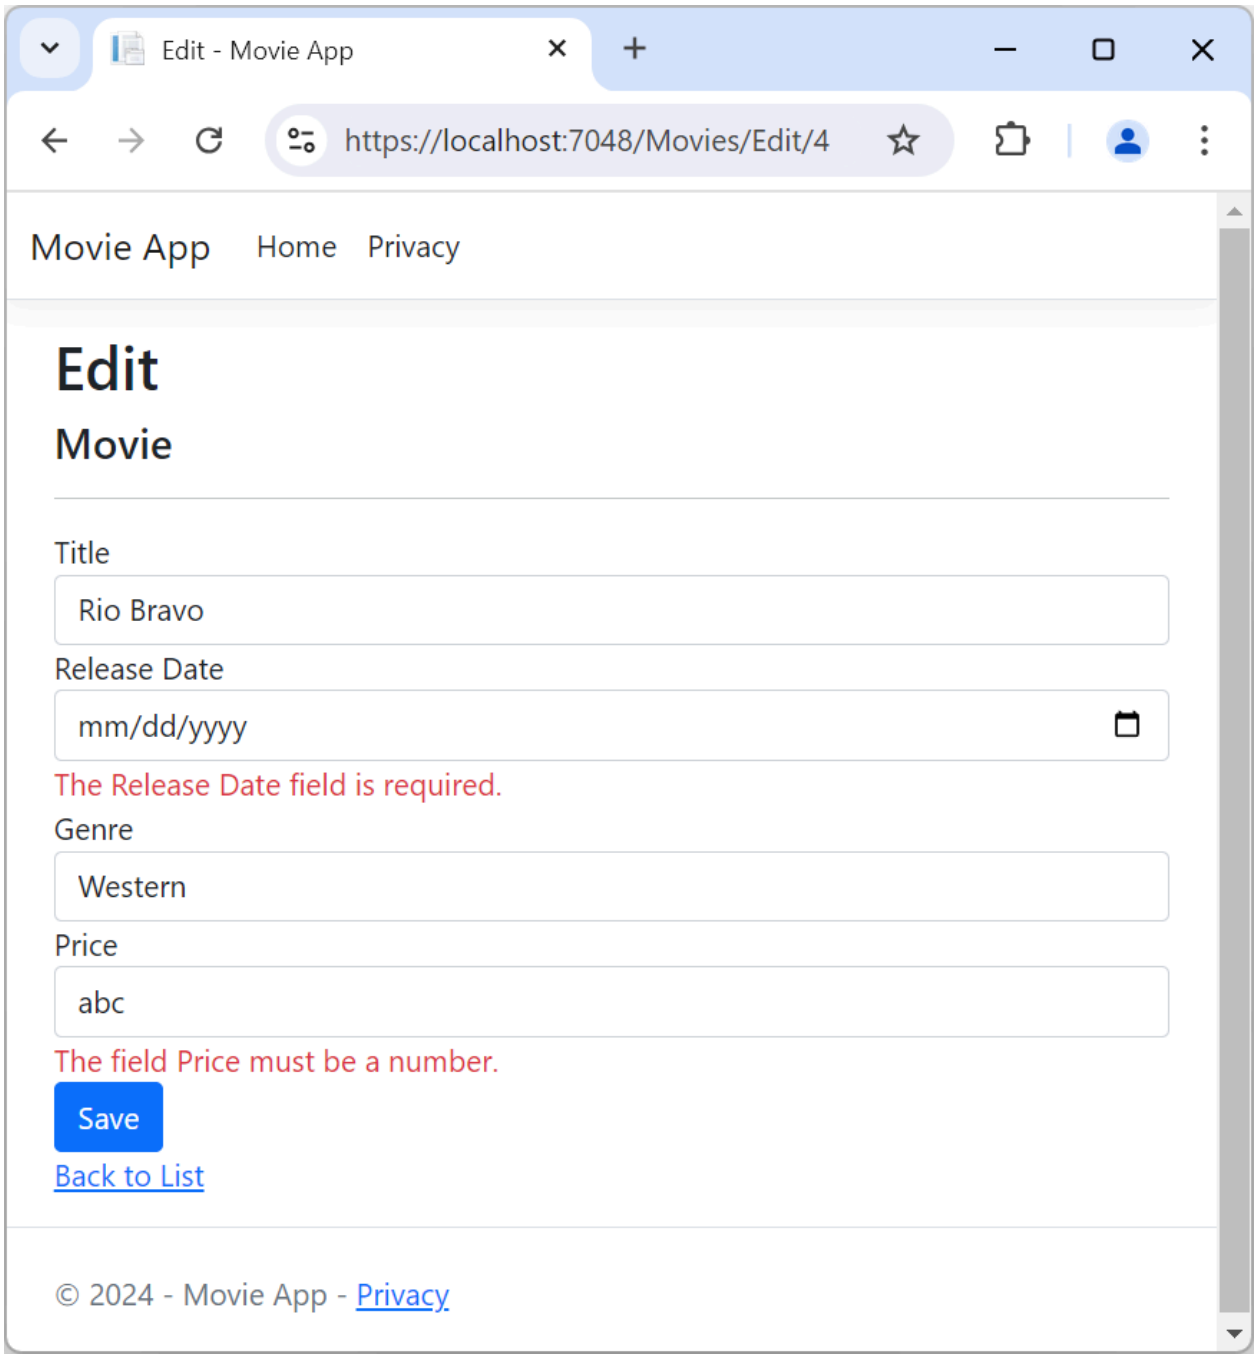
The `<input>` elements are in an `HTML <form>` element whose `action` attribute is set to post to the `/Movies/Edit/id` URL. The form data will be posted to the server when the `Save` button is clicked. The last line before the closing `</form>` element shows the hidden XSRF token generated by the Form Tag Helper.

Processing the POST Request

The following listing shows the `[HttpPost]` version of the `Edit` action method.

C#

```
// POST: Movies/Edit/5
// To protect from overposting attacks, enable the specific properties you
want to bind to.
// For more details, see http://go.microsoft.com/fwlink/?LinkId=317598.
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<IActionResult> Edit(int id,
[Bind("Id,Title,ReleaseDate,Genre,Price,Rating")] Movie movie)
{
    if (id != movie.Id)
```



```
    {
        return NotFound();
    }

    if (ModelState.IsValid)
    {
        try
        {
            _context.Update(movie);
            await _context.SaveChangesAsync();
        }
        catch (DbUpdateConcurrencyException)
        {
            if (!MovieExists(movie.Id))
            {
                return NotFound();
            }
            else
            {
                throw;
            }
        }
        return RedirectToAction(nameof(Index));
    }
    return View(movie);
}
```

The `[ValidateAntiForgeryToken]` attribute validates the hidden XSRF token generated by the antiforgery token generator in the Form Tag Helper

The model binding system takes the posted form values and creates a `Movie` object that's passed as the `movie` parameter. The `ModelState.IsValid` property verifies that the data submitted in the form can be used to modify (edit or update) a `Movie` object. If the data is valid, it's saved. The updated (edited) movie data is saved to the database by calling the `SaveChangesAsync` method of database context. After saving the data, the code redirects the user to the `Index` action method of the `MoviesController` class, which displays the movie collection, including the changes just made.

Before the form is posted to the server, client-side validation checks any validation rules on the fields. If there are any validation errors, an error message is displayed and the form isn't posted. If JavaScript is disabled, you won't have client-side validation but the server will detect the posted values that are not valid, and the form values will be redisplayed with error messages. Later in the tutorial we examine Model Validation in more detail. The Validation Tag Helper in the `Views/Movies/Edit.cshtml` view template takes care of displaying appropriate error messages.

All the `HttpGet` methods in the movie controller follow a similar pattern. They get a movie object (or list of objects, in the case of `Index`), and pass the object (model) to the view. The `Create` method passes an empty movie object to the `Create` view. All the methods that create, edit, delete, or otherwise modify data do so in the `[HttpPost]` overload of the method. Modifying data in an `HTTP GET` method is a security risk. Modifying data in an `HTTP GET` method also violates HTTP best practices and the architectural REST pattern, which specifies that GET requests shouldn't change the state of your application. In other words, performing a GET operation should be a safe operation that has no side effects and doesn't modify your persisted data.

Part 7, add search to an ASP.NET Core MVC app

Article • 09/18/2024

By Rick Anderson

In this section, you add search capability to the `Index` action method that lets you search movies by *genre* or *name*.

Update the `Index` method found inside `Controllers/MoviesController.cs` with the following code:

C#

```
public async Task<IActionResult> Index(string searchString)
{
    if (_context.Movie == null)
    {
        return Problem("Entity set 'MvcMovieContext.Movie'  is null.");
    }

    var movies = from m in _context.Movie
                 select m;

    if (!String.IsNullOrEmpty(searchString))
    {
        movies = movies.Where(s =>
s.Title!.ToUpper().Contains(searchString.ToUpper()));
    }

    return View(await movies.ToListAsync());
}
```

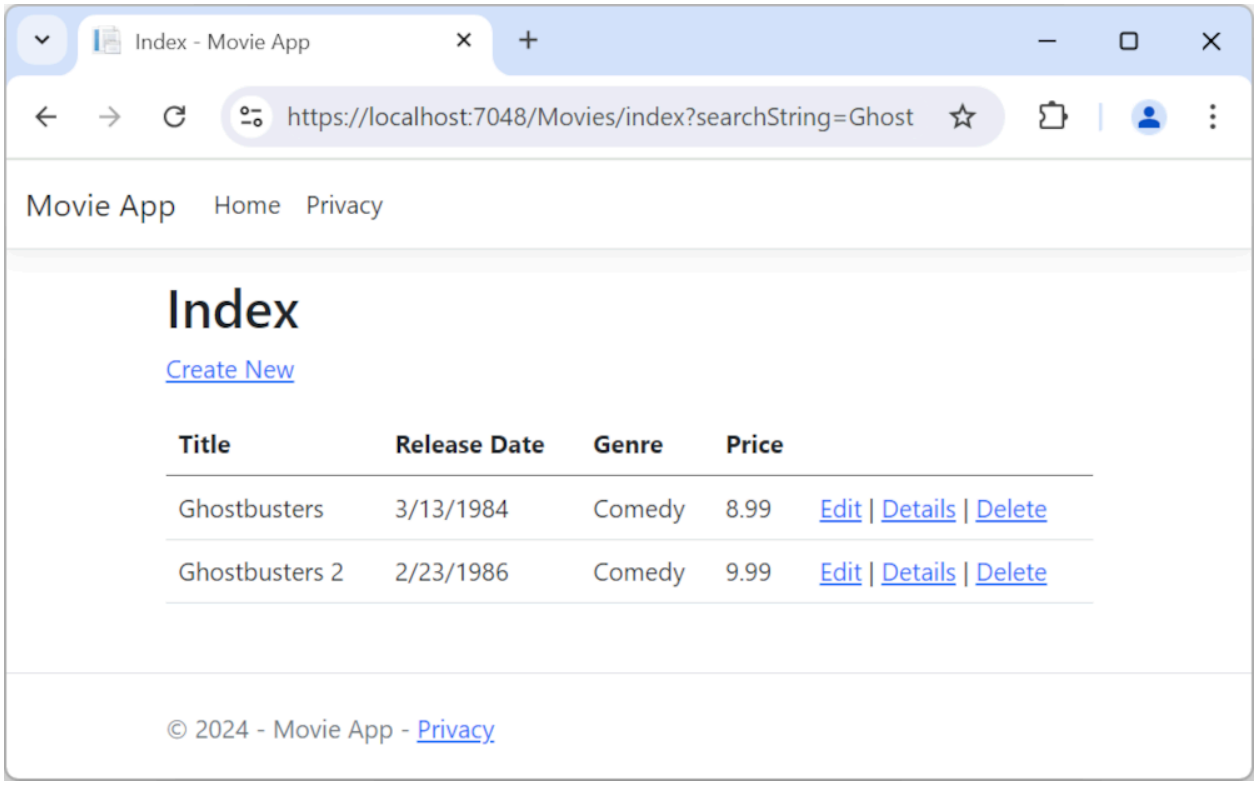
The following line in the `Index` action method creates a LINQ query to select the movies:

C#

```
var movies = from m in _context.Movie
             select m;
```

The query is *only defined* at this point, it has **not** been run against the database.

If the `searchString` parameter contains a string, the movies query is modified to filter on the value of the search string:



C#

```
if (!String.IsNullOrEmpty(searchString))
{
    movies = movies.Where(s =>
s.Title!.ToUpper().Contains(searchString.ToUpper()));
}
```

The `s => s.Title!.ToUpper().Contains(searchString.ToUpper())` code above is a Lambda Expression. Lambdas are used in method-based LINQ queries as arguments to standard query operator methods such as the Where method or `Contains` (used in the code above). LINQ queries are not executed when they're defined or when they're modified by calling a method such as `Where`, `Contains`, or `OrderBy`. Rather, query execution is deferred. That means that the evaluation of an expression is delayed until its realized value is actually iterated over or the `ToListAsync` method is called. For more information about deferred query execution, see Query Execution.

> ⓘ Note
>
> The Contains method is run on the database, not in the C# code. The case sensitivity on the query depends on the database and the collation. On SQL Server, `Contains` maps to SQL LIKE, which is case insensitive. SQLite with the default collation is a mixture of case sensitive and case ***IN***sensitive, depending on the query. For information on making case insensitive SQLite queries, see the following:
>
> - How to use case-insensitive query with Sqlite provider? (dotnet/efcore #11414)
> - How to make a SQLite column case insensitive (dotnet/AspNetCore.Docs #22314)
> - Collations and Case Sensitivity

Navigate to `/Movies/Index`. Append a query string such as `?searchString=Ghost` to the URL. The filtered movies are displayed.

If you change the signature of the `Index` method to have a parameter named `id`, the `id` parameter will match the optional `{id}` placeholder for the default routes set in `Program.cs`.

C#

```
app.MapControllerRoute(
    name: "default",
    pattern: "{controller=Home}/{action=Index}/{id?}");
```

Change the parameter to `id` and change all occurrences of `searchString` to `id`.

The previous `Index` method:

C#

```
public async Task<IActionResult> Index(string searchString)
{
    if (_context.Movie == null)
    {
        return Problem("Entity set 'MvcMovieContext.Movie'  is null.");
    }

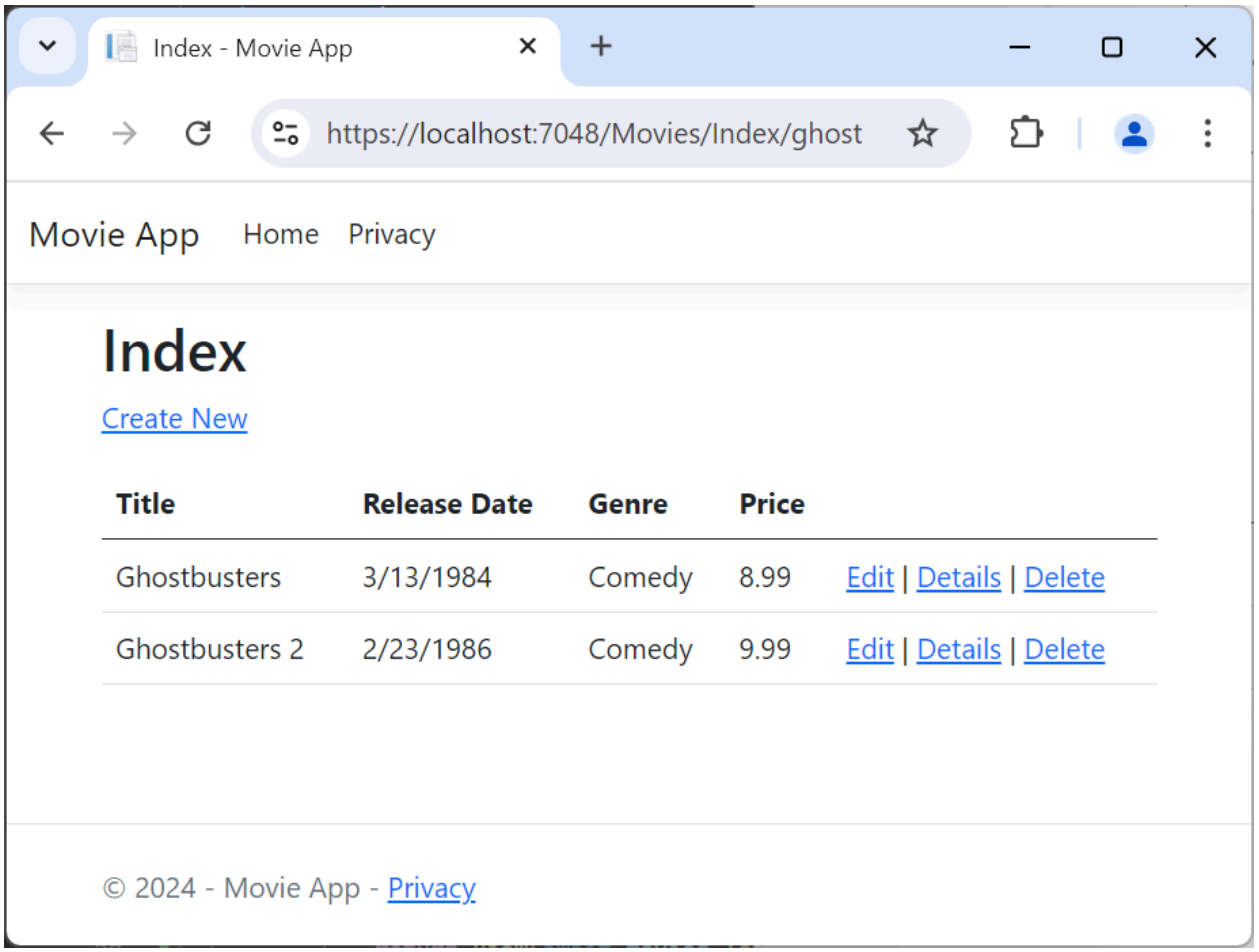
    var movies = from m in _context.Movie
                 select m;
```

```
    if (!String.IsNullOrEmpty(searchString))
    {
        movies = movies.Where(s =>
s.Title!.ToUpper().Contains(searchString.ToUpper()));
    }

    return View(await movies.ToListAsync());
}
```

The updated `Index` method with `id` parameter:

C#



```
public async Task<IActionResult> Index(string id)
{
    if (_context.Movie == null)
    {
        return Problem("Entity set 'MvcMovieContext.Movie'  is null.");
    }

    var movies = from m in _context.Movie
                 select m;

    if (!String.IsNullOrEmpty(id))
    {
        movies = movies.Where(s =>
s.Title!.ToUpper().Contains(id.ToUpper()));
    }

    return View(await movies.ToListAsync());
}
```

You can now pass the search title as route data (a URL segment) instead of as a query string value.

However, you can't expect users to modify the URL every time they want to search for a movie. So now you'll add UI elements to help them filter movies. If you changed the signature of the `Index` method to test how to pass the route-bound `ID` parameter, change it back so that it takes a parameter named `searchString`:

C#

```
public async Task<IActionResult> Index(string searchString)
{
    if (_context.Movie == null)
    {
        return Problem("Entity set 'MvcMovieContext.Movie'  is null.");
    }

    var movies = from m in _context.Movie
                 select m;

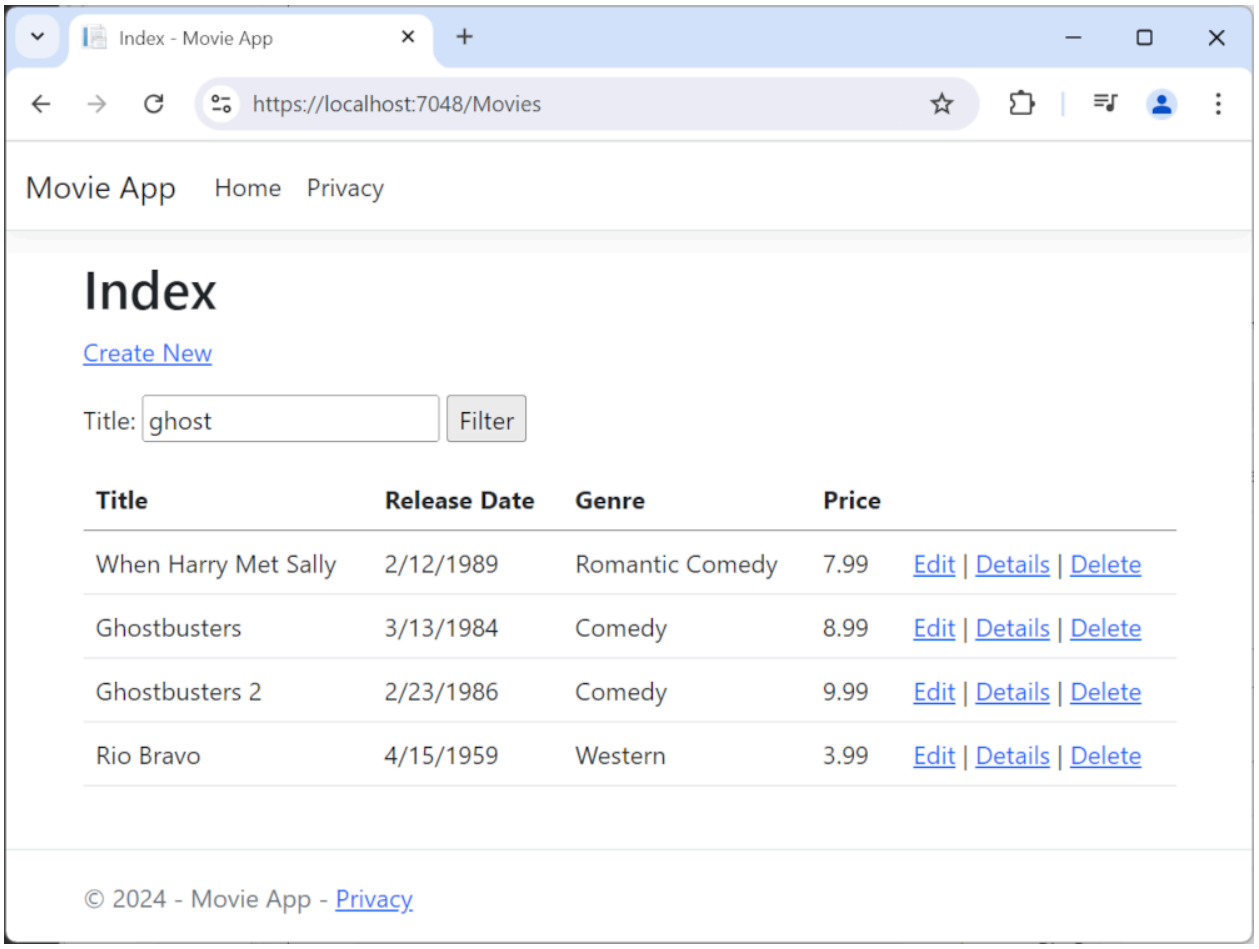
    if (!String.IsNullOrEmpty(searchString))
    {
        movies = movies.Where(s =>
s.Title!.ToUpper().Contains(searchString.ToUpper()));
    }

    return View(await movies.ToListAsync());
}
```

Open the `Views/Movies/Index.cshtml` file, and add the `<form>` markup highlighted below:

CSHTML

```
@model IEnumerable<MvcMovie.Models.Movie>



@{
    ViewData["Title"] = "Index";
}

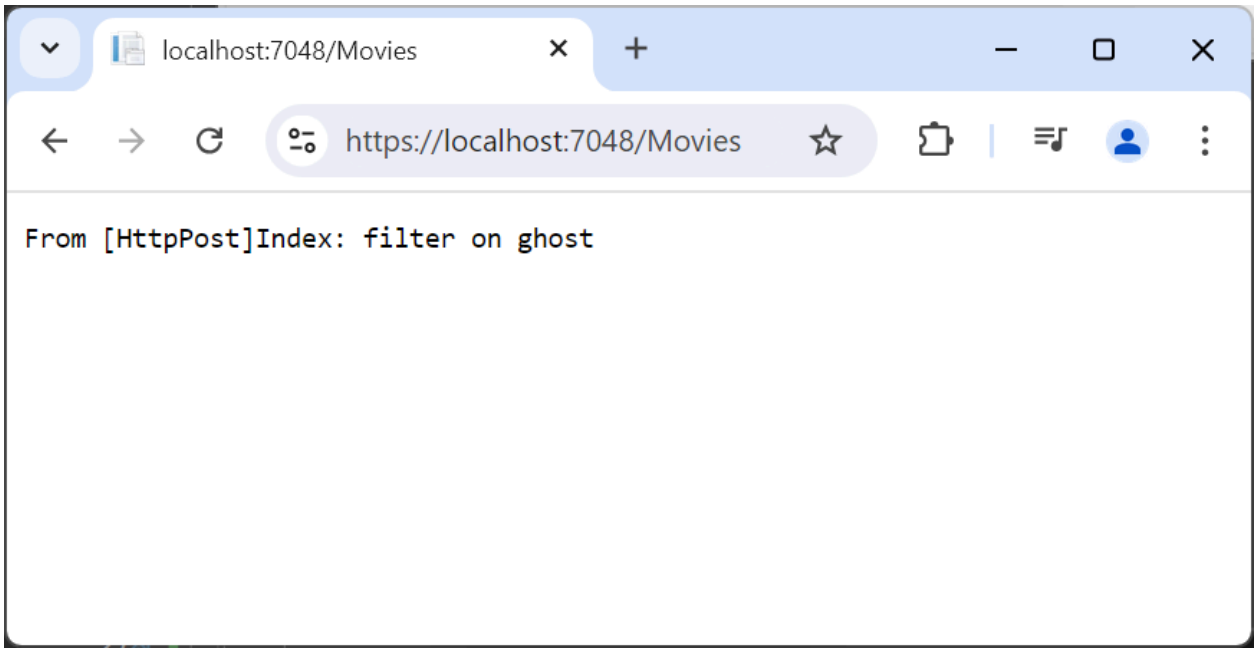
<h1>Index</h1>

<p>
    <a asp-action="Create">Create New</a>
</p>

<form asp-controller="Movies" asp-action="Index">
    <p>
        <label>Title: <input type="text" name="SearchString" /></label>
        <input type="submit" value="Filter" />
    </p>
</form>
<table class="table">
```

The HTML `<form>` tag uses the Form Tag Helper, so when you submit the form, the filter string is posted to the `Index` action of the movies controller. Save your changes and then test the filter.

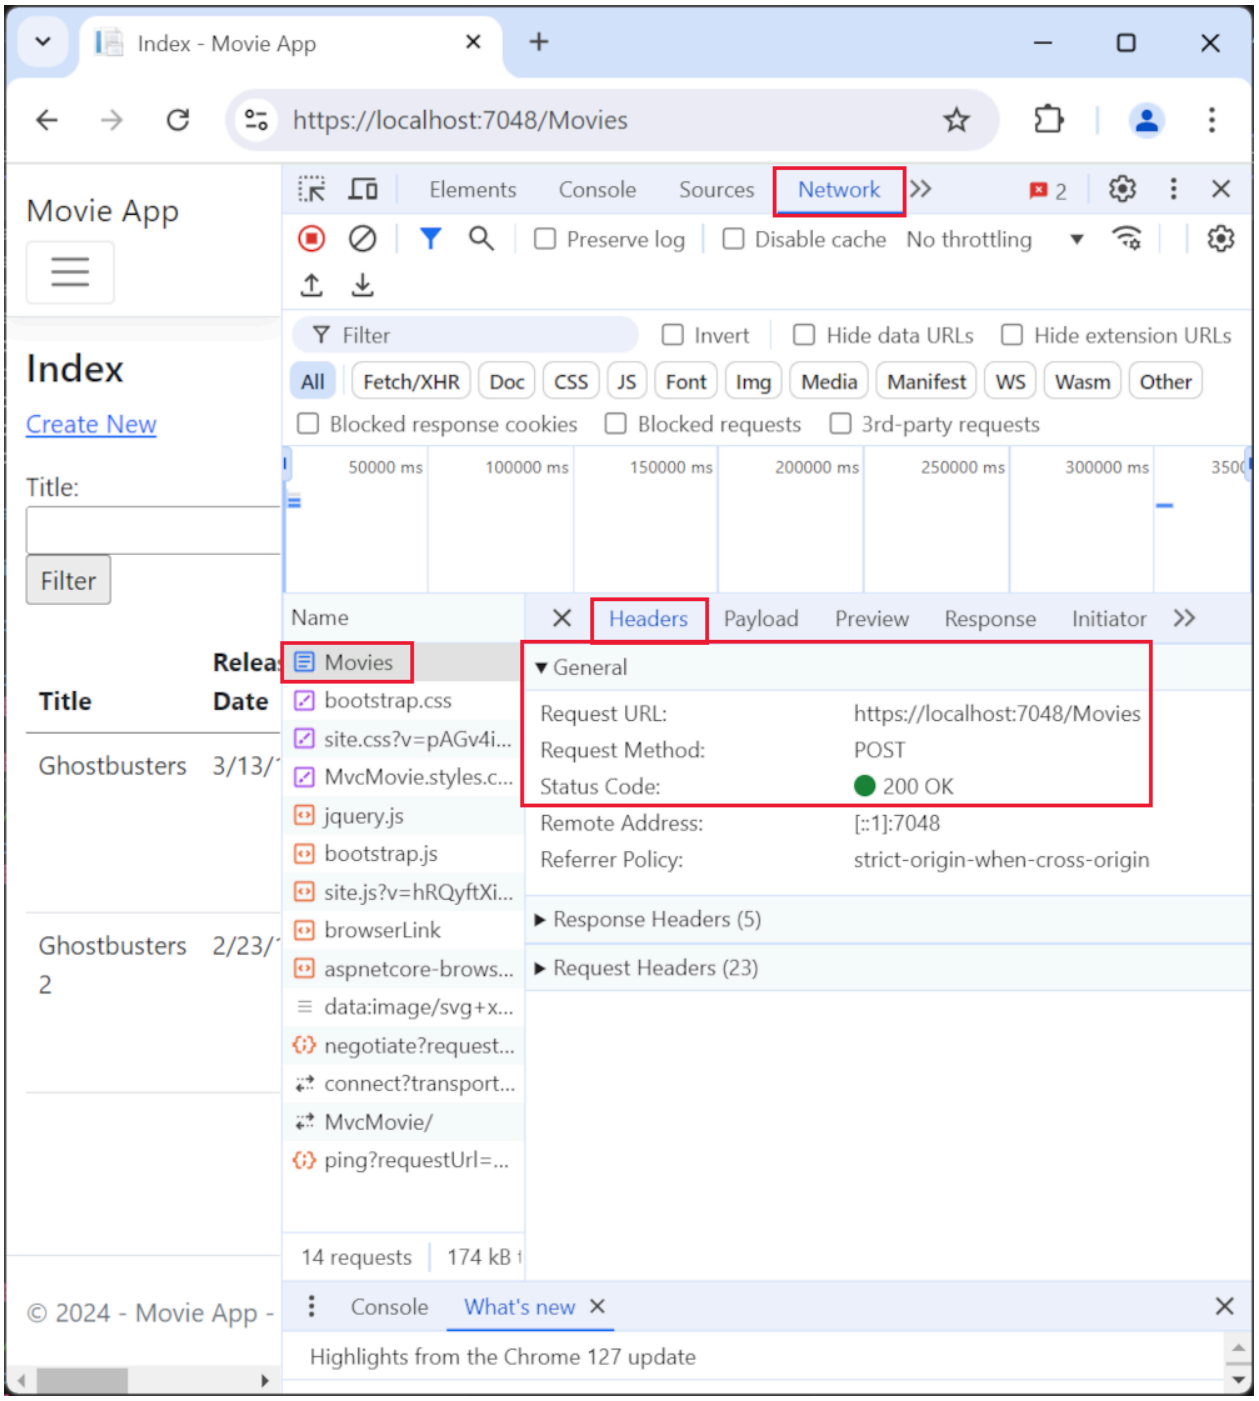
There's no `[HttpPost]` overload of the `Index` method as you might expect. You don't need it, because the method isn't changing the state of the app, just filtering data.



You could add the following `[HttpPost] Index` method.

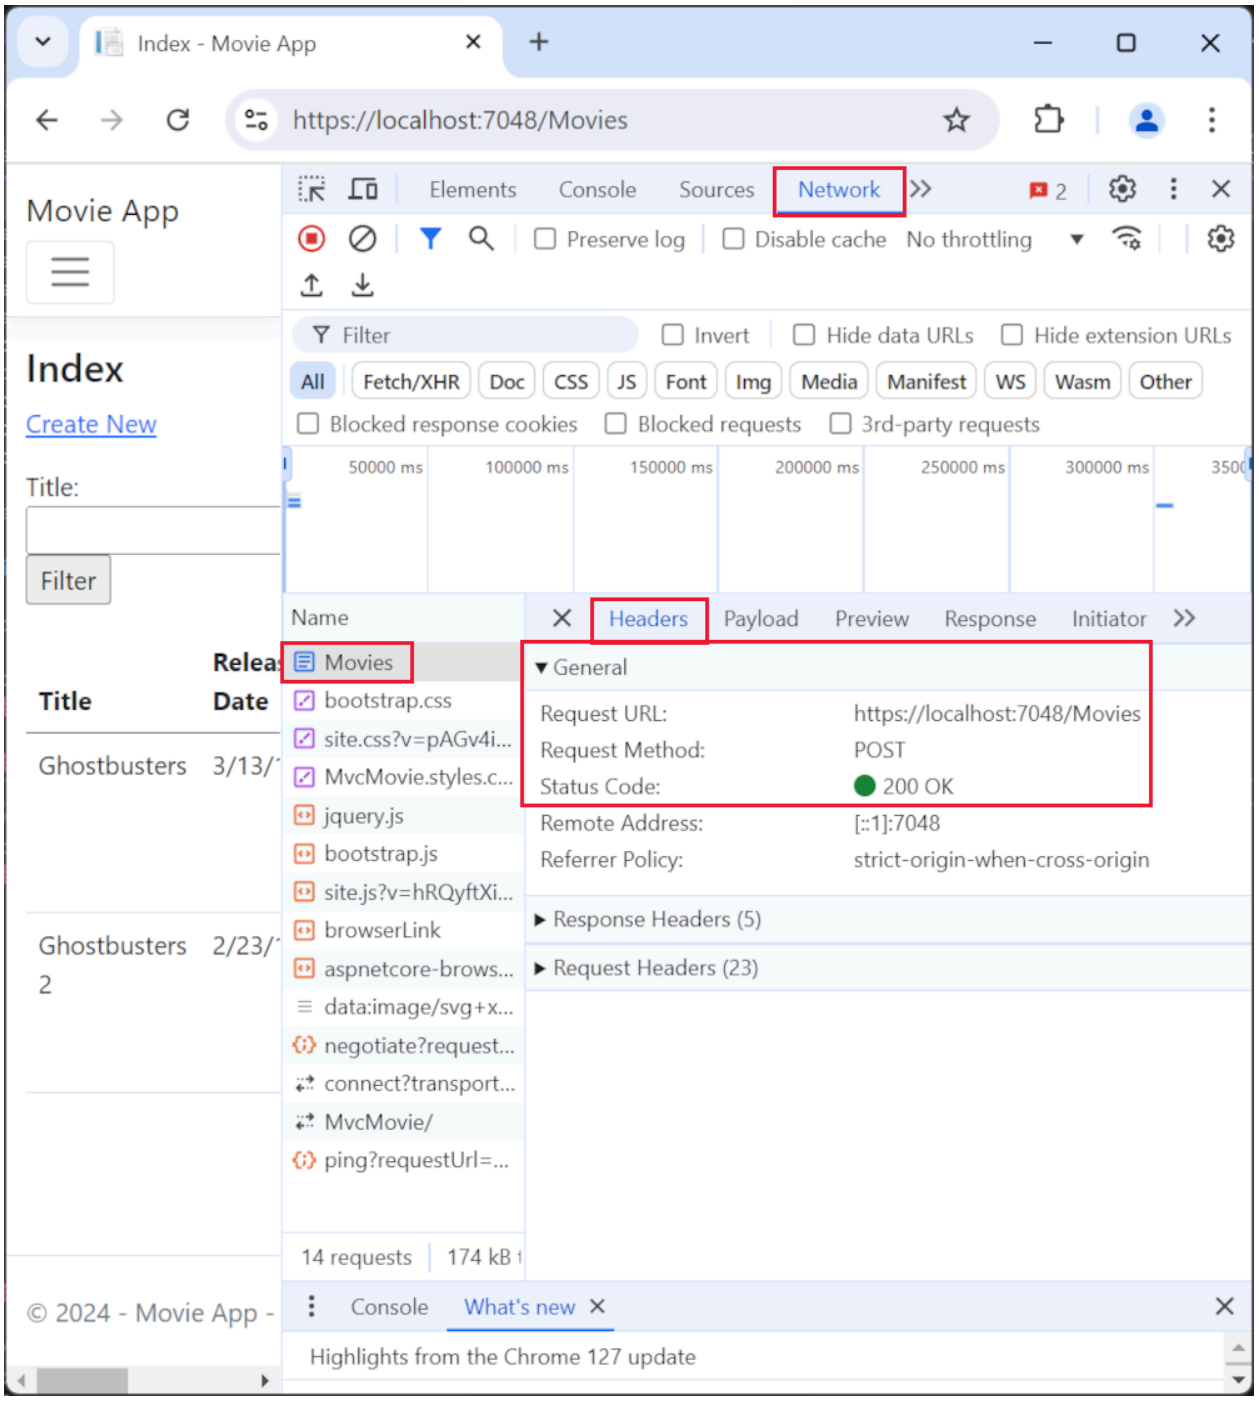
C#

```
[HttpPost]
public string Index(string searchString, bool notUsed)
{
    return "From [HttpPost]Index: filter on " + searchString;
}
```



The `notUsed` parameter is used to create an overload for the `Index` method. We'll talk about that later in the tutorial.

If you add this method, the action invoker would match the `[HttpPost] Index` method, and the `[HttpPost] Index` method would run as shown in the image below.



However, even if you add this `[HttpPost]` version of the `Index` method, there's a limitation in how this has all been implemented. Imagine that you want to bookmark a particular search or you want to send a link to friends that they can click in order to see the same filtered list of movies. Notice that the URL for the HTTP POST request is the same as the URL for the GET request (localhost:{PORT}/Movies/Index) -- there's no search information in the URL. The search string information is sent to the server as a form field value. You can verify that with the browser Developer tools or the excellent Fiddler tool.

The following image shows the Chrome browser Developer tools with the **Network** and **Headers** tabs selected:

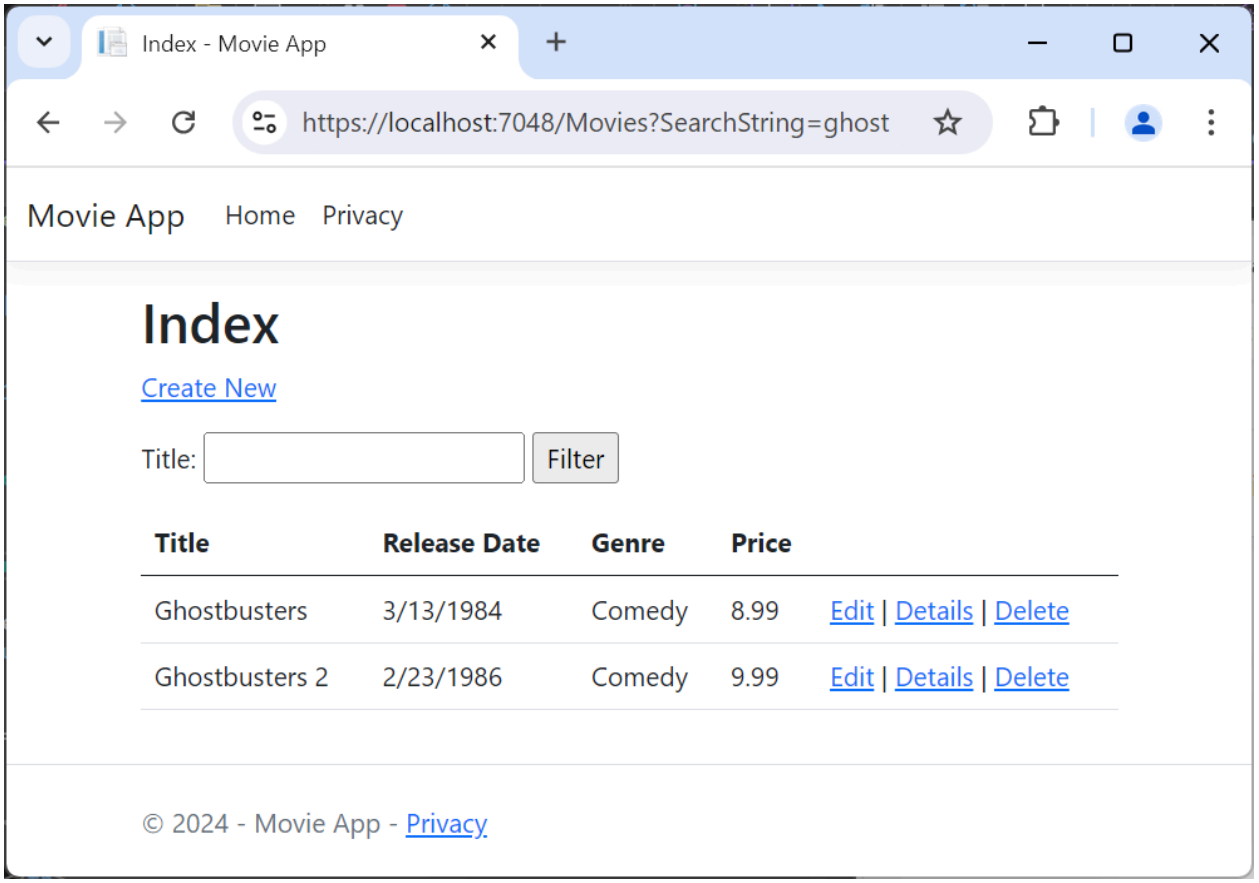
The **Network** and **Payload** tabs are selected to view form data:

You can see the search parameter and XSRF token in the request body. Note, as mentioned in the previous tutorial, the Form Tag Helper generates an XSRF antiforgery token. We're not modifying data, so we don't need to validate the token in the controller method.

Because the search parameter is in the request body and not the URL, you can't capture that search information to bookmark or share with others. Fix this by specifying the request should be `HTTP GET` in the `form` tag found in the `Views/Movies/Index.cshtml` file.

CSHTML

```
@model IEnumerable<MvcMovie.Models.Movie>
```



```
@{
    ViewData["Title"] = "Index";
}

<h1>Index</h1>

<p>
    <a asp-action="Create">Create New</a>
</p>

<form asp-controller="Movies" asp-action="Index" method="get">
    <p>
        <label>Title: <input type="text" name="SearchString" /></label>
        <input type="submit" value="Filter" />
    </p>
</form>
<table class="table">
```

Now when you submit a search, the URL contains the search query string. Searching will also go to the `HttpGet Index` action method, even if you have a `HttpPost Index` method.

Add Search by genre

Add the following `MovieGenreViewModel` class to the *Models* folder:

C#

```
using Microsoft.AspNetCore.Mvc.Rendering;
using System.Collections.Generic;

namespace MvcMovie.Models;

public class MovieGenreViewModel
{
    public List<Movie>? Movies { get; set; }
    public SelectList? Genres { get; set; }
    public string? MovieGenre { get; set; }
    public string? SearchString { get; set; }
}
```

The movie-genre view model will contain:

- A list of movies.
- A `SelectList` containing the list of genres. This allows the user to select a genre from the list.
- `MovieGenre`, which contains the selected genre.
- `SearchString`, which contains the text users enter in the search text box.

Replace the `Index` method in `MoviesController.cs` with the following code:

C#

```
// GET: Movies
public async Task<IActionResult> Index(string movieGenre, string
searchString)
{
    if (_context.Movie == null)
    {
        return Problem("Entity set 'MvcMovieContext.Movie'  is null.");
    }

    // Use LINQ to get list of genres.
    IQueryable<string> genreQuery = from m in _context.Movie
                                    orderby m.Genre
                                    select m.Genre;
    var movies = from m in _context.Movie
                 select m;

    if (!string.IsNullOrEmpty(searchString))
    {
        movies = movies.Where(s =>
s.Title!.ToUpper().Contains(searchString.ToUpper()));
    }

    if (!string.IsNullOrEmpty(movieGenre))
    {
```

```
        movies = movies.Where(x => x.Genre == movieGenre);
    }

    var movieGenreVM = new MovieGenreViewModel
    {
        Genres = new SelectList(await genreQuery.Distinct().ToListAsync()),
        Movies = await movies.ToListAsync()
    };

    return View(movieGenreVM);
}
```

The following code is a `LINQ` query that retrieves all the genres from the database.

C#

```
// Use LINQ to get list of genres.
IQueryable<string> genreQuery = from m in _context.Movie
                                orderby m.Genre
                                select m.Genre;
```

The `SelectList` of genres is created by projecting the distinct genres (we don't want our select list to have duplicate genres).

When the user searches for the item, the search value is retained in the search box.

Add search by genre to the Index view

Update `Index.cshtml` found in *Views/Movies/* as follows:

CSHTML

```
@model MvcMovie.Models.MovieGenreViewModel

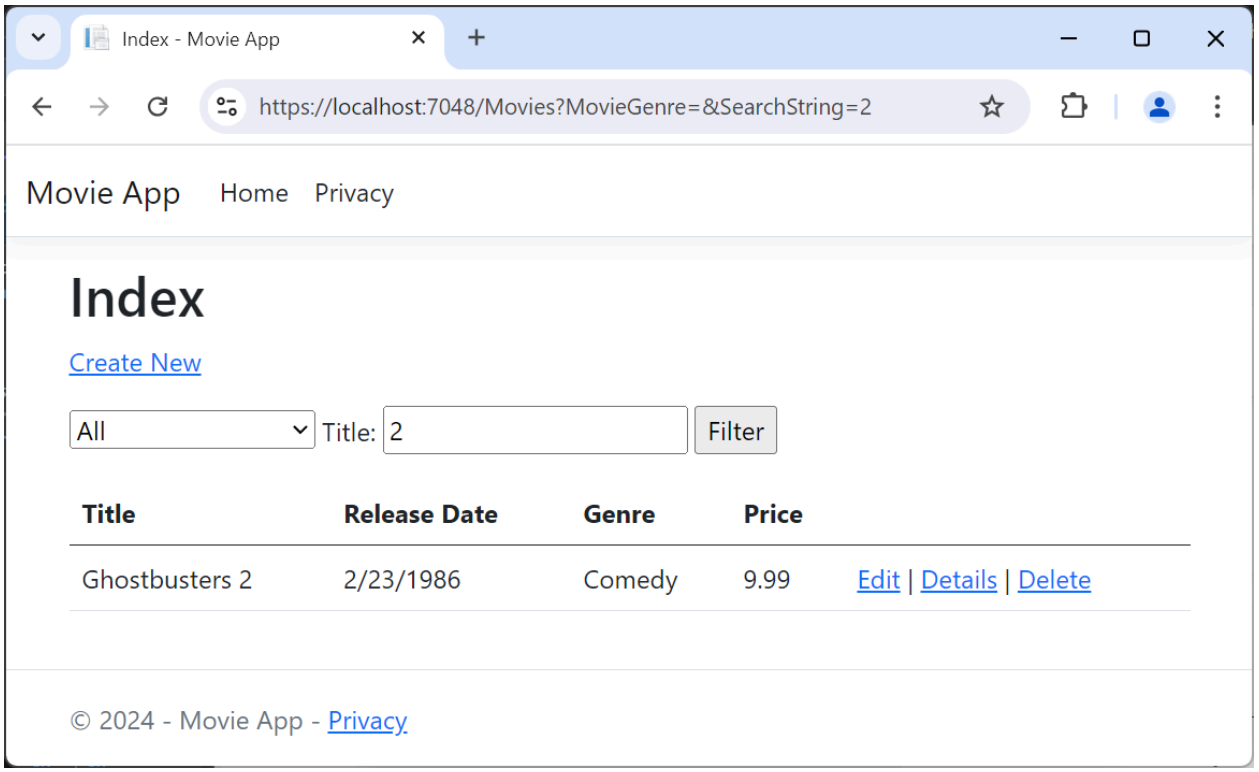
@{
    ViewData["Title"] = "Index";
}

<h1>Index</h1>

<p>
    <a asp-action="Create">Create New</a>
</p>
<form asp-controller="Movies" asp-action="Index" method="get">
    <p>

        <select asp-for="MovieGenre" asp-items="Model.Genres">
            <option value="">All</option>
        </select>
```

```
        <label>Title: <input type="text" asp-for="SearchString" /></label>
        <input type="submit" value="Filter" />
    </p>
</form>



<table class="table">
    <thead>
        <tr>
            <th>
                @Html.DisplayNameFor(model => model.Movies![0].Title)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Movies![0].ReleaseDate)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Movies![0].Genre)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Movies![0].Price)
            </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
        @foreach (var item in Model.Movies!)
        {
            <tr>
                <td>
                    @Html.DisplayFor(modelItem => item.Title)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.ReleaseDate)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Genre)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Price)
                </td>
                <td>
                    <a asp-action="Edit" asp-route-id="@item.Id">Edit</a> |
                    <a asp-action="Details" asp-route-
id="@item.Id">Details</a> |
                    <a asp-action="Delete" asp-route-
id="@item.Id">Delete</a>
                </td>
            </tr>
        }
    </tbody>
</table>
```

Examine the lambda expression used in the following HTML Helper:

```
@Html.DisplayNameFor(model => model.Movies![0].Title)
```

In the preceding code, the `DisplayNameFor` HTML Helper inspects the `Title` property referenced in the lambda expression to determine the display name. Since the lambda expression is inspected rather than evaluated, you don't receive an access violation when `model`, `model.Movies`, or `model.Movies[0]` are `null` or empty. When the lambda expression is evaluated (for example, `@Html.DisplayFor(modelItem => item.Title)`), the model's property values are evaluated. The `!` after `model.Movies` is the null-forgiving operator, which is used to declare that `Movies` isn't null.

Test the app by searching by genre, by movie title, and by both:

Part 8, add a new field to an ASP.NET Core MVC app

Article • 07/26/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

By Rick Anderson

In this section Entity Framework Migrations is used to:

- Add a new field to the model.
- Migrate the new field to the database.

When Entity Framework (EF) is used to automatically create a database from model classes:

- A table is added to the database to track the schema of the database.
- The database is verified to be in sync with the model classes it was generated from. If they aren't in sync, EF throws an exception. This makes it easier to find inconsistent database/code issues.

Add a Rating Property to the Movie Model

Add a `Rating` property to `Models/Movie.cs`:

C#

```
using System;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace MvcMovie.Models;

public class Movie
{
    public int Id { get; set; }
    public string? Title { get; set; }
```

```
    [Display(Name = "Release Date")]
    [DataType(DataType.Date)]
    public DateTime ReleaseDate { get; set; }
    public string? Genre { get; set; }

    [Column(TypeName = "decimal(18, 2)")]
    public decimal Price { get; set; }
    public string? Rating {  get; set; }
}
```

Build the app

Visual Studio

Press Ctrl+Shift+B

Because you've added a new field to the `Movie` class, you need to update the property binding list so this new property will be included. In `MoviesController.cs`, update the `[Bind]` attribute for both the `Create` and `Edit` action methods to include the `Rating` property:

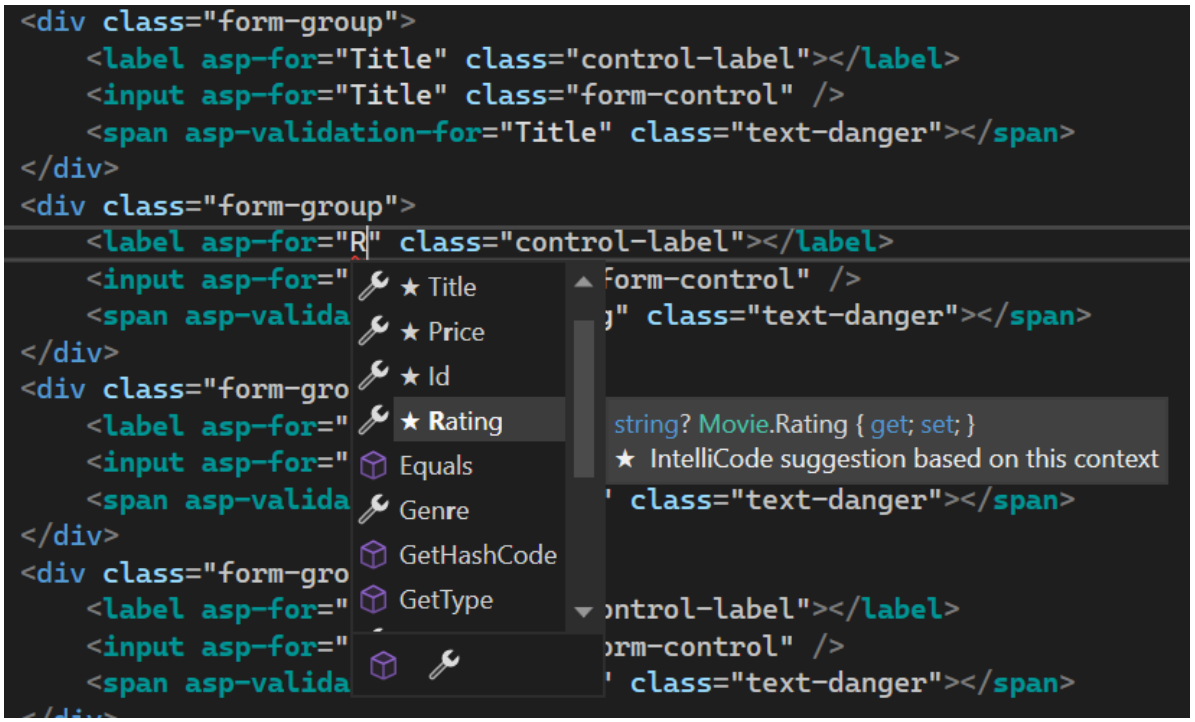
C#

```
[Bind("Id,Title,ReleaseDate,Genre,Price,Rating")]
```

Update the view templates in order to display, create, and edit the new `Rating` property in the browser view.

Edit the `/Views/Movies/Index.cshtml` file and add a `Rating` field:

CSHTML



```
<table class="table">
    <thead>
        <tr>
            <th>
                @Html.DisplayNameFor(model => model.Movies![0].Title)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Movies![0].ReleaseDate)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Movies![0].Genre)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Movies![0].Price)
```

```
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Movies![0].Rating)
            </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
        @foreach (var item in Model.Movies!)
        {
            <tr>
                <td>
                    @Html.DisplayFor(modelItem => item.Title)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.ReleaseDate)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Genre)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Price)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Rating)
                </td>
                <td>
                    <a asp-action="Edit" asp-route-id="@item.Id">Edit</a> |
                    <a asp-action="Details" asp-route-
id="@item.Id">Details</a> |
                    <a asp-action="Delete" asp-route-
id="@item.Id">Delete</a>
                </td>
            </tr>
        }
    </tbody>
</table>
```

Update the `/Views/Movies/Create.cshtml` with a `Rating` field.

Visual Studio

You can copy/paste the previous "form group" and let intelliSense help you update the fields. IntelliSense works with Tag Helpers.

Add the `Rating` property to the remaining `Create.cshtml`, `Delete.cshtml`, `Details.cshtml`, and `Edit.cshtml` view templates.

Update the `SeedData` class so that it provides a value for the new column. A sample change is shown below, but you'll want to make this change for each `new Movie`.

C#

```
new Movie
{
    Title = "When Harry Met Sally",
    ReleaseDate = DateTime.Parse("1989-1-11"),
    Genre = "Romantic Comedy",
    Rating = "R",
    Price = 7.99M
},
```

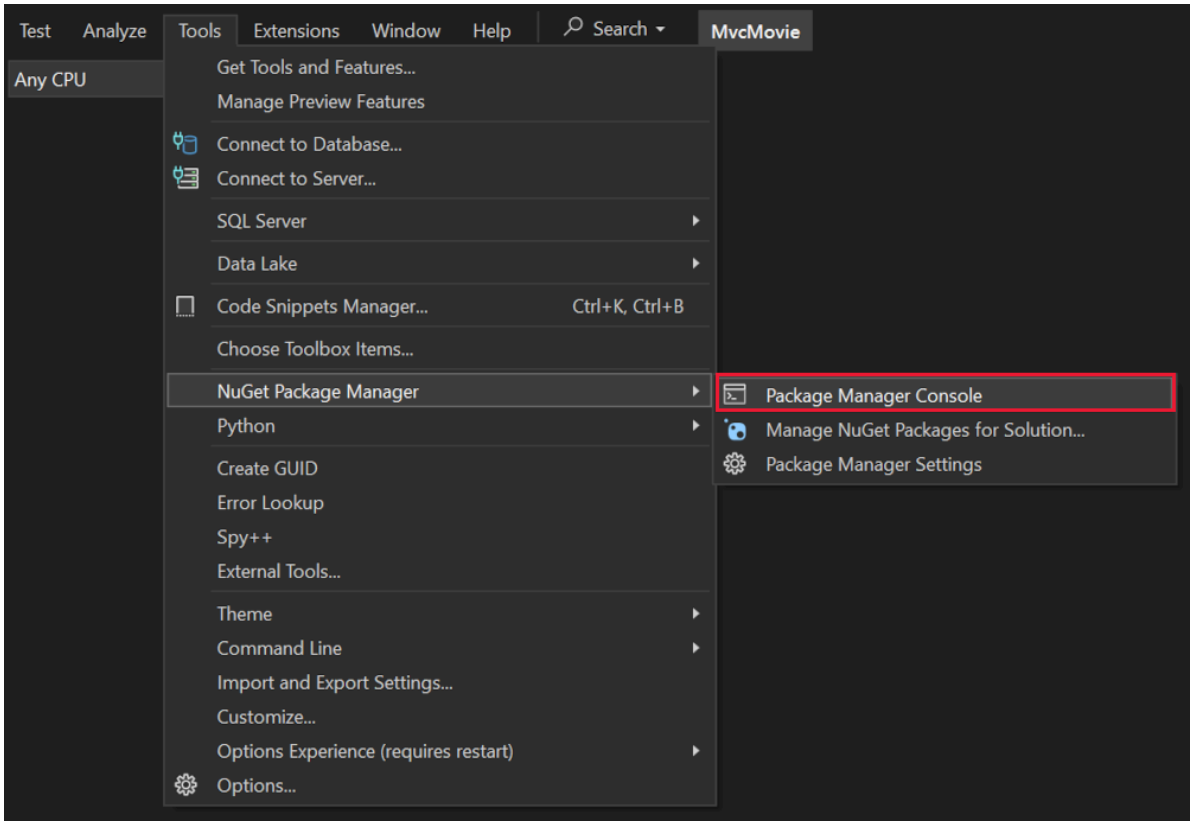
The app won't work until the DB is updated to include the new field. If it's run now, the following `SqlException` is thrown:

```
SqlException: Invalid column name 'Rating'.
```

This error occurs because the updated Movie model class is different than the schema of the Movie table of the existing database. (There's no `Rating` column in the database table.)

There are a few approaches to resolving the error:

1. Have the Entity Framework automatically drop and re-create the database based on the new model class schema. This approach is very convenient early in the development cycle when you're doing active development on a test database; it allows you to quickly evolve the model and database schema together. The downside, though, is that you lose existing data in the database — so you don't want to use this approach on a production database! Using an initializer to automatically seed a database with test data is often a productive way to develop an application. This is a good approach for early development and when using SQLite.



2. Explicitly modify the schema of the existing database so that it matches the model classes. The advantage of this approach is that you keep your data. You can make this change either manually or by creating a database change script.

3. Use Entity Framework Migrations to update the database schema.

For this tutorial, Entity Framework Migrations is used.

Visual Studio

From the **Tools** menu, select **NuGet Package Manager** > **Package Manager Console**.

In the Package Manager Console, enter the following command:

```
PowerShell
```

```
Add-Migration Rating
```

The `Add-Migration` command tells the migration framework to examine the current `Movie` model with the current `Movie` DB schema and create the necessary code to migrate the DB to the new model.

The name "Rating" is arbitrary and is used to name the migration file. It's helpful to use a meaningful name for the migration file.

If all the records in the DB are deleted, the initialize method will seed the DB and include the `Rating` field.

In the Package Manager Console, enter the following command:

PowerShell

```
Update-Database
```

The Update-Database command runs the Up method in migrations that have not been applied.

Run the app and verify you can create, edit, and display movies with a `Rating` field.

Part 9, add validation to an ASP.NET Core MVC app

Article • 07/26/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

By Rick Anderson

In this section:

- Validation logic is added to the `Movie` model.
- You ensure that the validation rules are enforced any time a user creates or edits a movie.

Keeping things DRY

One of the design tenets of MVC is DRY ("Don't Repeat Yourself"). ASP.NET Core MVC encourages you to specify functionality or behavior only once, and then have it be reflected everywhere in an app. This reduces the amount of code you need to write and makes the code you do write less error prone, easier to test, and easier to maintain.

The validation support provided by MVC and Entity Framework Core is a good example of the DRY principle in action. You can declaratively specify validation rules in one place (in the model class) and the rules are enforced everywhere in the app.

Delete the previously edited data

In the next step, validation rules are added that don't allow null values. Run the app, navigate to `/Movies/Index`, delete all listed movies, and stop the app. The app will use the seed data the next time it is run.

Add validation rules to the movie model

The DataAnnotations namespace provides a set of built-in validation attributes that are applied declaratively to a class or property. DataAnnotations also contains formatting attributes like `DataType` that help with formatting and don't provide any validation.

Update the `Movie` class to take advantage of the built-in validation attributes `Required`, `StringLength`, `RegularExpression`, `Range` and the `DataType` formatting attribute.

C#

```
using System;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace MvcMovie.Models;

public class Movie
{
    public int Id { get; set; }

    [StringLength(60, MinimumLength = 3)]
    [Required]
    public string? Title { get; set; }

    [Display(Name = "Release Date")]
    [DataType(DataType.Date)]
    public DateTime ReleaseDate { get; set; }

    [Range(1, 100)]
    [DataType(DataType.Currency)]
    [Column(TypeName = "decimal(18, 2)")]
    public decimal Price { get; set; }

    [RegularExpression(@"^[A-Z]+[a-zA-Z\s]*$")]
    [Required]
    [StringLength(30)]
    public string? Genre { get; set; }

    [RegularExpression(@"^[A-Z]+[a-zA-Z0-9""'\s-]*$")]
    [StringLength(5)]
    [Required]
    public string? Rating { get; set; }
}
```

The validation attributes specify behavior that you want to enforce on the model properties they're applied to:

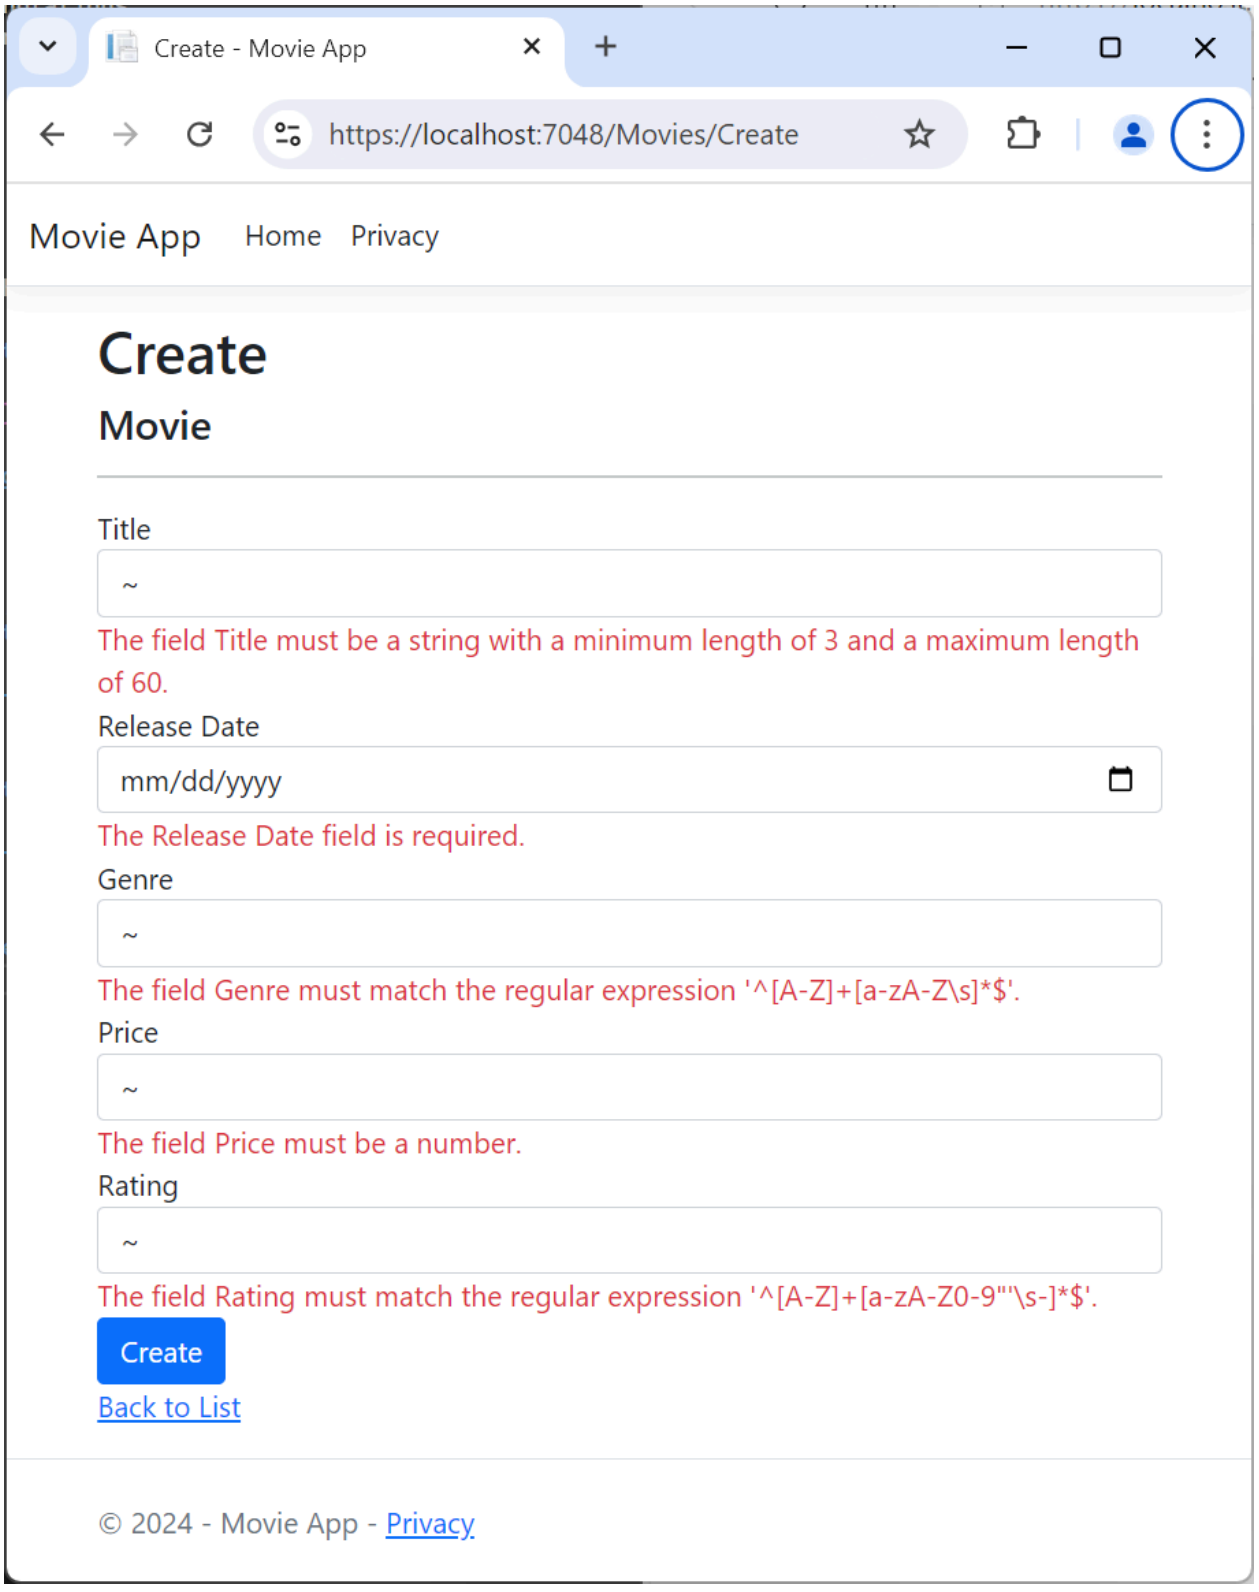
- The `Required` and `MinimumLength` attributes indicate that a property must have a value; but nothing prevents a user from entering white space to satisfy this validation.

- The `RegularExpression` attribute is used to limit what characters can be input. In the preceding code, "Genre":
  - Must only use letters.
  - The first letter is required to be uppercase. White spaces are allowed while numbers, and special characters are not allowed.

- The `RegularExpression` "Rating":
  - Requires that the first character be an uppercase letter.
  - Allows special characters and numbers in subsequent spaces. "PG-13" is valid for a rating, but fails for a "Genre".

- The `Range` attribute constrains a value to within a specified range.

- The `StringLength` attribute lets you set the maximum length of a string property, and optionally its minimum length.



- Value types (such as `decimal`, `int`, `float`, `DateTime`) are inherently required and don't need the `[Required]` attribute.

Having validation rules automatically enforced by ASP.NET Core helps make your app more robust. It also ensures that you can't forget to validate something and inadvertently let bad data into the database.

Validation Error UI

Run the app and navigate to the Movies controller.

Select the **Create New** link to add a new movie. Fill out the form with some invalid values. As soon as jQuery client side validation detects the error, it displays an error message.

> **Note**
>
> You may not be able to enter decimal commas in decimal fields. To support jQuery validation for non-English locales that use a comma (",") for a decimal point, and non US-English date formats, you must take steps to globalize your app. See this GitHub comment 4076 for instructions on adding decimal comma.

Notice how the form has automatically rendered an appropriate validation error message in each field containing an invalid value. The errors are enforced both client-side (using JavaScript and jQuery) and server-side (in case a user has JavaScript disabled).

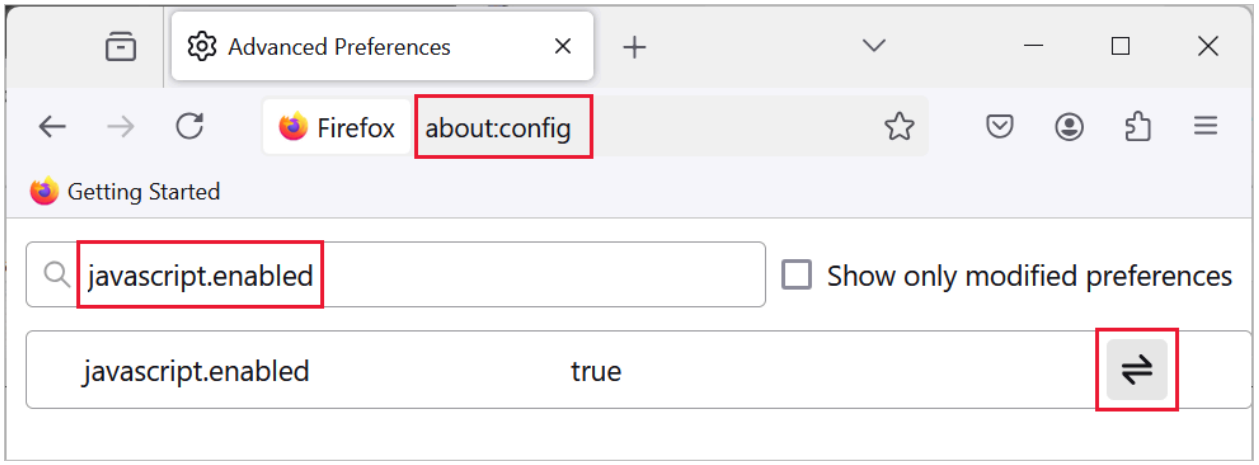
A significant benefit is that you didn't need to change a single line of code in the `MoviesController` class or in the `Create.cshtml` view in order to enable this validation UI. The controller and views you created earlier in this tutorial automatically picked up the validation rules that you specified by using validation attributes on the properties of the `Movie` model class. Test validation using the `Edit` action method, and the same validation is applied.

The form data isn't sent to the server until there are no client side validation errors. You can verify this by putting a break point in the `HTTP Post` method, by using the Fiddler tool, or the F12 Developer tools.

How validation works

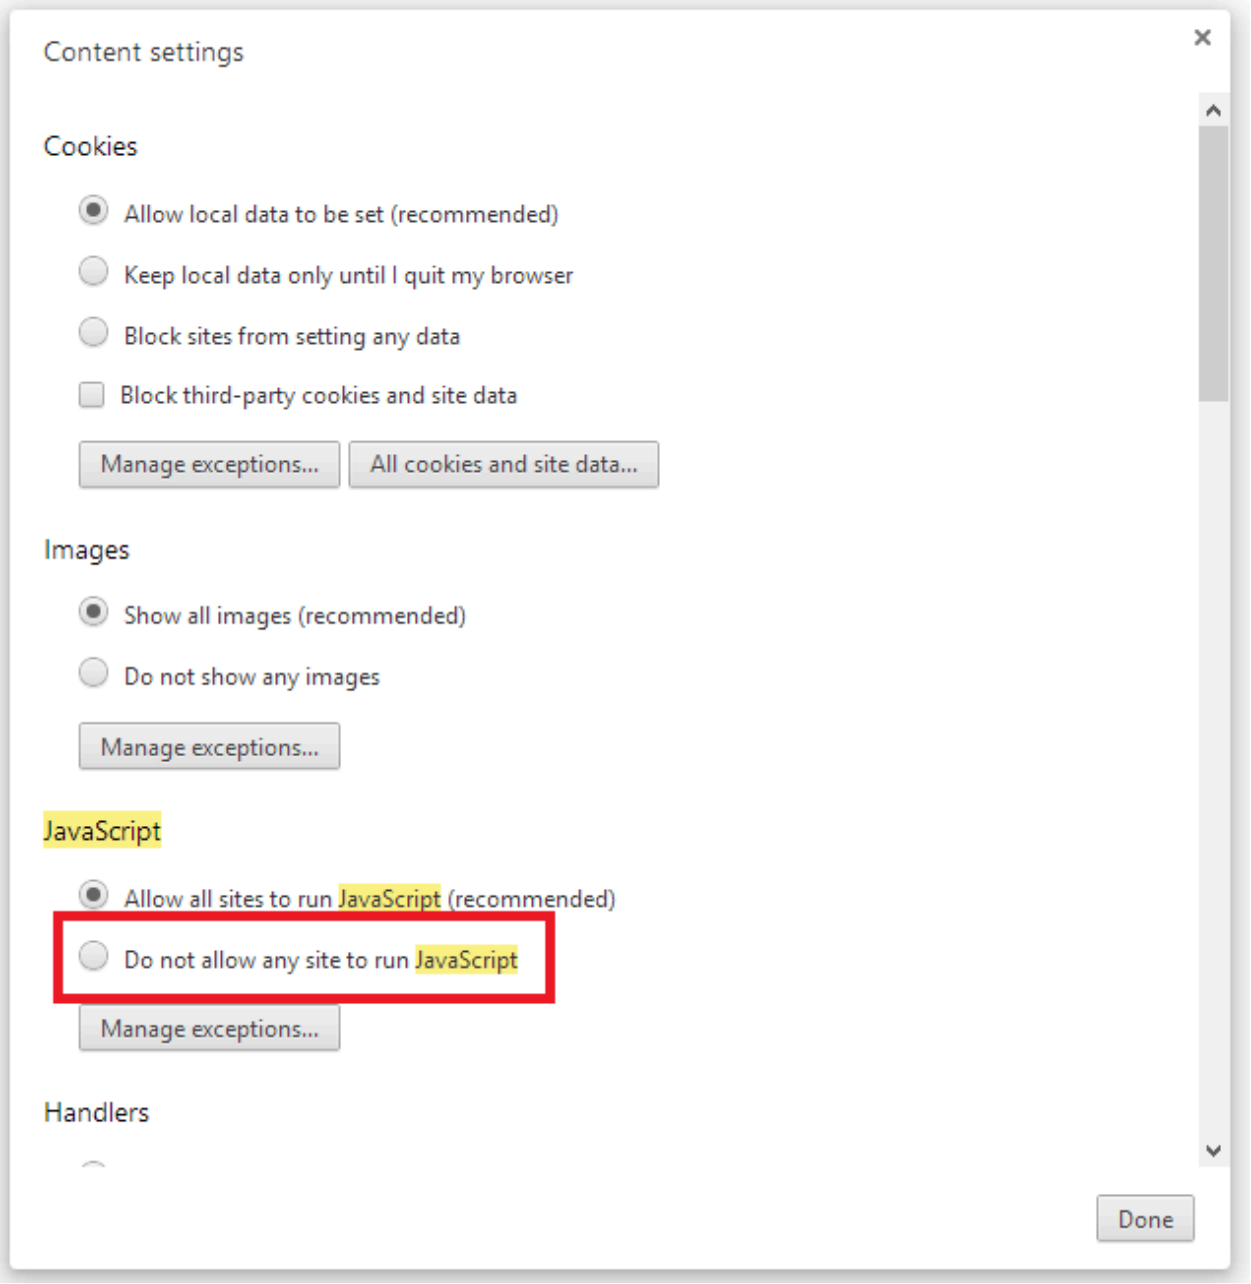
You might wonder how the validation UI was generated without any updates to the code in the controller or views. The following code shows the two `Create` methods.

C#



```
// GET: Movies/Create
public IActionResult Create()
{
    return View();
}

// POST: Movies/Create
// To protect from overposting attacks, enable the specific properties you
want to bind to.
// For more details, see http://go.microsoft.com/fwlink/?LinkId=317598.
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<IActionResult>
Create([Bind("Id,Title,ReleaseDate,Genre,Price,Rating")] Movie movie)
{
    if (ModelState.IsValid)
    {
        _context.Add(movie);
        await _context.SaveChangesAsync();
        return RedirectToAction(nameof(Index));
    }
    return View(movie);
}
```



The first (HTTP GET) `Create` action method displays the initial Create form. The second (`[HttpPost]`) version handles the form post. The second `Create` method (The `[HttpPost]` version) calls `ModelState.IsValid` to check whether the movie has any validation errors. Calling this method evaluates any validation attributes that have been applied to the object. If the object has validation errors, the `Create` method re-displays the form. If there are no errors, the method saves the new movie in the database. In our movie example, the form isn't posted to the server when there are validation errors detected on the client side; the second `Create` method is never called when there are client side validation errors. If you disable JavaScript in your browser, client validation is disabled and you can test the HTTP POST `Create` method `ModelState.IsValid` detecting any validation errors.

You can set a break point in the `[HttpPost] Create` method and verify the method is never called, client side validation won't submit the form data when validation errors are detected. If you disable JavaScript in your browser, then submit the form with errors, the break point will be hit. You still get full validation without JavaScript.

The following image shows how to disable JavaScript in the Firefox browser.

The following image shows how to disable JavaScript in the Chrome browser.

After you disable JavaScript, post invalid data and step through the debugger.

```
74          // POST: Movies/Create
75          // To protect from overposting attacks, please enable t
76          // more details see http://go.microsoft.com/fwlink/?Lin
77          [HttpPost]
78          [ValidateAntiForgeryToken]
            0 references
79          public async Task<IAc          t> Create([Bind("ID,Title
80          {                              false
81              if (ModelState.IsValid)
82              {
83                  _context.Add(movie);
84                  await _context.SaveChangesAsync();
85                  return RedirectToAction("Index");
86              }
87              return View(movie);
88          }
89
```

A portion of the `Create.cshtml` view template is shown in the following markup:

HTML

```
<h4>Movie</h4>
<hr />
<div class="row">
    <div class="col-md-4">
        <form asp-action="Create">
            <div asp-validation-summary="ModelOnly" class="text-danger">
</div>
            <div class="form-group">
                <label asp-for="Title" class="control-label"></label>
                <input asp-for="Title" class="form-control" />
                <span asp-validation-for="Title" class="text-danger"></span>
            </div>

            @*Markup removed for brevity.*@
```

The preceding markup is used by the action methods to display the initial form and to redisplay it in the event of an error.

The Input Tag Helper uses the DataAnnotations attributes and produces HTML attributes needed for jQuery Validation on the client side. The Validation Tag Helper displays validation errors. See Validation for more information.

What's really nice about this approach is that neither the controller nor the `Create` view template knows anything about the actual validation rules being enforced or about the specific error messages displayed. The validation rules and the error strings are specified only in the `Movie` class. These same validation rules are automatically applied to the `Edit` view and any other views templates you might create that edit your model.

When you need to change validation logic, you can do so in exactly one place by adding validation attributes to the model (in this example, the `Movie` class). You won't have to worry about different parts of the application being inconsistent with how the rules are enforced — all validation logic will be defined in one place and used everywhere. This keeps the code very clean, and makes it easy to maintain and evolve. And it means that you'll be fully honoring the DRY principle.

Using DataType Attributes

Open the `Movie.cs` file and examine the `Movie` class. The `System.ComponentModel.DataAnnotations` namespace provides formatting attributes in addition to the built-in set of validation attributes. We've already applied a `DataType`

enumeration value to the release date and to the price fields. The following code shows the `ReleaseDate` and `Price` properties with the appropriate `DataType` attribute.

C#

```
[Display(Name = "Release Date")]
[DataType(DataType.Date)]
public DateTime ReleaseDate { get; set; }

[Range(1, 100)]
[DataType(DataType.Currency)]
[Column(TypeName = "decimal(18, 2)")]
public decimal Price { get; set; }
```

The `DataType` attributes only provide hints for the view engine to format the data and supplies elements/attributes such as `<a>` for URL's and `<a href="mailto:EmailAddress.com">` for email. You can use the `RegularExpression` attribute to validate the format of the data. The `DataType` attribute is used to specify a data type that's more specific than the database intrinsic type, they're not validation attributes. In this case we only want to keep track of the date, not the time. The `DataType` Enumeration provides for many data types, such as Date, Time, PhoneNumber, Currency, EmailAddress and more. The `DataType` attribute can also enable the application to automatically provide type-specific features. For example, a `mailto:` link can be created for `DataType.EmailAddress`, and a date selector can be provided for `DataType.Date` in browsers that support HTML5. The `DataType` attributes emit HTML 5 `data-` (pronounced data dash) attributes that HTML 5 browsers can understand. The `DataType` attributes do **not** provide any validation.

`DataType.Date` doesn't specify the format of the date that's displayed. By default, the data field is displayed according to the default formats based on the server's `CultureInfo`.

The `DisplayFormat` attribute is used to explicitly specify the date format:

C#

```
[DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode =
true)]
public DateTime ReleaseDate { get; set; }
```

The `ApplyFormatInEditMode` setting specifies that the formatting should also be applied when the value is displayed in a text box for editing. (You might not want that for some

fields — for example, for currency values, you probably don't want the currency symbol in the text box for editing.)

You can use the `DisplayFormat` attribute by itself, but it's generally a good idea to use the `DataType` attribute. The `DataType` attribute conveys the semantics of the data as opposed to how to render it on a screen, and provides the following benefits that you don't get with DisplayFormat:

- The browser can enable HTML5 features (for example to show a calendar control, the locale-appropriate currency symbol, email links, etc.)
- By default, the browser will render data using the correct format based on your locale.
- The `DataType` attribute can enable MVC to choose the right field template to render the data (the `DisplayFormat` if used by itself uses the string template).

> ⓘ **Note**
>
> jQuery validation doesn't work with the `Range` attribute and `DateTime`. For example, the following code will always display a client side validation error, even when the date is in the specified range:
>
> `[Range(typeof(DateTime), "1/1/1966", "1/1/2020")]`

You will need to disable jQuery date validation to use the `Range` attribute with `DateTime`. It's generally not a good practice to compile hard dates in your models, so using the `Range` attribute and `DateTime` is discouraged.

The following code shows combining attributes on one line:

C#

```
using System;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace MvcMovie.Models;

public class Movie
{
    public int Id { get; set; }
    [StringLength(60, MinimumLength = 3)]
    public string Title { get; set; }
    [Display(Name = "Release Date"), DataType(DataType.Date)]
    public DateTime ReleaseDate { get; set; }
```

```
    [RegularExpression(@"^[A-Z]+[a-zA-Z\s]*$"), Required, StringLength(30)]
    public string Genre { get; set; }
    [Range(1, 100), DataType(DataType.Currency)]
    [Column(TypeName = "decimal(18, 2)")]
    public decimal Price { get; set; }
    [RegularExpression(@"^[A-Z]+[a-zA-Z0-9""'\s-]*$"), StringLength(5)]
    public string Rating { get; set; }
}
```

In the next part of the series, we review the app and make some improvements to the automatically generated `Details` and `Delete` methods.

Provide product feedback

Part 10, examine the Details and Delete methods of an ASP.NET Core app

Article • 08/04/2024

> **ⓘ Important**
>

By Rick Anderson

Open the Movie controller and examine the `Details` method:

C#

```
// GET: Movies/Details/5
public async Task<IActionResult> Details(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    var movie = await _context.Movie
        .FirstOrDefaultAsync(m => m.Id == id);
    if (movie == null)
    {
        return NotFound();
    }

    return View(movie);
}
```

The MVC scaffolding engine that created this action method adds a comment showing an HTTP request that invokes the method. In this case it's a GET request with three URL segments, the `Movies` controller, the `Details` method, and an `id` value. Recall these segments are defined in `Program.cs`.

C#

```
app.MapControllerRoute(
    name: "default",
    pattern: "{controller=Home}/{action=Index}/{id?}");
```

EF makes it easy to search for data using the `FirstOrDefaultAsync` method. An important security feature built into the method is that the code verifies that the search method has found a movie before it tries to do anything with it. For example, a hacker could introduce errors into the site by changing the URL created by the links from `http://localhost:{PORT}/Movies/Details/1` to something like `http://localhost:{PORT}/Movies/Details/12345` (or some other value that doesn't represent an actual movie). If you didn't check for a null movie, the app would throw an exception.

Examine the `Delete` and `DeleteConfirmed` methods.

C#

```
// GET: Movies/Delete/5
public async Task<IActionResult> Delete(int? id)
{

    if (id == null)
    {
        return NotFound();
    }

    var movie = await _context.Movie
        .FirstOrDefaultAsync(m => m.Id == id);
    if (movie == null)
    {
        return NotFound();
    }

    return View(movie);
}

// POST: Movies/Delete/5
[HttpPost, ActionName("Delete")]
[ValidateAntiForgeryToken]
public async Task<IActionResult> DeleteConfirmed(int id)
{
    var movie = await _context.Movie.FindAsync(id);
    if (movie != null)
    {
        _context.Movie.Remove(movie);
    }

    await _context.SaveChangesAsync();
    return RedirectToAction(nameof(Index));
}
```

Note that the `HTTP GET Delete` method doesn't delete the specified movie, it returns a view of the movie where you can submit (HttpPost) the deletion. Performing a delete operation in response to a GET request (or for that matter, performing an edit operation, create operation, or any other operation that changes data) opens up a security hole.

The `[HttpPost]` method that deletes the data is named `DeleteConfirmed` to give the HTTP POST method a unique signature or name. The two method signatures are shown below:

C#

```
// GET: Movies/Delete/5
public async Task<IActionResult> Delete(int? id)
{
```

C#

```
// POST: Movies/Delete/5
[HttpPost, ActionName("Delete")]
[ValidateAntiForgeryToken]
public async Task<IActionResult> DeleteConfirmed(int id)
{
```

The common language runtime (CLR) requires overloaded methods to have a unique parameter signature (same method name but different list of parameters). However, here you need two `Delete` methods -- one for GET and one for POST -- that both have the same parameter signature. (They both need to accept a single integer as a parameter.)

There are two approaches to this problem, one is to give the methods different names. That's what the scaffolding mechanism did in the preceding example. However, this introduces a small problem: ASP.NET maps segments of a URL to action methods by name, and if you rename a method, routing normally wouldn't be able to find that method. The solution is what you see in the example, which is to add the `ActionName("Delete")` attribute to the `DeleteConfirmed` method. That attribute performs mapping for the routing system so that a URL that includes /Delete/ for a POST request will find the `DeleteConfirmed` method.

Another common work around for methods that have identical names and signatures is to artificially change the signature of the POST method to include an extra (unused) parameter. That's what we did in a previous post when we added the `notUsed` parameter. You could do the same thing here for the `[HttpPost] Delete` method:

C#

```
// POST: Movies/Delete/6
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<IActionResult> Delete(int id, bool notUsed)
```

Publish to Azure

For information on deploying to Azure, see Tutorial: Build an ASP.NET Core and SQL Database app in Azure App Service.

Reliable web app patterns

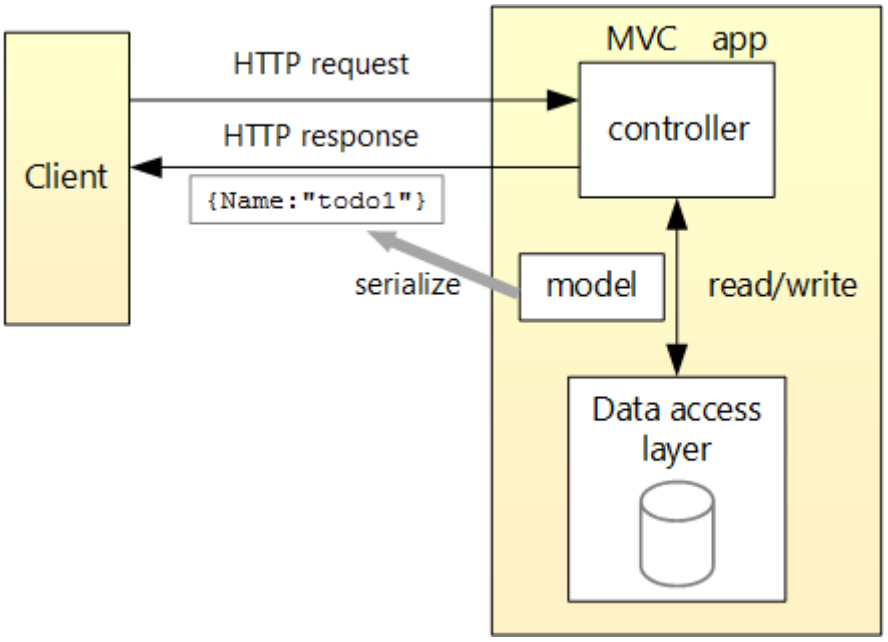
Tutorial: Create a web API with ASP.NET Core

Article • 08/23/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

By Rick Anderson and Kirk Larkin

This tutorial teaches the basics of building a controller-based web API that uses a database. Another approach to creating APIs in ASP.NET Core is to create *minimal APIs*. For help with choosing between minimal APIs and controller-based APIs, see APIs overview. For a tutorial on creating a minimal API, see Tutorial: Create a minimal API with ASP.NET Core.

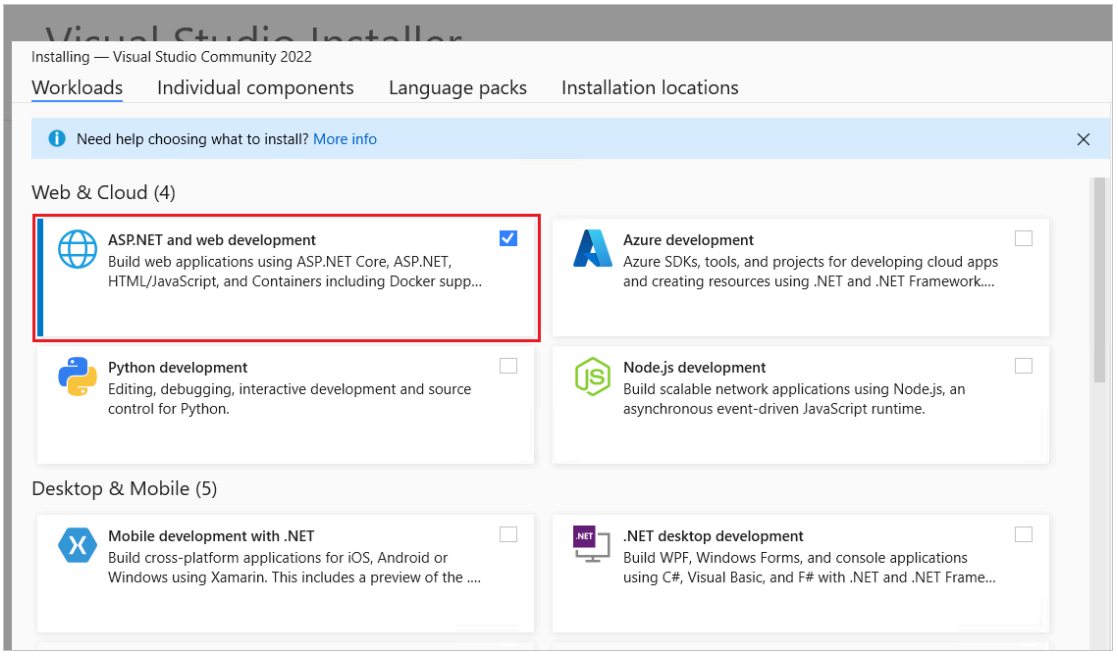


Overview

This tutorial creates the following API:

Expand table

API	Description	Request body	Response body
`GET /api/todoitems`	Get all to-do items	None	Array of to-do items
`GET /api/todoitems/{id}`	Get an item by ID	None	To-do item
`POST /api/todoitems`	Add a new item	To-do item	To-do item
`PUT /api/todoitems/{id}`	Update an existing item	To-do item	None
`DELETE /api/todoitems/{id}`	Delete an item	None	None



The following diagram shows the design of the app.

Prerequisites

Visual Studio

- Visual Studio 2022 with the **ASP.NET and web development** workload.

Create a web project

Visual Studio

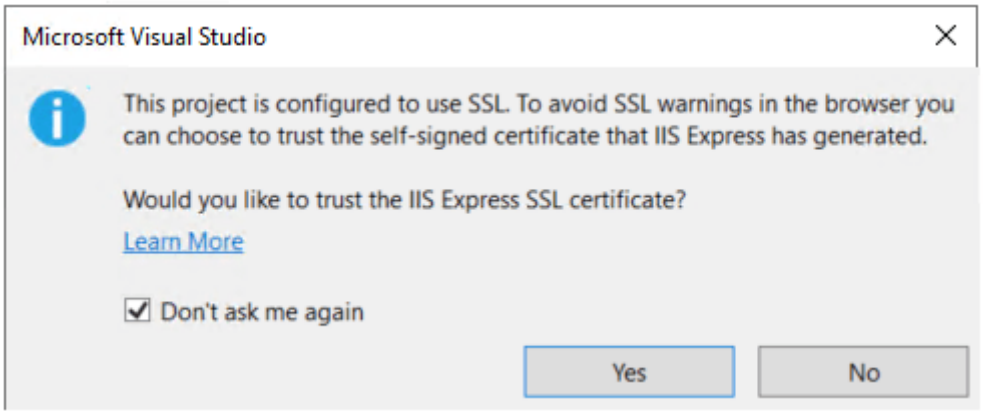
- From the **File** menu, select **New** > **Project**.
- Enter *Web API* in the search box.
- Select the **ASP.NET Core Web API** template and select **Next**.
- In the **Configure your new project dialog**, name the project *TodoApi* and select **Next**.
- In the **Additional information** dialog:
  - Confirm the **Framework** is **.NET 8.0 (Long Term Support)**.
  - Confirm the checkbox for **Use controllers(uncheck to use minimal APIs)** is checked.
  - Confirm the checkbox for **Enable OpenAPI support** is checked.
  - Select **Create**.

Add a NuGet package

A NuGet package must be added to support the database used in this tutorial.

- From the **Tools** menu, select **NuGet Package Manager** > **Manage NuGet Packages for Solution**.
- Select the **Browse** tab.
- Enter **Microsoft.EntityFrameworkCore.InMemory** in the search box, and then select `Microsoft.EntityFrameworkCore.InMemory`.
- Select the **Project** checkbox in the right pane and then select **Install**.

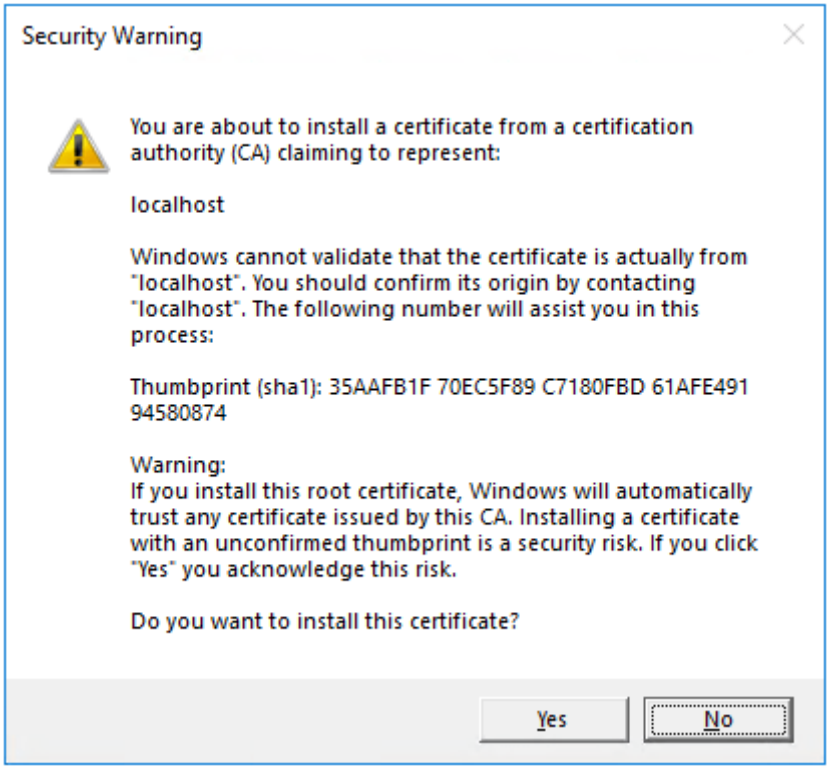
> **Note**
>
> For guidance on adding packages to .NET apps, see the articles under *Install and manage packages* at Package consumption workflow (NuGet documentation). Confirm correct package versions at NuGet.org.



Test the project

The project template creates a `WeatherForecast` API with support for Swagger.

Visual Studio



Press Ctrl+F5 to run without the debugger.

Visual Studio displays the following dialog when a project is not yet configured to use SSL:

Select **Yes** if you trust the IIS Express SSL certificate.

The following dialog is displayed:

Select **Yes** if you agree to trust the development certificate.

For information on trusting the Firefox browser, see Firefox SEC_ERROR_INADEQUATE_KEY_USAGE certificate error.

Visual Studio launches the default browser and navigates to `https://localhost:<port>/swagger/index.html`, where `<port>` is a randomly chosen port number set at the project creation.

The Swagger page `/swagger/index.html` is displayed. Select **GET** > **Try it out** > **Execute**. The page displays:

- The Curl command to test the WeatherForecast API.
- The URL to test the WeatherForecast API.
- The response code, body, and headers.
- A drop-down list box with media types and the example value and schema.

If the Swagger page doesn't appear, see this GitHub issue.

Swagger is used to generate useful documentation and help pages for web APIs. This tutorial uses Swagger to test the app. For more information on Swagger, see ASP.NET Core web API documentation with Swagger / OpenAPI.

Copy and paste the **Request URL** in the browser: `https://localhost:<port>/weatherforecast`

JSON similar to the following example is returned:

JSON

```
[
    {
        "date": "2019-07-16T19:04:05.7257911-06:00",
        "temperatureC": 52,
        "temperatureF": 125,
        "summary": "Mild"
    },
    {
        "date": "2019-07-17T19:04:05.7258461-06:00",
        "temperatureC": 36,
        "temperatureF": 96,
        "summary": "Warm"
    },
    {
        "date": "2019-07-18T19:04:05.7258467-06:00",
        "temperatureC": 39,
        "temperatureF": 102,
        "summary": "Cool"
    },
    {
        "date": "2019-07-19T19:04:05.7258471-06:00",
        "temperatureC": 10,
        "temperatureF": 49,
        "summary": "Bracing"
    },
    {
        "date": "2019-07-20T19:04:05.7258474-06:00",
        "temperatureC": -1,
        "temperatureF": 31,
```

```
        "summary": "Chilly"
    }
]
```

Add a model class

A *model* is a set of classes that represent the data that the app manages. The model for this app is the `TodoItem` class.

Visual Studio

- In **Solution Explorer**, right-click the project. Select **Add** > **New Folder**. Name the folder `Models`.
- Right-click the `Models` folder and select **Add** > **Class**. Name the class *TodoItem* and select **Add**.
- Replace the template code with the following:

C#

```
namespace TodoApi.Models;

public class TodoItem
{
    public long Id { get; set; }
    public string? Name { get; set; }
    public bool IsComplete { get; set; }
}
```

The `Id` property functions as the unique key in a relational database.

Model classes can go anywhere in the project, but the `Models` folder is used by convention.

Add a database context

The *database context* is the main class that coordinates Entity Framework functionality for a data model. This class is created by deriving from the Microsoft.EntityFrameworkCore.DbContext class.

Visual Studio

- Right-click the `Models` folder and select **Add** > **Class**. Name the class *TodoContext* and click **Add**.

- Enter the following code:

```
C#

using Microsoft.EntityFrameworkCore;

namespace TodoApi.Models;

public class TodoContext : DbContext
{
    public TodoContext(DbContextOptions<TodoContext> options)
        : base(options)
    {
    }

    public DbSet<TodoItem> TodoItems { get; set; } = null!;
}
```

Register the database context

In ASP.NET Core, services such as the DB context must be registered with the dependency injection (DI) container. The container provides the service to controllers.

Update `Program.cs` with the following highlighted code:

```
C#

using Microsoft.EntityFrameworkCore;
using TodoApi.Models;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddControllers();
builder.Services.AddDbContext<TodoContext>(opt =>
    opt.UseInMemoryDatabase("TodoList"));
builder.Services.AddEndpointsApiExplorer();
builder.Services.AddSwaggerGen();

var app = builder.Build();

if (app.Environment.IsDevelopment())
{
    app.UseSwagger();
    app.UseSwaggerUI();
```

```
}

app.UseHttpsRedirection();

app.UseAuthorization();

app.MapControllers();

app.Run();
```

The preceding code:

- Adds `using` directives.
- Adds the database context to the DI container.
- Specifies that the database context will use an in-memory database.

Scaffold a controller

Visual Studio

- Right-click the `Controllers` folder.
- Select **Add** > **New Scaffolded Item**.
- Select **API Controller with actions, using Entity Framework**, and then select **Add**.
- In the **Add API Controller with actions, using Entity Framework** dialog:
  - Select **TodoItem (TodoApi.Models)** in the **Model class**.
  - Select **TodoContext (TodoApi.Models)** in the **Data context class**.
  - Select **Add**.

  If the scaffolding operation fails, select **Add** to try scaffolding a second time.

The generated code:

- Marks the class with the [ApiController] attribute. This attribute indicates that the controller responds to web API requests. For information about specific behaviors that the attribute enables, see Create web APIs with ASP.NET Core.
- Uses DI to inject the database context (`TodoContext`) into the controller. The database context is used in each of the CRUD methods in the controller.

The ASP.NET Core templates for:

- Controllers with views include `[action]` in the route template.
- API controllers don't include `[action]` in the route template.

When the `[action]` token isn't in the route template, the action name (method name) isn't included in the endpoint. That is, the action's associated method name isn't used in the matching route.

Update the PostTodoItem create method

Update the return statement in the `PostTodoItem` to use the nameof operator:

C#

```
[HttpPost]
public async Task<ActionResult<TodoItem>> PostTodoItem(TodoItem todoItem)
{
    _context.TodoItems.Add(todoItem);
    await _context.SaveChangesAsync();

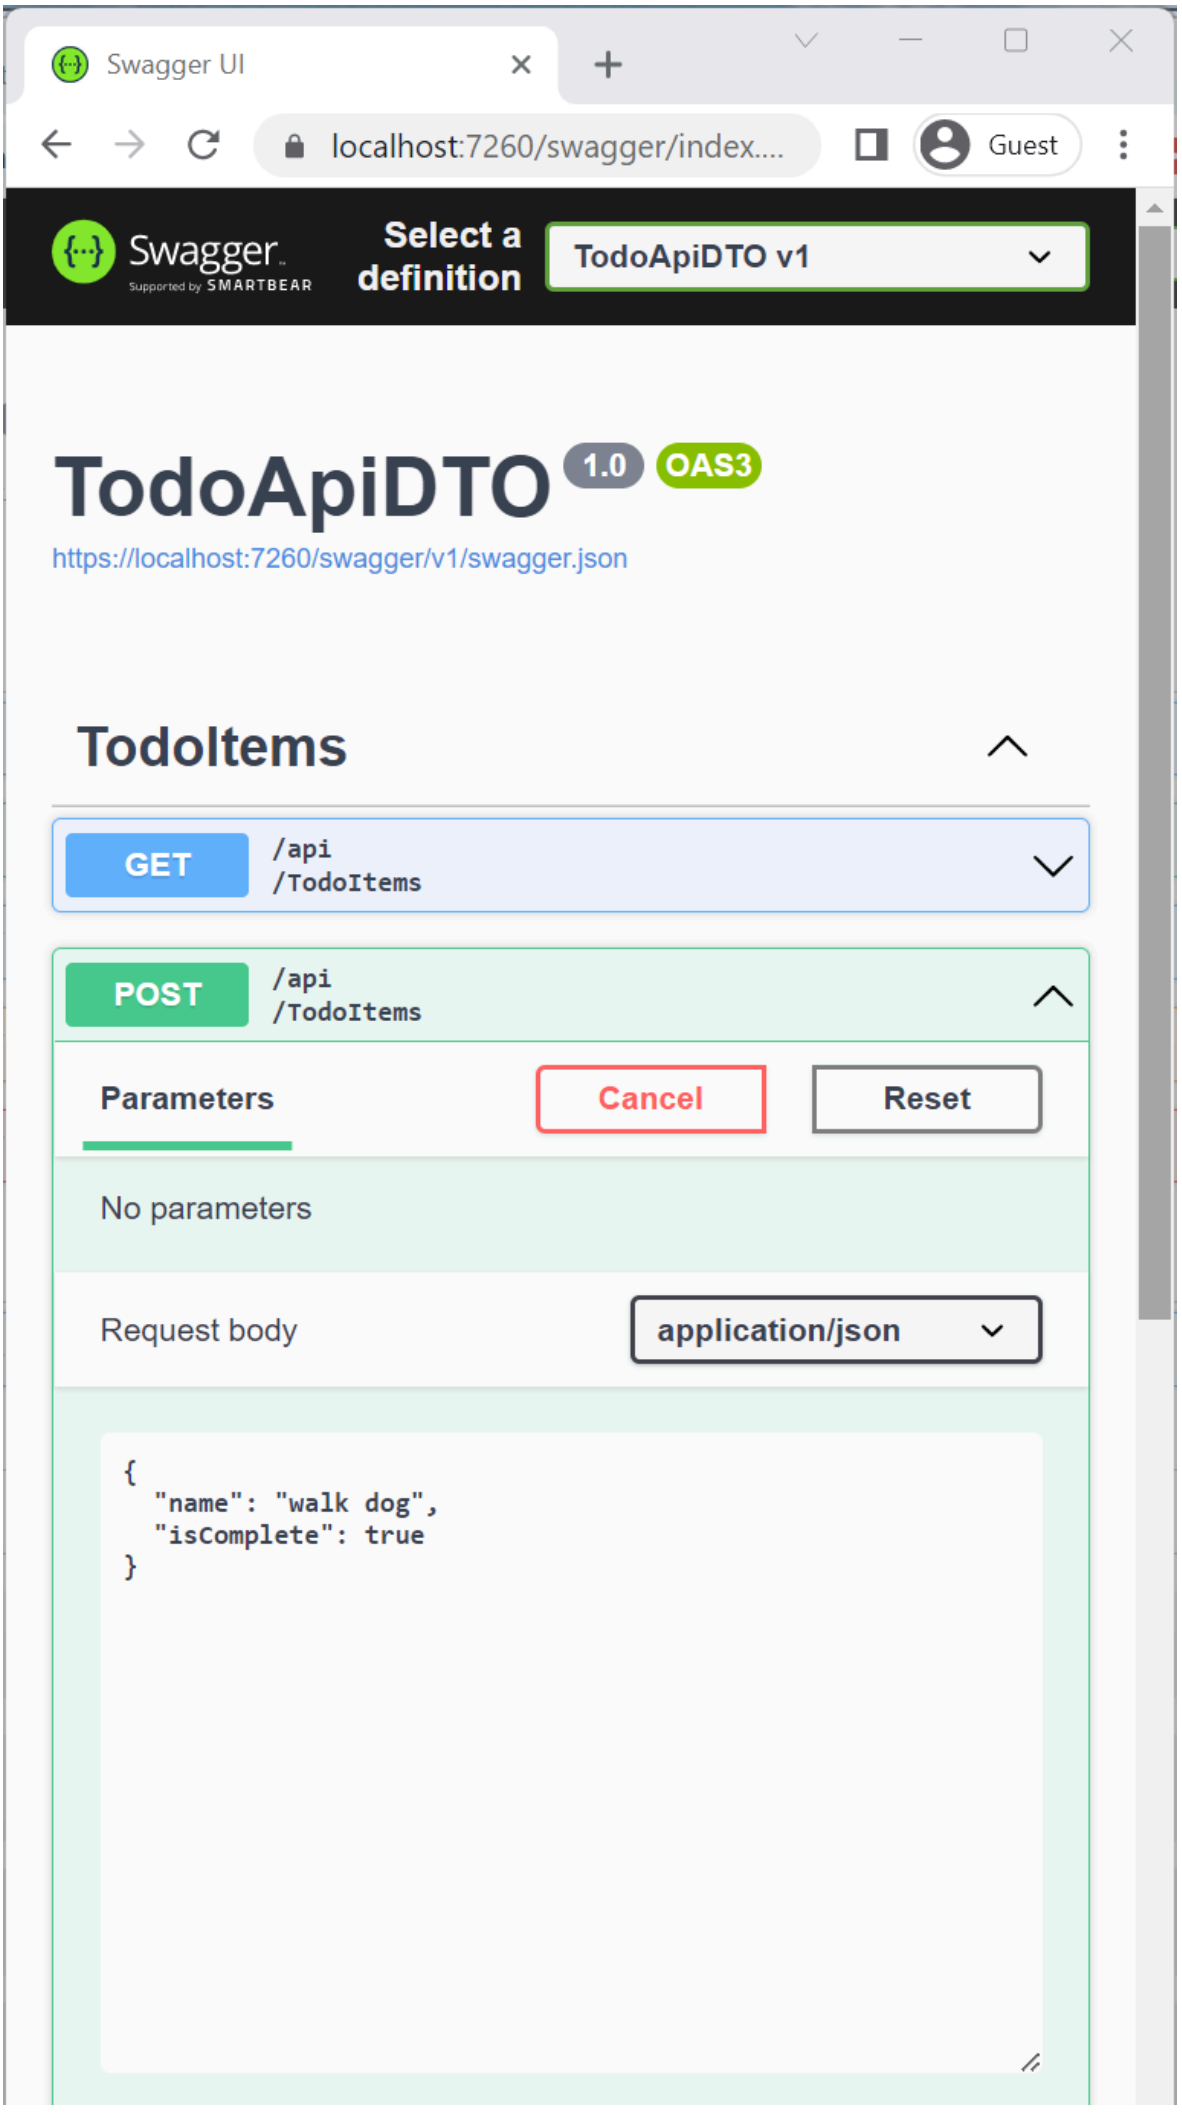
    //    return CreatedAtAction("GetTodoItem", new { id = todoItem.Id },
todoItem);
    return CreatedAtAction(nameof(GetTodoItem), new { id = todoItem.Id },
todoItem);
}
```

The preceding code is an `HTTP POST` method, as indicated by the [HttpPost] attribute. The method gets the value of the `TodoItem` from the body of the HTTP request.

For more information, see Attribute routing with Http[Verb] attributes.

The CreatedAtAction method:

- Returns an HTTP 201 status code if successful. `HTTP 201` is the standard response for an `HTTP POST` method that creates a new resource on the server.
- Adds a Location header to the response. The `Location` header specifies the URI of the newly created to-do item. For more information, see 10.2.2 201 Created.
- References the `GetTodoItem` action to create the `Location` header's URI. The C# `nameof` keyword is used to avoid hard-coding the action name in the `CreatedAtAction` call.



Test PostTodoItem

- Press Ctrl+F5 to run the app.

- In the Swagger browser window, select **POST /api/TodoItems**, and then select **Try it out**.
- In the **Request body** input window, update the JSON. For example,

```JSON
{
  "name": "walk dog",
  "isComplete": true
}
```

- Select **Execute**

{
"name": "walk dog",
"isComplete": true
}

Test the location header URI

In the preceding POST, the Swagger UI shows the location header under **Response headers**. For example, `location: https://localhost:7260/api/TodoItems/1`. The location header shows the URI to the created resource.

To test the location header:

- In the Swagger browser window, select **GET /api/TodoItems/{id}**, and then select **Try it out**.
- Enter `1` in the `id` input box, and then select **Execute**.

GET /api/TodoItems/{id}

Parameters Cancel

Name	Description
id * required integer($int64) (path)	1

Execute Clear

Responses

Curl

```
curl -X 'GET' \
  'https://localhost:7260/api/TodoItems/1' \
  -H 'accept: text/plain'
```

Request URL

```
https://localhost:7260/api/TodoItems/1
```

Server response

Code	Details
200	Response body `{ "id": 1, "name": "walk dog", "isComplete": true }` Download Response headers `content-type: application/json; charset=utf-8` `date: Fri,21 Oct 2022 00:32:45 GMT` `server: Kestrel`

Responses

Code	Description	Links
200	Success Media type: text/plain Controls Accept header. Example Value | Schema `{ "id": 0, "name": "string", "isComplete": true }`	*No links*

Examine the GET methods

Two GET endpoints are implemented:

- `GET /api/todoitems`
- `GET /api/todoitems/{id}`

The previous section showed an example of the `/api/todoitems/{id}` route.

Follow the POST instructions to add another todo item, and then test the `/api/todoitems` route using Swagger.

This app uses an in-memory database. If the app is stopped and started, the preceding GET request doesn't return any data. If no data is returned, POST data to the app.

Routing and URL paths

The [HttpGet] attribute denotes a method that responds to an `HTTP GET` request. The URL path for each method is constructed as follows:

- Start with the template string in the controller's `Route` attribute:

```
C#

[Route("api/[controller]")]
[ApiController]
public class TodoItemsController : ControllerBase
```

- Replace `[controller]` with the name of the controller, which by convention is the controller class name minus the "Controller" suffix. For this sample, the controller class name is **TodoItems**Controller, so the controller name is "TodoItems". ASP.NET Core routing is case insensitive.

- If the `[HttpGet]` attribute has a route template (for example, `[HttpGet("products")]`), append that to the path. This sample doesn't use a template. For more information, see Attribute routing with Http[Verb] attributes.

In the following `GetTodoItem` method, `"{id}"` is a placeholder variable for the unique identifier of the to-do item. When `GetTodoItem` is invoked, the value of `"{id}"` in the URL is provided to the method in its `id` parameter.

C#

```
[HttpGet("{id}")]
public async Task<ActionResult<TodoItem>> GetTodoItem(long id)
{
    var todoItem = await _context.TodoItems.FindAsync(id);

    if (todoItem == null)
    {
        return NotFound();
    }

    return todoItem;
}
```

Return values

The return type of the `GetTodoItems` and `GetTodoItem` methods is ActionResult<T> type. ASP.NET Core automatically serializes the object to JSON and writes the JSON into the body of the response message. The response code for this return type is 200 OK, assuming there are no unhandled exceptions. Unhandled exceptions are translated into 5xx errors.

`ActionResult` return types can represent a wide range of HTTP status codes. For example, `GetTodoItem` can return two different status values:

- If no item matches the requested ID, the method returns a 404 status NotFound error code.
- Otherwise, the method returns 200 with a JSON response body. Returning `item` results in an `HTTP 200` response.

The PutTodoItem method

Examine the `PutTodoItem` method:

C#

```
[HttpPut("{id}")]
public async Task<IActionResult> PutTodoItem(long id, TodoItem todoItem)
{
    if (id != todoItem.Id)
    {
        return BadRequest();
    }

    _context.Entry(todoItem).State = EntityState.Modified;
```

```
    try
    {
        await _context.SaveChangesAsync();
    }
    catch (DbUpdateConcurrencyException)
    {
        if (!TodoItemExists(id))
        {
            return NotFound();
        }
        else
        {
            throw;
        }
    }

    return NoContent();
}
```

`PutTodoItem` is similar to `PostTodoItem`, except it uses `HTTP PUT`. The response is 204 (No Content). According to the HTTP specification, a `PUT` request requires the client to send the entire updated entity, not just the changes. To support partial updates, use HTTP PATCH.

Test the PutTodoItem method

This sample uses an in-memory database that must be initialized each time the app is started. There must be an item in the database before you make a PUT call. Call GET to ensure there's an item in the database before making a PUT call.

Using the Swagger UI, use the PUT button to update the `TodoItem` that has Id = 1 and set its name to `"feed fish"`. Note the response is HTTP 204 No Content.

The DeleteTodoItem method

Examine the `DeleteTodoItem` method:

C#

```
[HttpDelete("{id}")]
public async Task<IActionResult> DeleteTodoItem(long id)
{
    var todoItem = await _context.TodoItems.FindAsync(id);
    if (todoItem == null)
    {
        return NotFound();
```

```
    }

    _context.TodoItems.Remove(todoItem);
    await _context.SaveChangesAsync();

    return NoContent();
}
```

Test the DeleteTodoItem method

Use the Swagger UI to delete the `TodoItem` that has Id = 1. Note the response is HTTP 204 No Content.

Test with other tools

There are many other tools that can be used to test web APIs, for example:

- Visual Studio Endpoints Explorer and .http files
- http-repl
- curl. Swagger uses `curl` and shows the `curl` commands it submits.
- Fiddler

For more information, see:

- Minimal API tutorial: test with .http files and Endpoints Explorer
- Install and test APIs with http-repl

Prevent over-posting

Currently the sample app exposes the entire `TodoItem` object. Production apps typically limit the data that's input and returned using a subset of the model. There are multiple reasons behind this, and security is a major one. The subset of a model is usually referred to as a Data Transfer Object (DTO), input model, or view model. **DTO** is used in this tutorial.

A DTO may be used to:

- Prevent over-posting.
- Hide properties that clients are not supposed to view.
- Omit some properties in order to reduce payload size.
- Flatten object graphs that contain nested objects. Flattened object graphs can be more convenient for clients.

To demonstrate the DTO approach, update the `TodoItem` class to include a secret field:

C#

```
namespace TodoApi.Models
{
    public class TodoItem
    {
        public long Id { get; set; }
        public string? Name { get; set; }
        public bool IsComplete { get; set; }
        public string? Secret { get; set; }
    }
}
```

The secret field needs to be hidden from this app, but an administrative app could choose to expose it.

Verify you can post and get the secret field.

Create a DTO model:

C#

```
namespace TodoApi.Models;

public class TodoItemDTO
{
    public long Id { get; set; }
    public string? Name { get; set; }
    public bool IsComplete { get; set; }
}
```

Update the `TodoItemsController` to use `TodoItemDTO`:

C#

```
using Microsoft.AspNetCore.Mvc;
using Microsoft.EntityFrameworkCore;
using TodoApi.Models;

namespace TodoApi.Controllers;

[Route("api/[controller]")]
[ApiController]
public class TodoItemsController : ControllerBase
{
    private readonly TodoContext _context;

    public TodoItemsController(TodoContext context)
```

```
    {
        _context = context;
    }

    // GET: api/TodoItems
    [HttpGet]
    public async Task<ActionResult<IEnumerable<TodoItemDTO>>> GetTodoItems()
    {
        return await _context.TodoItems
            .Select(x => ItemToDTO(x))
            .ToListAsync();
    }

    // GET: api/TodoItems/5
    // <snippet_GetByID>
    [HttpGet("{id}")]
    public async Task<ActionResult<TodoItemDTO>> GetTodoItem(long id)
    {
        var todoItem = await _context.TodoItems.FindAsync(id);

        if (todoItem == null)
        {
            return NotFound();
        }

        return ItemToDTO(todoItem);
    }
    // </snippet_GetByID>

    // PUT: api/TodoItems/5
    // To protect from overposting attacks, see
https://go.microsoft.com/fwlink/?linkid=2123754
    // <snippet_Update>
    [HttpPut("{id}")]
    public async Task<IActionResult> PutTodoItem(long id, TodoItemDTO
todoDTO)
    {
        if (id != todoDTO.Id)
        {
            return BadRequest();
        }

        var todoItem = await _context.TodoItems.FindAsync(id);
        if (todoItem == null)
        {
            return NotFound();
        }

        todoItem.Name = todoDTO.Name;
        todoItem.IsComplete = todoDTO.IsComplete;

        try
        {
            await _context.SaveChangesAsync();
        }
```

```
        catch (DbUpdateConcurrencyException) when (!TodoItemExists(id))
        {
            return NotFound();
        }

        return NoContent();
    }
    // </snippet_Update>

    // POST: api/TodoItems
    // To protect from overposting attacks, see
https://go.microsoft.com/fwlink/?linkid=2123754
    // <snippet_Create>
    [HttpPost]
    public async Task<ActionResult<TodoItemDTO>> PostTodoItem(TodoItemDTO
todoDTO)
    {
        var todoItem = new TodoItem
        {
            IsComplete = todoDTO.IsComplete,
            Name = todoDTO.Name
        };

        _context.TodoItems.Add(todoItem);
        await _context.SaveChangesAsync();

        return CreatedAtAction(
            nameof(GetTodoItem),
            new { id = todoItem.Id },
            ItemToDTO(todoItem));
    }
    // </snippet_Create>

    // DELETE: api/TodoItems/5
    [HttpDelete("{id}")]
    public async Task<IActionResult> DeleteTodoItem(long id)
    {
        var todoItem = await _context.TodoItems.FindAsync(id);
        if (todoItem == null)
        {
            return NotFound();
        }

        _context.TodoItems.Remove(todoItem);
        await _context.SaveChangesAsync();

        return NoContent();
    }

    private bool TodoItemExists(long id)
    {
        return _context.TodoItems.Any(e => e.Id == id);
    }

    private static TodoItemDTO ItemToDTO(TodoItem todoItem) =>
```

```
        new TodoItemDTO
        {
            Id = todoItem.Id,
            Name = todoItem.Name,
            IsComplete = todoItem.IsComplete
        };
}
```

Verify you can't post or get the secret field.

Call the web API with JavaScript

See Tutorial: Call an ASP.NET Core web API with JavaScript.

Web API video series

See Video: Beginner's Series to: Web APIs.

Reliable web app patterns

See *The Reliable Web App Pattern for.NET* YouTube videos and article for guidance on creating a modern, reliable, performant, testable, cost-efficient, and scalable ASP.NET Core app, whether from scratch or refactoring an existing app.

Add authentication support to a web API

ASP.NET Core Identity adds user interface (UI) login functionality to ASP.NET Core web apps. To secure web APIs and SPAs, use one of the following:

- Microsoft Entra ID
- Azure Active Directory B2C (Azure AD B2C)
- Duende Identity Server

Duende Identity Server is an OpenID Connect and OAuth 2.0 framework for ASP.NET Core. Duende Identity Server enables the following security features:

- Authentication as a Service (AaaS)
- Single sign-on/off (SSO) over multiple application types
- Access control for APIs
- Federation Gateway

> **Important**
>
> Duende Software might require you to pay a license fee for production use of Duende Identity Server. For more information, see **Migrate from ASP.NET Core 5.0 to 6.0**.

For more information, see the Duende Identity Server documentation (Duende Software website).

Publish to Azure

For information on deploying to Azure, see Quickstart: Deploy an ASP.NET web app.

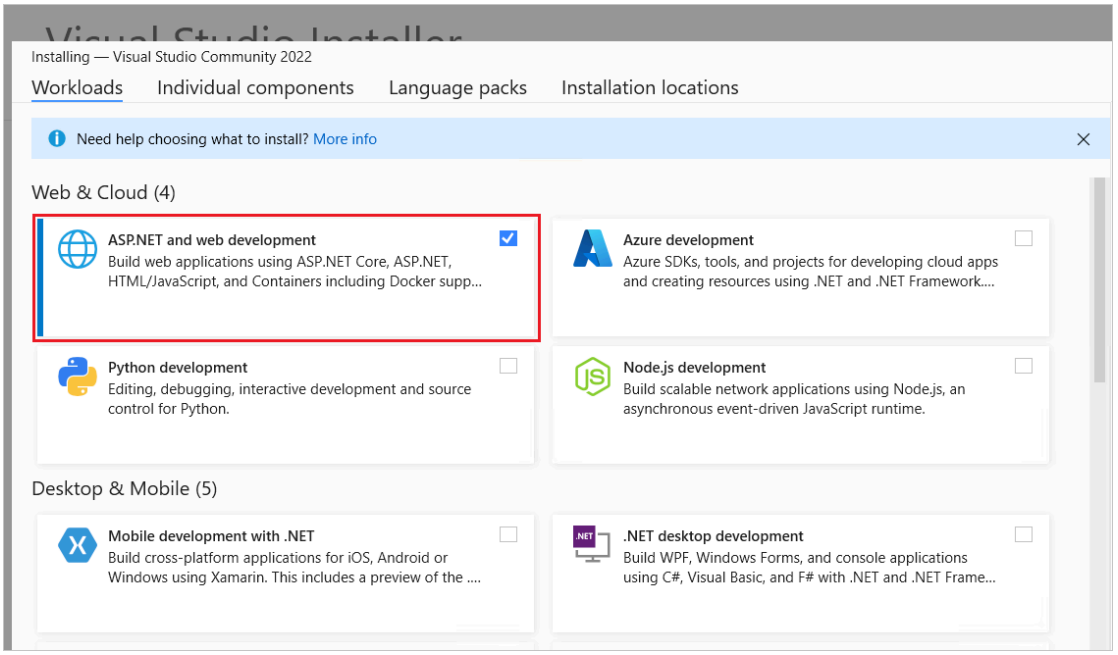
> For the current release, see the .NET 8 version of this article.

By Pratik Khandelwal and Scott Addie

This tutorial creates a web API that runs Create, Read, Update, and Delete (CRUD) operations on a MongoDB NoSQL database.

In this tutorial, you learn how to:



- ✓ Configure MongoDB
- ✓ Create a MongoDB database
- ✓ Define a MongoDB collection and schema
- ✓ Perform MongoDB CRUD operations from a web API
- ✓ Customize JSON serialization

Prerequisites

- MongoDB 6.0.5 or later
- MongoDB Shell

Visual Studio

- Visual Studio 2022 with the **ASP.NET and web development** workload.

Configure MongoDB

Enable MongoDB and MongoDB Shell access from anywhere on the development machine (Windows/Linux/macOS):

1. Download and Install MongoDB Shell:

    - macOS/Linux: Choose a directory to extract the MongoDB Shell to. Add the resulting path for `mongosh` to the `PATH` environment variable.
    - Windows: MongoDB Shell (mongosh.exe) is installed at *C:\Users<user>\AppData\Local\Programs\mongosh*. Add the resulting path for `mongosh.exe` to the `PATH` environment variable.

2. Download and Install MongoDB:

    - macOS/Linux: Verify the directory that MongoDB was installed at, usually in */usr/local/mongodb*. Add the resulting path for `mongodb` to the `PATH` environment variable.
    - Windows: MongoDB is installed at *C:\Program Files\MongoDB* by default. Add *C:\Program Files\MongoDB\Server\<version_number>\bin* to the `PATH` environment variable.

3. Choose a Data Storage Directory: Select a directory on your development machine for storing data. Create the directory if it doesn't exist. The MongoDB Shell doesn't create new directories:

    - macOS/Linux: For example, `/usr/local/var/mongodb`.

- Windows: For example, `C:\\BooksData`.

4. In the OS command shell (not the MongoDB Shell), use the following command to connect to MongoDB on default port 27017. Replace `<data_directory_path>` with the directory chosen in the previous step.

```
Console

mongod --dbpath <data_directory_path>
```

Use the previously installed MongoDB Shell in the following steps to create a database, make collections, and store documents. For more information on MongoDB Shell commands, see mongosh.

1. Open a MongoDB command shell instance by launching `mongosh.exe`.

2. In the command shell, connect to the default test database by running the following command:

```
Console

mongosh
```

3. Run the following command in the command shell:

```
Console

use BookStore
```

   A database named *BookStore* is created if it doesn't already exist. If the database does exist, its connection is opened for transactions.

4. Create a `Books` collection using following command:

```
Console

db.createCollection('Books')
```

   The following result is displayed:

```
Console

{ "ok" : 1 }
```

5. Define a schema for the `Books` collection and insert two documents using the following command:

```
Console

db.Books.insertMany([{ "Name": "Design Patterns", "Price": 54.93,
"Category": "Computers", "Author": "Ralph Johnson" }, { "Name": "Clean
Code", "Price": 43.15, "Category": "Computers","Author": "Robert C.
Martin" }])
```

A result similar to the following is displayed:

```
Console

{
    "acknowledged" : true,
    "insertedIds" : [
        ObjectId("61a6058e6c43f32854e51f51"),
        ObjectId("61a6058e6c43f32854e51f52")
    ]
}
```

> **Note**
>
> The `ObjectId`s shown in the preceding result won't match those shown in the command shell.

6. View the documents in the database using the following command:

```
Console

db.Books.find().pretty()
```

A result similar to the following is displayed:

```
Console

{
    "_id" : ObjectId("61a6058e6c43f32854e51f51"),
    "Name" : "Design Patterns",
    "Price" : 54.93,
    "Category" : "Computers",
    "Author" : "Ralph Johnson"
}
{
    "_id" : ObjectId("61a6058e6c43f32854e51f52"),
```

```
    "Name" : "Clean Code",
    "Price" : 43.15,
    "Category" : "Computers",
    "Author" : "Robert C. Martin"
}
```

The schema adds an autogenerated `_id` property of type `ObjectId` for each document.

Create the ASP.NET Core web API project

Visual Studio

1. Go to **File** > **New** > **Project**.
2. Select the **ASP.NET Core Web API** project type, and select **Next**.
3. Name the project *BookStoreApi*, and select **Next**.
4. Select the **.NET 8.0 (Long Term support)** framework and select **Create**.
5. In the **Package Manager Console** window, navigate to the project root. Run the following command to install the .NET driver for MongoDB:

PowerShell

```
Install-Package MongoDB.Driver
```

Add an entity model

1. Add a *Models* directory to the project root.
2. Add a `Book` class to the *Models* directory with the following code:

C#

```
using MongoDB.Bson;
using MongoDB.Bson.Serialization.Attributes;

namespace BookStoreApi.Models;

public class Book
{
```

```
    [BsonId]
    [BsonRepresentation(BsonType.ObjectId)]
    public string? Id { get; set; }

    [BsonElement("Name")]
    public string BookName { get; set; } = null!;

    public decimal Price { get; set; }

    public string Category { get; set; } = null!;

    public string Author { get; set; } = null!;
}
```

In the preceding class, the `Id` property is:

- Required for mapping the Common Language Runtime (CLR) object to the MongoDB collection.
- Annotated with [BsonId] to make this property the document's primary key.
- Annotated with [BsonRepresentation(BsonType.ObjectId)] to allow passing the parameter as type `string` instead of an ObjectId structure. Mongo handles the conversion from `string` to `ObjectId`.

The `BookName` property is annotated with the [BsonElement] attribute. The attribute's value of `Name` represents the property name in the MongoDB collection.

Add a configuration model

1. Add the following database configuration values to `appsettings.json`:

JSON

```
{
    "BookStoreDatabase": {
        "ConnectionString": "mongodb://localhost:27017",
        "DatabaseName": "BookStore",
        "BooksCollectionName": "Books"
    },
    "Logging": {
        "LogLevel": {
            "Default": "Information",
            "Microsoft.AspNetCore": "Warning"
        }
    },
    "AllowedHosts": "*"
}
```

2. Add a `BookStoreDatabaseSettings` class to the *Models* directory with the following code:

```C#
namespace BookStoreApi.Models;

public class BookStoreDatabaseSettings
{
    public string ConnectionString { get; set; } = null!;

    public string DatabaseName { get; set; } = null!;

    public string BooksCollectionName { get; set; } = null!;
}
```

   The preceding `BookStoreDatabaseSettings` class is used to store the `appsettings.json` file's `BookStoreDatabase` property values. The JSON and C# property names are named identically to ease the mapping process.

3. Add the following highlighted code to `Program.cs`:

```C#
var builder = WebApplication.CreateBuilder(args);

// Add services to the container.
builder.Services.Configure<BookStoreDatabaseSettings>(
    builder.Configuration.GetSection("BookStoreDatabase"));
```

   In the preceding code, the configuration instance to which the `appsettings.json` file's `BookStoreDatabase` section binds is registered in the Dependency Injection (DI) container. For example, the `BookStoreDatabaseSettings` object's `ConnectionString` property is populated with the `BookStoreDatabase:ConnectionString` property in `appsettings.json`.

4. Add the following code to the top of `Program.cs` to resolve the `BookStoreDatabaseSettings` reference:

```C#
using BookStoreApi.Models;
```

Add a CRUD operations service

1. Add a *Services* directory to the project root.

2. Add a `BooksService` class to the *Services* directory with the following code:

C#

```
using BookStoreApi.Models;
using Microsoft.Extensions.Options;
using MongoDB.Driver;

namespace BookStoreApi.Services;

public class BooksService
{
    private readonly IMongoCollection<Book> _booksCollection;

    public BooksService(
        IOptions<BookStoreDatabaseSettings> bookStoreDatabaseSettings)
    {
        var mongoClient = new MongoClient(
            bookStoreDatabaseSettings.Value.ConnectionString);

        var mongoDatabase = mongoClient.GetDatabase(
            bookStoreDatabaseSettings.Value.DatabaseName);

        _booksCollection = mongoDatabase.GetCollection<Book>(
            bookStoreDatabaseSettings.Value.BooksCollectionName);
    }

    public async Task<List<Book>> GetAsync() =>
        await _booksCollection.Find(_ => true).ToListAsync();

    public async Task<Book?> GetAsync(string id) =>
        await _booksCollection.Find(x => x.Id ==
id).FirstOrDefaultAsync();

    public async Task CreateAsync(Book newBook) =>
        await _booksCollection.InsertOneAsync(newBook);

    public async Task UpdateAsync(string id, Book updatedBook) =>
        await _booksCollection.ReplaceOneAsync(x => x.Id == id,
updatedBook);

    public async Task RemoveAsync(string id) =>
        await _booksCollection.DeleteOneAsync(x => x.Id == id);
}
```

In the preceding code, a `BookStoreDatabaseSettings` instance is retrieved from DI via constructor injection. This technique provides access to the `appsettings.json` configuration values that were added in the Add a configuration model section.

3. Add the following highlighted code to `Program.cs`:

```C#
var builder = WebApplication.CreateBuilder(args);

// Add services to the container.
builder.Services.Configure<BookStoreDatabaseSettings>(
    builder.Configuration.GetSection("BookStoreDatabase"));

builder.Services.AddSingleton<BooksService>();
```

In the preceding code, the `BooksService` class is registered with DI to support constructor injection in consuming classes. The singleton service lifetime is most appropriate because `BooksService` takes a direct dependency on `MongoClient`. Per the official Mongo Client reuse guidelines, `MongoClient` should be registered in DI with a singleton service lifetime.

4. Add the following code to the top of `Program.cs` to resolve the `BooksService` reference:

```C#
using BookStoreApi.Services;
```

The `BooksService` class uses the following `MongoDB.Driver` members to run CRUD operations against the database:

- MongoClient: Reads the server instance for running database operations. The constructor of this class is provided in the MongoDB connection string:

```C#
public BooksService(
    IOptions<BookStoreDatabaseSettings> bookStoreDatabaseSettings)
{
    var mongoClient = new MongoClient(
        bookStoreDatabaseSettings.Value.ConnectionString);

    var mongoDatabase = mongoClient.GetDatabase(
        bookStoreDatabaseSettings.Value.DatabaseName);

    _booksCollection = mongoDatabase.GetCollection<Book>(
        bookStoreDatabaseSettings.Value.BooksCollectionName);
}
```

- IMongoDatabase: Represents the Mongo database for running operations. This tutorial uses the generic GetCollection<TDocument>(collection) method on the interface to gain access to data in a specific collection. Run CRUD operations against the collection after this method is called. In the `GetCollection<TDocument>(collection)` method call:
  - `collection` represents the collection name.
  - `TDocument` represents the CLR object type stored in the collection.

`GetCollection<TDocument>(collection)` returns a MongoCollection object representing the collection. In this tutorial, the following methods are invoked on the collection:

- DeleteOneAsync: Deletes a single document matching the provided search criteria.
- Find<TDocument>: Returns all documents in the collection matching the provided search criteria.
- InsertOneAsync: Inserts the provided object as a new document in the collection.
- ReplaceOneAsync: Replaces the single document matching the provided search criteria with the provided object.

Add a controller

Add a `BooksController` class to the *Controllers* directory with the following code:

C#

```
using BookStoreApi.Models;
using BookStoreApi.Services;
using Microsoft.AspNetCore.Mvc;

namespace BookStoreApi.Controllers;

[ApiController]
[Route("api/[controller]")]
public class BooksController : ControllerBase
{
    private readonly BooksService _booksService;

    public BooksController(BooksService booksService) =>
        _booksService = booksService;

    [HttpGet]
    public async Task<List<Book>> Get() =>
        await _booksService.GetAsync();

    [HttpGet("{id:length(24)}")]
```

```
    public async Task<ActionResult<Book>> Get(string id)
    {
        var book = await _booksService.GetAsync(id);

        if (book is null)
        {
            return NotFound();
        }

        return book;
    }

    [HttpPost]
    public async Task<IActionResult> Post(Book newBook)
    {
        await _booksService.CreateAsync(newBook);

        return CreatedAtAction(nameof(Get), new { id = newBook.Id },
newBook);
    }

    [HttpPut("{id:length(24)}")]
    public async Task<IActionResult> Update(string id, Book updatedBook)
    {
        var book = await _booksService.GetAsync(id);

        if (book is null)
        {
            return NotFound();
        }

        updatedBook.Id = book.Id;

        await _booksService.UpdateAsync(id, updatedBook);

        return NoContent();
    }

    [HttpDelete("{id:length(24)}")]
    public async Task<IActionResult> Delete(string id)
    {
        var book = await _booksService.GetAsync(id);

        if (book is null)
        {
            return NotFound();
        }

        await _booksService.RemoveAsync(id);

        return NoContent();
    }
}
```

The preceding web API controller:

- Uses the `BooksService` class to run CRUD operations.
- Contains action methods to support GET, POST, PUT, and DELETE HTTP requests.
- Calls CreatedAtAction in the `Create` action method to return an HTTP 201 response. Status code 201 is the standard response for an HTTP POST method that creates a new resource on the server. `CreatedAtAction` also adds a `Location` header to the response. The `Location` header specifies the URI of the newly created book.

Test the web API

1. Build and run the app.

2. Navigate to `https://localhost:<port>/api/books`, where `<port>` is the automatically assigned port number for the app, to test the controller's parameterless `Get` action method, select **Try it out** > **Execute**. A JSON response similar to the following is displayed:

   JSON

   ```
   [
     {
       "id": "61a6058e6c43f32854e51f51",
       "bookName": "Design Patterns",
       "price": 54.93,
       "category": "Computers",
       "author": "Ralph Johnson"
     },
     {
       "id": "61a6058e6c43f32854e51f52",
       "bookName": "Clean Code",
       "price": 43.15,
       "category": "Computers",
       "author": "Robert C. Martin"
     }
   ]
   ```

3. Navigate to `https://localhost:<port>/api/books/{id here}` to test the controller's overloaded `Get` action method. A JSON response similar to the following is displayed:

   JSON

   ```
   {
     "id": "61a6058e6c43f32854e51f52",
   ```

```
  "bookName": "Clean Code",
  "price": 43.15,
  "category": "Computers",
  "author": "Robert C. Martin"
}
```

Configure JSON serialization options

There are two details to change about the JSON responses returned in the Test the web API section:

- The property names' default camel casing should be changed to match the Pascal casing of the CLR object's property names.
- The `bookName` property should be returned as `Name`.

To satisfy the preceding requirements, make the following changes:

1. In `Program.cs`, chain the following highlighted code on to the `AddControllers` method call:

   C#

   ```
   var builder = WebApplication.CreateBuilder(args);

   // Add services to the container.
   builder.Services.Configure<BookStoreDatabaseSettings>(
       builder.Configuration.GetSection("BookStoreDatabase"));

   builder.Services.AddSingleton<BooksService>();

   builder.Services.AddControllers()
       .AddJsonOptions(
           options => options.JsonSerializerOptions.PropertyNamingPolicy =
   null);
   ```

   With the preceding change, property names in the web API's serialized JSON response match their corresponding property names in the CLR object type. For example, the `Book` class's `Author` property serializes as `Author` instead of `author`.

2. In `Models/Book.cs`, annotate the `BookName` property with the [JsonPropertyName] attribute:

   C#

   ```
   [BsonElement("Name")]
   [JsonPropertyName("Name")]
   ```

```
public string BookName { get; set; } = null!;
```

The `[JsonPropertyName]` attribute's value of `Name` represents the property name in the web API's serialized JSON response.

3. Add the following code to the top of `Models/Book.cs` to resolve the `[JsonProperty]` attribute reference:

```
C#

using System.Text.Json.Serialization;
```

4. Repeat the steps defined in the Test the web API section. Notice the difference in JSON property names.

Add authentication support to a web API

ASP.NET Core Identity adds user interface (UI) login functionality to ASP.NET Core web apps. To secure web APIs and SPAs, use one of the following:

- Microsoft Entra ID
- Azure Active Directory B2C (Azure AD B2C)
- Duende Identity Server

Duende Identity Server is an OpenID Connect and OAuth 2.0 framework for ASP.NET Core. Duende Identity Server enables the following security features:

- Authentication as a Service (AaaS)
- Single sign-on/off (SSO) over multiple application types
- Access control for APIs
- Federation Gateway

> **Important**
>
> Duende Software might require you to pay a license fee for production use of Duende Identity Server. For more information, see Migrate from ASP.NET Core 5.0 to 6.0.

For more information, see the Duende Identity Server documentation (Duende Software website).

Tutorial: Call an ASP.NET Core web API with JavaScript

Article • 04/24/2024

By Rick Anderson

This tutorial shows how to call an ASP.NET Core web API with JavaScript, using the Fetch API.

Prerequisites

- Complete Tutorial: Create a web API
- Familiarity with CSS, HTML, and JavaScript

Call the web API with JavaScript

In this section, you'll add an HTML page containing forms for creating and managing to-do items. Event handlers are attached to elements on the page. The event handlers result in HTTP requests to the web API's action methods. The Fetch API's `fetch` function initiates each HTTP request.

The `fetch` function returns a Promise object, which contains an HTTP response represented as a `Response` object. A common pattern is to extract the JSON response body by invoking the `json` function on the `Response` object. JavaScript updates the page with the details from the web API's response.

The simplest `fetch` call accepts a single parameter representing the route. A second parameter, known as the `init` object, is optional. `init` is used to configure the HTTP request.

1. Configure the app to serve static files and enable default file mapping. The following highlighted code is needed in `Program.cs`:

C#

```
using Microsoft.EntityFrameworkCore;
using TodoApi.Models;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddControllers();
```

```
builder.Services.AddDbContext<TodoContext>(opt =>
    opt.UseInMemoryDatabase("TodoList"));

var app = builder.Build();

if (builder.Environment.IsDevelopment())
{
    app.UseDeveloperExceptionPage();
}

app.UseDefaultFiles();
app.UseStaticFiles();

app.UseHttpsRedirection();

app.UseAuthorization();

app.MapControllers();

app.Run();
```

1. Create a *wwwroot* folder in the project root.
2. Create a *css* folder inside of the *wwwroot* folder.
3. Create a *js* folder inside of the *wwwroot* folder.
4. Add an HTML file named `index.html` to the *wwwroot* folder. Replace the contents of `index.html` with the following markup:

HTML

```
<!DOCTYPE html>
<html>
<head>
    <meta charset="UTF-8">
    <title>To-do CRUD</title>
    <link rel="stylesheet" href="css/site.css" />
</head>
<body>
    <h1>To-do CRUD</h1>
    <h3>Add</h3>
    <form action="javascript:void(0);" method="POST"
onsubmit="addItem()">
        <input type="text" id="add-name" placeholder="New to-do">
        <input type="submit" value="Add">
    </form>

    <div id="editForm">
        <h3>Edit</h3>
        <form action="javascript:void(0);" onsubmit="updateItem()">
            <input type="hidden" id="edit-id">
```

```
            <input type="checkbox" id="edit-isComplete">
            <input type="text" id="edit-name">
            <input type="submit" value="Save">
            <a onclick="closeInput()" aria-label="Close">&#10006;</a>
        </form>
    </div>

    <p id="counter"></p>

    <table>
        <tr>
            <th>Is Complete?</th>
            <th>Name</th>
            <th></th>
            <th></th>
        </tr>
        <tbody id="todos"></tbody>
    </table>

    <script src="js/site.js" asp-append-version="true"></script>
    <script type="text/javascript">
        getItems();
    </script>
</body>
</html>
```

5. Add a CSS file named `site.css` to the *wwwroot/css* folder. Replace the contents of `site.css` with the following styles:

```css
input[type='submit'], button, [aria-label] {
    cursor: pointer;
}

#editForm {
    display: none;
}

table {
    font-family: Arial, sans-serif;
    border: 1px solid;
    border-collapse: collapse;
}

th {
    background-color: #f8f8f8;
    padding: 5px;
}

td {
    border: 1px solid;
```

```
    padding: 5px;
}
```

6. Add a JavaScript file named `site.js` to the *wwwroot/js* folder. Replace the contents of `site.js` with the following code:

JavaScript

```
const uri = 'api/todoitems';
let todos = [];

function getItems() {
  fetch(uri)
    .then(response => response.json())
    .then(data => _displayItems(data))
    .catch(error => console.error('Unable to get items.', error));
}

function addItem() {
  const addNameTextbox = document.getElementById('add-name');

  const item = {
    isComplete: false,
    name: addNameTextbox.value.trim()
  };

  fetch(uri, {
    method: 'POST',
    headers: {
      'Accept': 'application/json',
      'Content-Type': 'application/json'
    },
    body: JSON.stringify(item)
  })
    .then(response => response.json())
    .then(() => {
      getItems();
      addNameTextbox.value = '';
    })
    .catch(error => console.error('Unable to add item.', error));
}

function deleteItem(id) {
  fetch(`${uri}/${id}`, {
    method: 'DELETE'
  })
  .then(() => getItems())
  .catch(error => console.error('Unable to delete item.', error));
}

function displayEditForm(id) {
  const item = todos.find(item => item.id === id);
```

```
  document.getElementById('edit-name').value = item.name;
  document.getElementById('edit-id').value = item.id;
  document.getElementById('edit-isComplete').checked = item.isComplete;
  document.getElementById('editForm').style.display = 'block';
}

function updateItem() {
  const itemId = document.getElementById('edit-id').value;
  const item = {
    id: parseInt(itemId, 10),
    isComplete: document.getElementById('edit-isComplete').checked,
    name: document.getElementById('edit-name').value.trim()
  };

  fetch(`${uri}/${itemId}`, {
    method: 'PUT',
    headers: {
      'Accept': 'application/json',
      'Content-Type': 'application/json'
    },
    body: JSON.stringify(item)
  })
  .then(() => getItems())
  .catch(error => console.error('Unable to update item.', error));

  closeInput();

  return false;
}

function closeInput() {
  document.getElementById('editForm').style.display = 'none';
}

function _displayCount(itemCount) {
  const name = (itemCount === 1) ? 'to-do' : 'to-dos';

  document.getElementById('counter').innerText = `${itemCount}
${name}`;
}

function _displayItems(data) {
  const tBody = document.getElementById('todos');
  tBody.innerHTML = '';

  _displayCount(data.length);

  const button = document.createElement('button');

  data.forEach(item => {
    let isCompleteCheckbox = document.createElement('input');
    isCompleteCheckbox.type = 'checkbox';
    isCompleteCheckbox.disabled = true;
    isCompleteCheckbox.checked = item.isComplete;
```

```
    let editButton = button.cloneNode(false);
    editButton.innerText = 'Edit';
    editButton.setAttribute('onclick', `displayEditForm(${item.id})`);

    let deleteButton = button.cloneNode(false);
    deleteButton.innerText = 'Delete';
    deleteButton.setAttribute('onclick', `deleteItem(${item.id})`);

    let tr = tBody.insertRow();

    let td1 = tr.insertCell(0);
    td1.appendChild(isCompleteCheckbox);

    let td2 = tr.insertCell(1);
    let textNode = document.createTextNode(item.name);
    td2.appendChild(textNode);

    let td3 = tr.insertCell(2);
    td3.appendChild(editButton);

    let td4 = tr.insertCell(3);
    td4.appendChild(deleteButton);
  });

  todos = data;
}
```

A change to the ASP.NET Core project's launch settings may be required to test the HTML page locally:

1. Open *Properties\launchSettings.json*.
2. Remove the `launchUrl` property to force the app to open at `index.html`—the project's default file.

This sample calls all of the CRUD methods of the web API. Following are explanations of the web API requests.

Get a list of to-do items

In the following code, an HTTP GET request is sent to the *api/todoitems* route:

JavaScript

```
fetch(uri)
  .then(response => response.json())
  .then(data => _displayItems(data))
  .catch(error => console.error('Unable to get items.', error));
```

When the web API returns a successful status code, the `_displayItems` function is invoked. Each to-do item in the array parameter accepted by `_displayItems` is added to a table with **Edit** and **Delete** buttons. If the web API request fails, an error is logged to the browser's console.

Add a to-do item

In the following code:

- An `item` variable is declared to construct an object literal representation of the to-do item.
- A Fetch request is configured with the following options:
  - `method`—specifies the POST HTTP action verb.
  - `body`—specifies the JSON representation of the request body. The JSON is produced by passing the object literal stored in `item` to the JSON.stringify function.
  - `headers`—specifies the `Accept` and `Content-Type` HTTP request headers. Both headers are set to `application/json` to specify the media type being received and sent, respectively.
- An HTTP POST request is sent to the *api/todoitems* route.

JavaScript

```
function addItem() {
  const addNameTextbox = document.getElementById('add-name');

  const item = {
    isComplete: false,
    name: addNameTextbox.value.trim()
  };

  fetch(uri, {
    method: 'POST',
    headers: {
      'Accept': 'application/json',
      'Content-Type': 'application/json'
    },
    body: JSON.stringify(item)
  })
    .then(response => response.json())
    .then(() => {
      getItems();
      addNameTextbox.value = '';
    })
    .catch(error => console.error('Unable to add item.', error));
}
```

When the web API returns a successful status code, the `getItems` function is invoked to update the HTML table. If the web API request fails, an error is logged to the browser's console.

Update a to-do item

Updating a to-do item is similar to adding one; however, there are two significant differences:

- The route is suffixed with the unique identifier of the item to update. For example, *api/todoitems/1*.
- The HTTP action verb is PUT, as indicated by the `method` option.

JavaScript

```
fetch(`${uri}/${itemId}`, {
  method: 'PUT',
  headers: {
    'Accept': 'application/json',
    'Content-Type': 'application/json'
  },
  body: JSON.stringify(item)
})
.then(() => getItems())
.catch(error => console.error('Unable to update item.', error));
```

Delete a to-do item

To delete a to-do item, set the request's `method` option to `DELETE` and specify the item's unique identifier in the URL.

JavaScript

```
fetch(`${uri}/${id}`, {
  method: 'DELETE'
})
.then(() => getItems())
.catch(error => console.error('Unable to delete item.', error));
```

Create backend services for native mobile apps with ASP.NET Core

Article • 07/23/2024

By James Montemagno

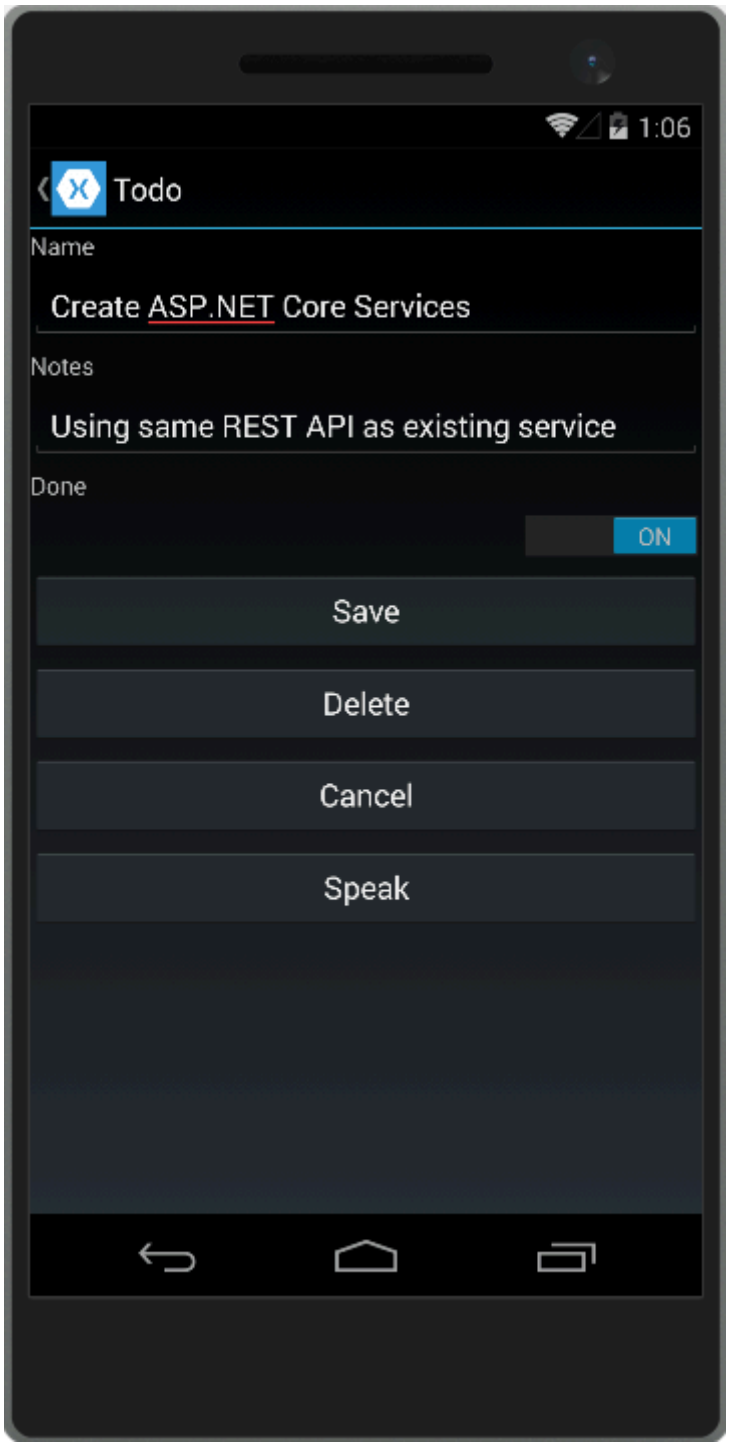
Mobile apps can communicate with ASP.NET Core backend services. For instructions on connecting local web services from iOS simulators and Android emulators, see Connect to Local Web Services from iOS Simulators and Android Emulators.

View or download sample backend services code

The Sample Native Mobile App

This tutorial demonstrates how to create backend services using ASP.NET Core to support native mobile apps. It uses the Xamarin.Forms TodoRest app as its native client, which includes separate native clients for Android, iOS, and Windows. You can follow the linked tutorial to create the native app (and install the necessary free Xamarin tools), and download the Xamarin sample solution. The Xamarin sample includes an ASP.NET Core Web API services project, which this article's ASP.NET Core app replaces (with no changes required by the client).

Features



The TodoREST app supports listing, adding, deleting, and updating To-Do items. Each item has an ID, a Name, Notes, and a property indicating whether it's been Done yet.

In the previous example, The main view of the items lists each item's name and indicates if it's done with a checkmark.

Tapping the `+` icon opens an add item dialog:

Tapping an item on the main list screen opens up an edit dialog where the item's Name, Notes, and Done settings can be modified, or the item can be deleted:

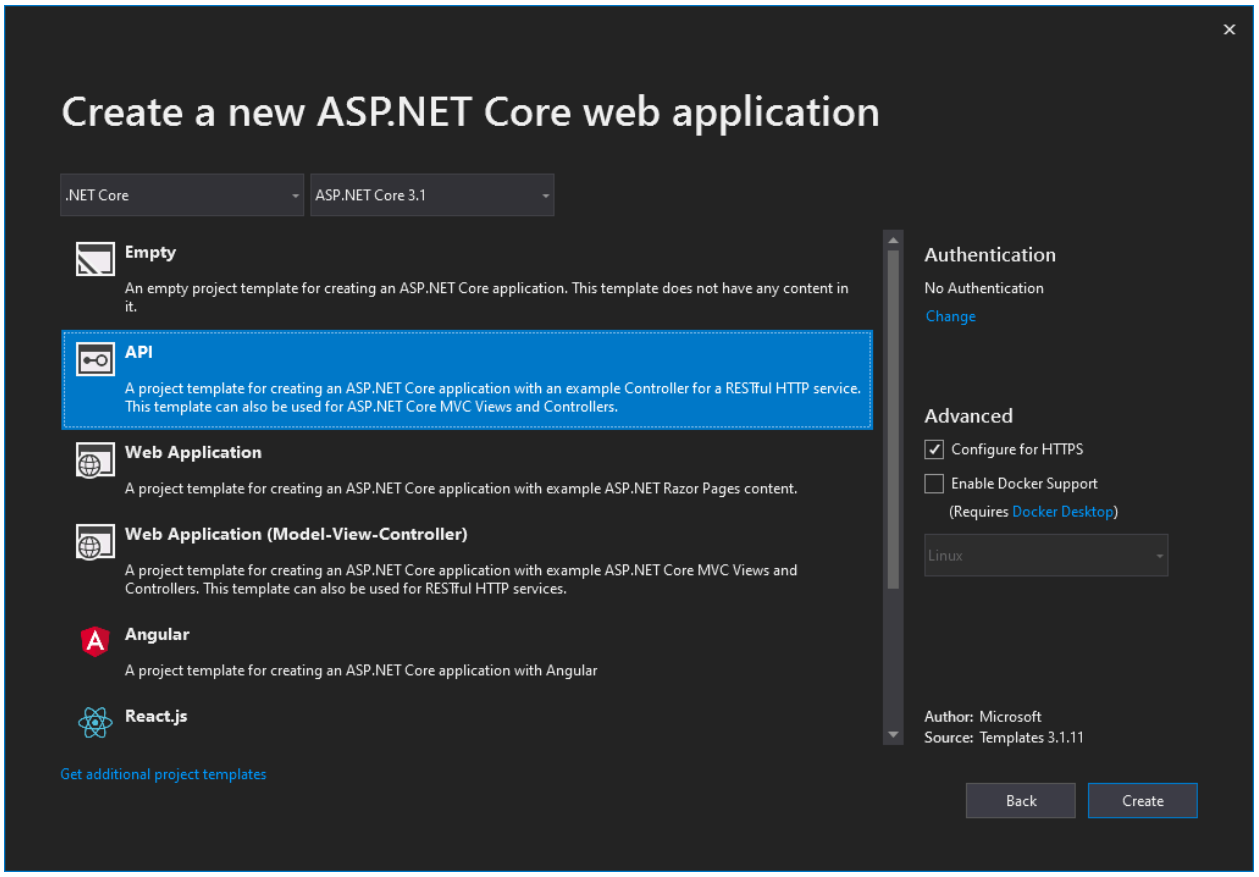
To test it out yourself against the ASP.NET Core app created in the next section running on your computer, update the app's RestUrl constant.

Android emulators don't run on the local machine and use a loopback IP (10.0.2.2) to communicate with the local machine. Use Xamarin.Essentials DeviceInfo to detect what operating the system is running to use the correct URL.

Navigate to the TodoREST project and open the Constants.cs file. The `Constants.cs` file contains the following configuration.

```
C#
```

```
using Xamarin.Essentials;
using Xamarin.Forms;



namespace TodoREST
{
    public static class Constants
    {
        // URL of REST service
        //public static string RestUrl =
"https://YOURPROJECT.azurewebsites.net:8081/api/todoitems/{0}";

        // URL of REST service (Android does not use localhost)
        // Use http cleartext for local deployment. Change to https for
production
        public static string RestUrl = DeviceInfo.Platform ==
DevicePlatform.Android ? "http://10.0.2.2:5000/api/todoitems/{0}" :
"http://localhost:5000/api/todoitems/{0}";
    }
}
```

You can optionally deploy the web service to a cloud service such as Azure and update the `RestUrl`.

Creating the ASP.NET Core Project

Create a new ASP.NET Core Web Application in Visual Studio. Choose the Web API template. Name the project *TodoAPI*.

The app should respond to all requests made to port 5000 including clear-text HTTP traffic for our mobile client. Update `Startup.cs` so UseHttpsRedirection doesn't run in development:

C#

```
public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }
    else
    {
        // For mobile apps, allow http traffic.
        app.UseHttpsRedirection();
    }

    app.UseRouting();

    app.UseAuthorization();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapControllers();
    });
}
```

> **Note**
>
> Run the app directly, rather than behind IIS Express. IIS Express ignores non-local requests by default. Run **dotnet run** from a command prompt, or choose the app name profile from the Debug Target dropdown in the Visual Studio toolbar.

Add a model class to represent To-Do items. Mark required fields with the `[Required]` attribute:

C#

```
using System.ComponentModel.DataAnnotations;

namespace TodoAPI.Models
{
    public class TodoItem
    {
        [Required]
        public string ID { get; set; }

        [Required]
        public string Name { get; set; }

        [Required]
        public string Notes { get; set; }

        public bool Done { get; set; }
    }
}
```

The API methods require some way to work with data. Use the same `ITodoRepository` interface the original Xamarin sample uses:

C#

```
using System.Collections.Generic;
using TodoAPI.Models;

namespace TodoAPI.Interfaces
{
    public interface ITodoRepository
    {
        bool DoesItemExist(string id);
        IEnumerable<TodoItem> All { get; }
        TodoItem Find(string id);
        void Insert(TodoItem item);
        void Update(TodoItem item);
        void Delete(string id);
```

```
    }
}
```

For this sample, the implementation just uses a private collection of items:

C#

```
using System.Collections.Generic;
using System.Linq;
using TodoAPI.Interfaces;
using TodoAPI.Models;

namespace TodoAPI.Services
{
    public class TodoRepository : ITodoRepository
    {
        private List<TodoItem> _todoList;

        public TodoRepository()
        {
            InitializeData();
        }

        public IEnumerable<TodoItem> All
        {
            get { return _todoList; }
        }

        public bool DoesItemExist(string id)
        {
            return _todoList.Any(item => item.ID == id);
        }

        public TodoItem Find(string id)
        {
            return _todoList.FirstOrDefault(item => item.ID == id);
        }

        public void Insert(TodoItem item)
        {
            _todoList.Add(item);
        }

        public void Update(TodoItem item)
        {
            var todoItem = this.Find(item.ID);
            var index = _todoList.IndexOf(todoItem);
            _todoList.RemoveAt(index);
            _todoList.Insert(index, item);
        }

        public void Delete(string id)
        {
```

```
            _todoList.Remove(this.Find(id));
        }

        private void InitializeData()
        {
            _todoList = new List<TodoItem>();

            var todoItem1 = new TodoItem
            {
                ID = "6bb8a868-dba1-4f1a-93b7-24ebce87e243",
                Name = "Learn app development",
                Notes = "Take Microsoft Learn Courses",
                Done = true
            };

            var todoItem2 = new TodoItem
            {
                ID = "b94afb54-a1cb-4313-8af3-b7511551b33b",
                Name = "Develop apps",
                Notes = "Use Visual Studio and Visual Studio for Mac",
                Done = false
            };

            var todoItem3 = new TodoItem
            {
                ID = "ecfa6f80-3671-4911-aabe-63cc442c1ecf",
                Name = "Publish apps",
                Notes = "All app stores",
                Done = false,
            };

            _todoList.Add(todoItem1);
            _todoList.Add(todoItem2);
            _todoList.Add(todoItem3);
        }
    }
}
```

Configure the implementation in `Startup.cs`:

C#

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddSingleton<ITodoRepository, TodoRepository>();
    services.AddControllers();
}
```

Creating the Controller

Add a new controller to the project, TodoItemsController. It should inherit from ControllerBase. Add a `Route` attribute to indicate that the controller handles requests made to paths starting with `api/todoitems`. The `[controller]` token in the route is replaced by the name of the controller (omitting the `Controller` suffix), and is especially helpful for global routes. Learn more about routing.

The controller requires an `ITodoRepository` to function; request an instance of this type through the controller's constructor. At runtime, this instance is provided using the framework's support for dependency injection.

C#

```
[ApiController]
[Route("api/[controller]")]
public class TodoItemsController : ControllerBase
{
    private readonly ITodoRepository _todoRepository;

    public TodoItemsController(ITodoRepository todoRepository)
    {
        _todoRepository = todoRepository;
    }
```

This API supports four different HTTP verbs to perform CRUD (Create, Read, Update, Delete) operations on the data source. The simplest of these is the Read operation, which corresponds to an HTTP `GET` request.

Test the API using curl

You can test the API method using a variety of tools. For this tutorial the following open source command-line tools are used:

- curl: Transfers data using various protocols including HTTP and HTTPS. curl is used in this tutorial to call the API using HTTP methods `GET`, `POST`, `PUT`, and `DELETE`.
- jq: A JSON processor used in this tutorial to format JSON data so that it's easy to read from the API response.

Install curl and jq

Windows

curl is installed with Windows 10, version 1802 or higher. For more information on installing curl, see the Official curl website.

Install jq with the following command in PowerShell or the Command Prompt:

PowerShell

```
winget install jqlang.jq
```

The `jq` command is available once the PowerShell or Command Prompt is closed and restarted.

For more details on jq installation, see jq.

Reading Items

Requesting a list of items is done with a GET request to the `List` method. The `[HttpGet]` attribute on the `List` method indicates that this action should only handle GET requests. The route for this action is the route specified on the controller. You don't necessarily need to use the action name as part of the route. You just need to ensure each action has a unique and unambiguous route. Routing attributes can be applied at both the controller and method levels to build up specific routes.

C#

```
[HttpGet]
public IActionResult List()
{
    return Ok(_todoRepository.All);
}
```

Windows

> **Note**
>
> Windows PowerShell 5.1 recognizes `curl` as an alias to `Invoke-WebRequest`. To use `curl.exe` instead, type the `&` operator followed by the full path to `curl.exe`. Find the full path to `curl.exe` by typing `where curl` in the Command Prompt. For example, if the full path to `curl.exe` is `C:\Windows\System32\curl.exe`. Then instead of typing the command `curl --`

`help`, use `& 'C:\Windows\System32\curl.exe' --help`. PowerShell 7 uses `curl` as the command for `curl.exe` and so a full path is not required.

In PowerShell, call the following curl command:

PowerShell

```
curl -v -X GET 'http://localhost:5000/api/todoitems/' | jq
```

The previous curl command includes the following components:

- `-v`: Activates verbose mode, providing detailed information about the HTTP response and is useful for API testing and troubleshooting.
- `-X GET`: Specifies the use of the HTTP `GET` method for the request. While curl can often infer the intended HTTP method, this option makes it explicit.
- `'http://localhost:5000/api/todoitems/'`: This is the request's target URL. In this instance, it's a REST API endpoint.
- `| jq`: This segment isn't related to curl directly. The pipe `|` is a shell operator that takes the output from the command on its left and "pipes" it to the command on its right. `jq` is a command-line JSON processor. While not required, `jq` makes the returned JSON data easier to read.

The `List` method returns a 200 OK response code and all of the Todo items, serialized as JSON:

Output

```
[
  {
    "id": "6bb8a868-dba1-4f1a-93b7-24ebce87e243",
    "name": "Learn app development",
    "notes": "Take Microsoft Learn Courses",
    "done": true
  },
  {
    "id": "b94afb54-a1cb-4313-8af3-b7511551b33b",
    "name": "Develop apps",
    "notes": "Use Visual Studio and Visual Studio for Mac",
    "done": false
  },
  {
    "id": "ecfa6f80-3671-4911-aabe-63cc442c1ecf",
    "name": "Publish apps",
    "notes": "All app stores",
    "done": false
```

```
  }
]
```

Creating Items

By convention, creating new data items is mapped to the HTTP `POST` verb. The `Create` method has an `[HttpPost]` attribute applied to it and accepts a `TodoItem` instance. Since the `item` argument is passed in the body of the POST, this parameter specifies the `[FromBody]` attribute.

Inside the method, the item is checked for validity and prior existence in the data store, and if no issues occur, it's added using the repository. Checking `ModelState.IsValid` performs model validation, and should be done in every API method that accepts user input.

C#

```
[HttpPost]
public IActionResult Create([FromBody]TodoItem item)
{
    try
    {
        if (item == null || !ModelState.IsValid)
        {
            return
BadRequest(ErrorCode.TodoItemNameAndNotesRequired.ToString());
        }
        bool itemExists = _todoRepository.DoesItemExist(item.ID);
        if (itemExists)
        {
            return StatusCode(StatusCodes.Status409Conflict,
ErrorCode.TodoItemIDInUse.ToString());
        }
        _todoRepository.Insert(item);
    }
    catch (Exception)
    {
        return BadRequest(ErrorCode.CouldNotCreateItem.ToString());
    }
    return Ok(item);
}
```

The sample uses an `enum` containing error codes that are passed to the mobile client:

C#

```
public enum ErrorCode
{
    TodoItemNameAndNotesRequired,
    TodoItemIDInUse,
    RecordNotFound,
    CouldNotCreateItem,
    CouldNotUpdateItem,
    CouldNotDeleteItem
}
```

In the terminal, test adding new items by calling the following curl command using the `POST` verb and providing the new object in JSON format in the Body of the request.

Windows

PowerShell

```
curl -v -X POST 'http://localhost:5000/api/todoitems/' `
--header 'Content-Type: application/json' `
--data '{
  "id": "6bb8b868-dba1-4f1a-93b7-24ebce87e243",
  "name": "A Test Item",
  "notes": "asdf",
  "done": false
}' | jq
```

The previous curl command includes the following options:

- `--header 'Content-Type: application/json'`: Sets the `Content-Type` header to `application/json`, indicating that the request body contains JSON data.
- `--data '{...}'`: Sends the specified data in the request body.

The method returns the newly created item in the response.

Updating Items

Modifying records is done using HTTP `PUT` requests. Other than this change, the `Edit` method is almost identical to `Create`. If the record isn't found, the `Edit` action returns a `NotFound` (404) response.

C#

```
[HttpPut]
public IActionResult Edit([FromBody] TodoItem item)
```

```
{
    try
    {
        if (item == null || !ModelState.IsValid)
        {
            return
BadRequest(ErrorCode.TodoItemNameAndNotesRequired.ToString());
        }
        var existingItem = _todoRepository.Find(item.ID);
        if (existingItem == null)
        {
            return NotFound(ErrorCode.RecordNotFound.ToString());
        }
        _todoRepository.Update(item);
    }
    catch (Exception)
    {
        return BadRequest(ErrorCode.CouldNotUpdateItem.ToString());
    }
    return NoContent();
}
```

To test with curl, change the verb to `PUT`. Specify the updated object data in the Body of the request.

Windows

PowerShell

```
curl -v -X PUT 'http://localhost:5000/api/todoitems/' `
--header 'Content-Type: application/json' `
--data '{
  "id": "6bb8b868-dba1-4f1a-93b7-24ebce87e243",
  "name": "A Test Item",
  "notes": "asdf",
  "done": true
}' | jq
```

This method returns a `NoContent` (204) response when successful, for consistency with the pre-existing API.

Deleting Items

Deleting records is accomplished by making `DELETE` requests to the service, and passing the ID of the item to be deleted. As with updates, requests for items that don't exist receive `NotFound` responses. Otherwise, a successful request returns a `NoContent` (204) response.

C#

```
[HttpDelete("{id}")]
public IActionResult Delete(string id)
{
    try
    {
        var item = _todoRepository.Find(id);
        if (item == null)
        {
            return NotFound(ErrorCode.RecordNotFound.ToString());
        }
        _todoRepository.Delete(id);
    }
    catch (Exception)
    {
        return BadRequest(ErrorCode.CouldNotDeleteItem.ToString());
    }
    return NoContent();
}
```

Test with curl by changing the HTTP verb to `DELETE` and appending the ID of the data object to delete at the end of the URL. Nothing is required in the Body of the request.

Windows

PowerShell

```
curl -v -X DELETE 'http://localhost:5000/api/todoitems/6bb8b868-dba1-4f1a-93b7-24ebce87e243'
```

Prevent over-posting

Currently the sample app exposes the entire `TodoItem` object. Production apps typically limit the data that's input and returned using a subset of the model. There are multiple reasons behind this and security is a major one. The subset of a model is usually referred to as a Data Transfer Object (DTO), input model, or view model. **DTO** is used in this article.

A DTO may be used to:

- Prevent over-posting.
- Hide properties that clients aren't supposed to view.
- Omit some properties to reduce payload size.

- Flatten object graphs that contain nested objects. Flattened object graphs can be more convenient for clients.

To demonstrate the DTO approach, see Prevent over-posting

Common Web API Conventions

As you develop the backend services for your app, you'll want to come up with a consistent set of conventions or policies for handling cross-cutting concerns. For example, in the service shown previously, requests for specific records that weren't found received a `NotFound` response, rather than a `BadRequest` response. Similarly, commands made to this service that passed in model bound types always checked `ModelState.IsValid` and returned a `BadRequest` for invalid model types.

Once you've identified a common policy for your APIs, you can usually encapsulate it in a filter. Learn more about how to encapsulate common API policies in ASP.NET Core MVC applications.

Publish an ASP.NET Core web API to Azure API Management with Visual Studio

Article • 06/18/2024

By Matt Soucoup

In this tutorial you'll learn how to create an ASP.NET Core web API project using Visual Studio, ensure it has OpenAPI support, and then publish the web API to both Azure App Service and Azure API Management.

Set up

To complete the tutorial you'll need an Azure account.

- Open a free Azure account if you don't have one.

Create an ASP.NET Core web API

Visual Studio allows you to easily create a new ASP.NET Core web API project from a template. Follow these directions to create a new ASP.NET Core web API project:

- From the File menu, select **New** > **Project**.
- Enter **Web API** in the search box.
- Select the **ASP.NET Core Web API** template and select **Next**.
- In the **Configure your new project dialog**, name the project **WeatherAPI** and select **Next**.
- In the **Additional information** dialog:
- Confirm the Framework is **.NET 6.0 (Long-term support)**.
- Confirm the checkbox for **Use controllers (uncheck to use minimal APIs)** is checked.
- Confirm the checkbox for **Enable OpenAPI support** is checked.
- Select **Create**.

Explore the code

Swagger definitions allow Azure API Management to read the app's API definitions. By checking the **Enable OpenAPI support** checkbox during app creation, Visual Studio

automatically adds the code to create the Swagger definitions. Open up the `Program.cs` file which shows the following code:

```
C#

...

builder.Services.AddSwaggerGen();

...

if (app.Environment.IsDevelopment())
{
    app.UseSwagger();
    app.UseSwaggerUI(); // Protected by if (env.IsDevelopment())
}

...
```

Ensure the Swagger definitions are always generated

Azure API Management needs the Swagger definitions to always be present, regardless of the application's environment. To ensure they are always generated, move `app.UseSwagger();` outside of the `if (app.Environment.IsDevelopment())` block.

The updated code:

```
C#

...

app.UseSwagger();

if (app.Environment.IsDevelopment())
{
    app.UseSwaggerUI();
}

...
```

Change the API routing

Change the URL structure needed to access the `Get` action of the `WeatherForecastController`. Complete the following steps:

1. Open the `WeatherForecastController.cs` file.
2. Replace the `[Route("[controller]")]` class-level attribute with `[Route("/")]`. The updated class definition :

```
C#

[ApiController]
[Route("/")]
public class WeatherForecastController : ControllerBase
```

Publish the web API to Azure App Service

Complete the following steps to publish the ASP.NET Core web API to Azure API Management:

1. Publish the API app to Azure App Service.
2. Publish the ASP.NET Core web API app to the Azure API Management service instance.

Publish the API app to Azure App Service

Complete the following steps to publish the ASP.NET Core web API to Azure API Management:

1. In **Solution Explorer**, right-click the project and select **Publish**.
2. In the **Publish** dialog, select **Azure** and select the **Next** button.
3. Select **Azure App Service (Windows)** and select the **Next** button.
4. Select **Create a new Azure App Service**.

   The **Create App Service** dialog appears. The **App Name**, **Resource Group**, and **App Service Plan** entry fields are populated. You can keep these names or change them.
5. Select the **Create** button.
6. Once the app service is created, select the **Next** button.

7. Select **Create a new API Management Service**.

   The **Create API Management Service** dialog appears. You can leave the **API Name**, **Subscription Name**, and **Resource Group** entry fields as they are. Select the **new** button next to the **API Management Service** entry and enter the required fields from that dialog box.

   Select the **OK** button to create the API Management service.

8. Select the **Create** button to proceed with the API Management service creation. This step may take several minutes to complete.

9. When that completes, select the **Finish** button.

10. The dialog closes and a summary screen appears with information about the publish. Select the **Publish** button.

    The web API publishes to both Azure App Service and Azure API Management. A new browser window will appear and show the API running in Azure App Service. You can close that window.

11. Open up the Azure portal in a web browser and navigate to the API Management instance you created.

12. Select the **APIs** option from the left-hand menu.

13. Select the API you created in the preceding steps. It's now populated and you can explore around.

Configure the published API name

Notice the name of the API is named *WeatherAPI*; however, we would like to call it *Weather Forecasts*. Complete the following steps to update the name:

1. Add the following to `Program.cs` immediately after `servies.AddSwaggerGen();`

```
C#
```

```
builder.Services.ConfigureSwaggerGen(setup =>
{
    setup.SwaggerDoc("v1", new Microsoft.OpenApi.Models.OpenApiInfo
    {
        Title = "Weather Forecasts",
        Version = "v1"
    });
});
```

2. Republish the ASP.NET Core web API and open the Azure API Management instance in the Azure portal.

3. Refresh the page in your browser. You'll see the name of the API is now correct.

Verify the web API is working

You can test the deployed ASP.NET Core web API in Azure API Management from the Azure portal with the following steps:

1. Open the **Test** tab.
2. Select **/** or the **Get** operation.
3. Select **Send**.

Clean up

When you've finished testing the app, go to the Azure portal and delete the app.

1. Select **Resource groups**, then select the resource group you created.

2. In the **Resource groups** page, select **Delete**.

3. Enter the name of the resource group and select **Delete**. Your app and all other resources created in this tutorial are now deleted from Azure.

Tutorial: Create a minimal API with ASP.NET Core

Article • 08/21/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

By Rick Anderson and Tom Dykstra

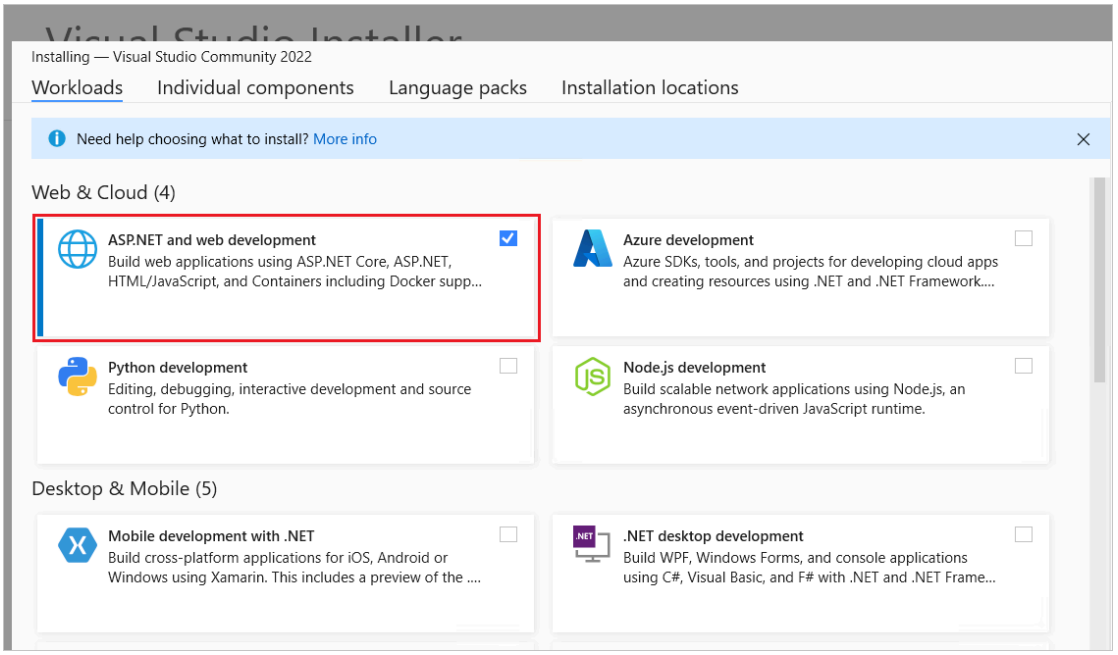
Minimal APIs are architected to create HTTP APIs with minimal dependencies. They're ideal for microservices and apps that want to include only the minimum files, features, and dependencies in ASP.NET Core.

This tutorial teaches the basics of building a minimal API with ASP.NET Core. Another approach to creating APIs in ASP.NET Core is to use controllers. For help with choosing between minimal APIs and controller-based APIs, see APIs overview. For a tutorial on creating an API project based on controllers that contains more features, see Create a web API.

Overview

This tutorial creates the following API:

Expand table

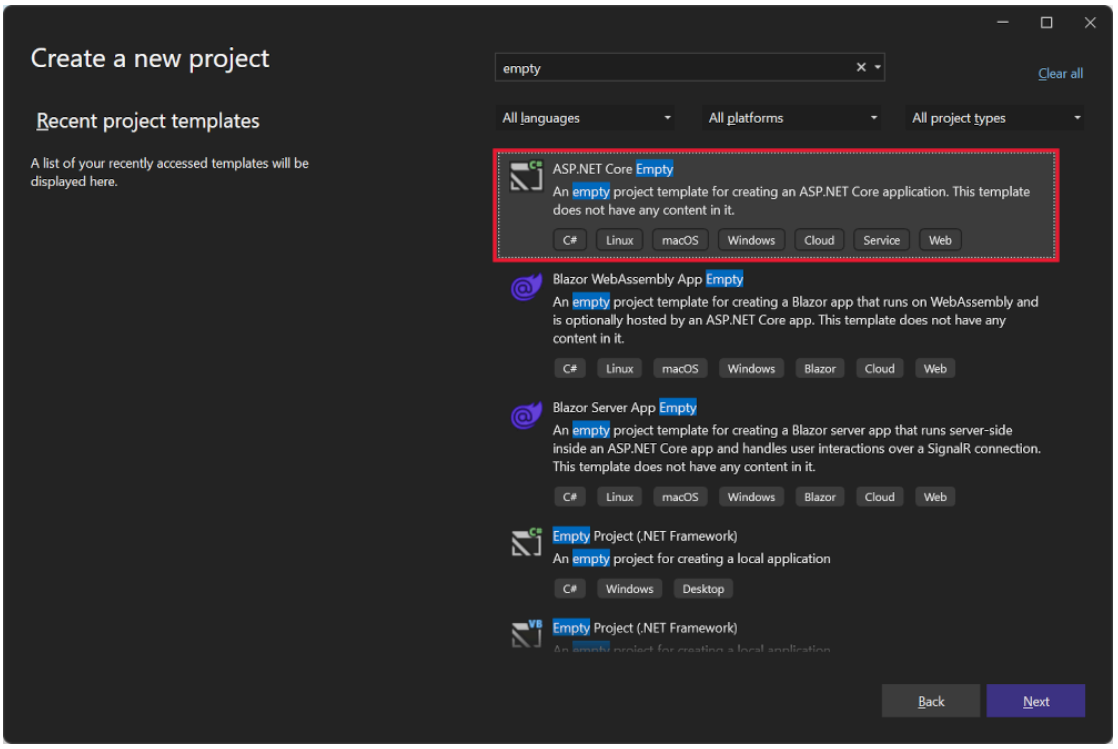


API	Description	Request body	Response body
`GET /todoitems`	Get all to-do items	None	Array of to-do items
`GET /todoitems/complete`	Get completed to-do items	None	Array of to-do items
`GET /todoitems/{id}`	Get an item by ID	None	To-do item
`POST /todoitems`	Add a new item	To-do item	To-do item
`PUT /todoitems/{id}`	Update an existing item	To-do item	None

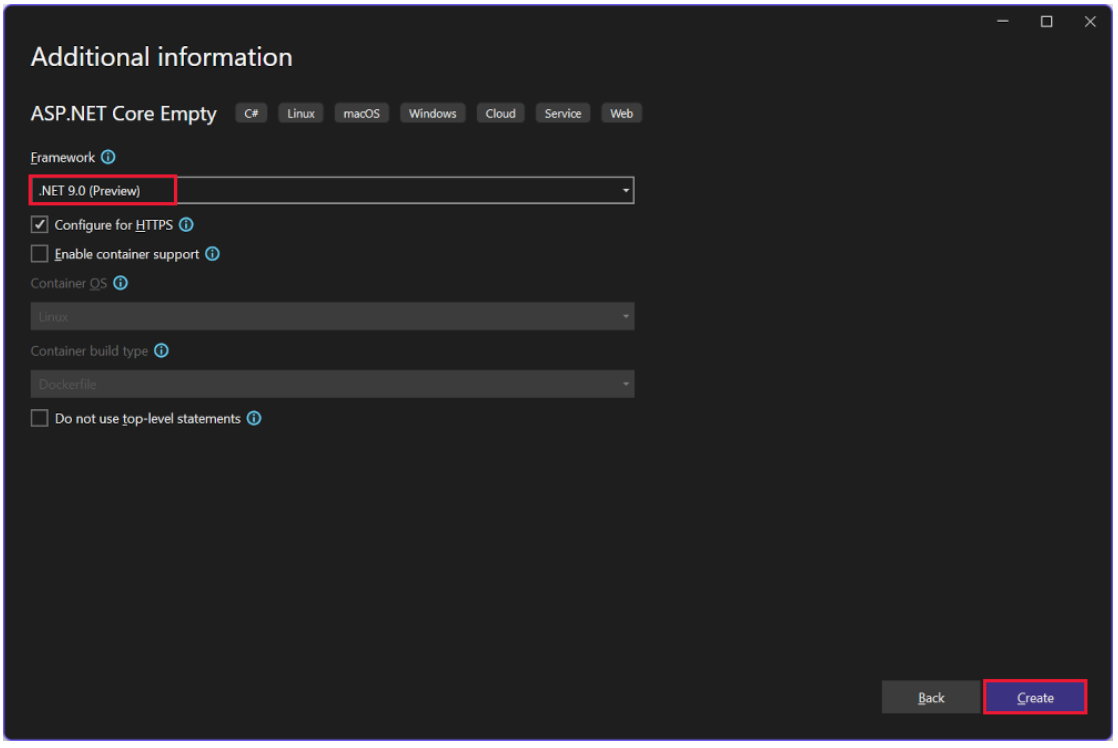
API	Description	Request body	Response body
`DELETE /todoitems/{id}`	Delete an item	None	None

Prerequisites

Visual Studio



- Visual Studio 2022 Preview with the **ASP.NET and web development** workload.



Create an API project

Visual Studio

- Start Visual Studio 2022 and select **Create a new project**.
- In the **Create a new project** dialog:
  - Enter `Empty` in the **Search for templates** search box.
  - Select the **ASP.NET Core Empty** template and select **Next**.

- Name the project *TodoApi* and select **Next**.
- In the **Additional information** dialog:
  - Select **.NET 9.0 (Preview)**
  - Uncheck **Do not use top-level statements**
  - Select **Create**

Examine the code

The `Program.cs` file contains the following code:

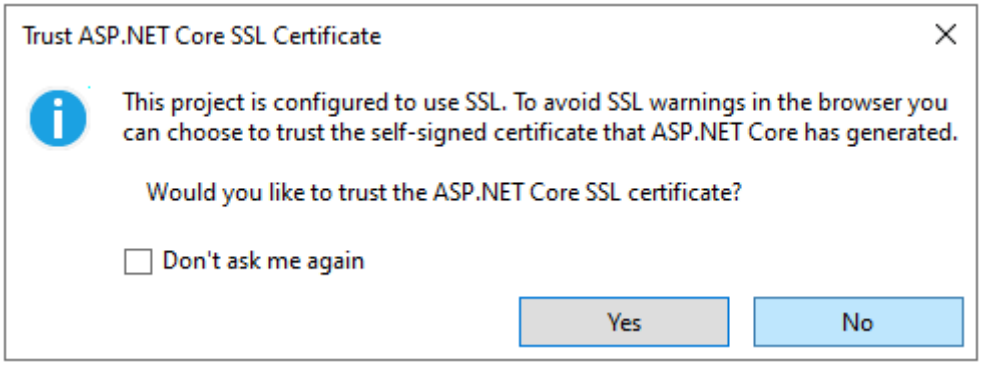
C#

```
var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

app.MapGet("/", () => "Hello World!");

app.Run();
```

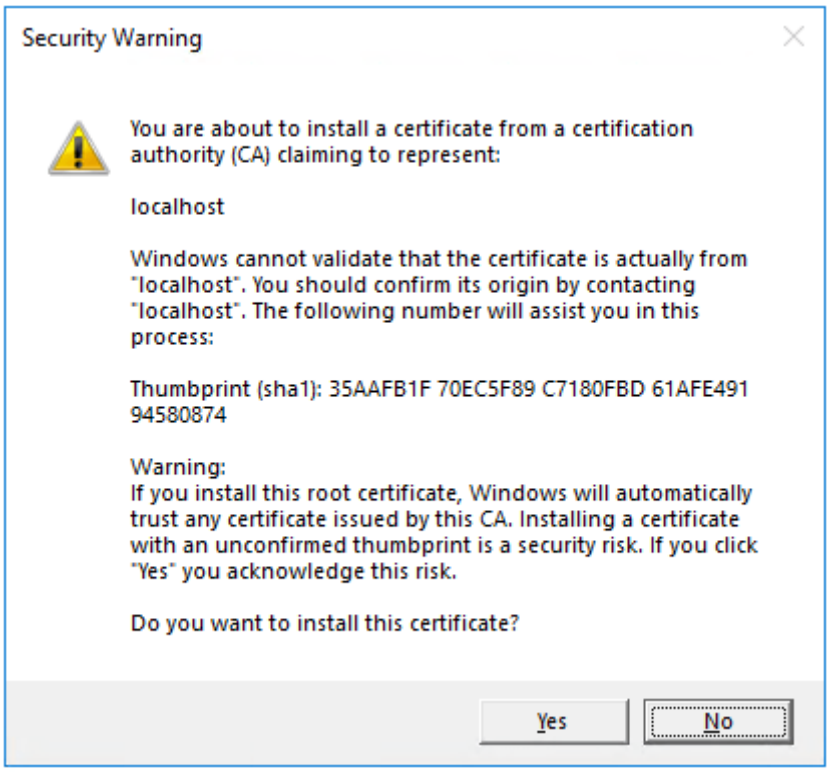
The preceding code:



- Creates a WebApplicationBuilder and a WebApplication with preconfigured defaults.
- Creates an HTTP GET endpoint `/` that returns `Hello World!`:

Run the app

Visual Studio



Press Ctrl+F5 to run without the debugger.

Visual Studio displays the following dialog:

Select **Yes** if you trust the IIS Express SSL certificate.

The following dialog is displayed:

Select **Yes** if you agree to trust the development certificate.

For information on trusting the Firefox browser, see Firefox SEC_ERROR_INADEQUATE_KEY_USAGE certificate error.

Visual Studio launches the Kestrel web server and opens a browser window.

`Hello World!` is displayed in the browser. The `Program.cs` file contains a minimal but complete app.

Close the browser window.

Add NuGet packages

NuGet packages must be added to support the database and diagnostics used in this tutorial.

Visual Studio

- From the **Tools** menu, select **NuGet Package Manager** > **Manage NuGet Packages for Solution**.
- Select the **Browse** tab.
- Select **Include Prelease**.
- Enter **Microsoft.EntityFrameworkCore.InMemory** in the search box, and then select `Microsoft.EntityFrameworkCore.InMemory`.

- Select the **Project** checkbox in the right pane and then select **Install**.
- Follow the preceding instructions to add the `Microsoft.AspNetCore.Diagnostics.EntityFrameworkCore` package.

The model and database context classes

- In the project folder, create a file named `Todo.cs` with the following code:

C#

```
public class Todo
{
    public int Id { get; set; }
    public string? Name { get; set; }
    public bool IsComplete { get; set; }
}
```

The preceding code creates the model for this app. A *model* is a class that represents data that the app manages.

- Create a file named `TodoDb.cs` with the following code:

C#

```
using Microsoft.EntityFrameworkCore;

class TodoDb : DbContext
{
    public TodoDb(DbContextOptions<TodoDb> options)
        : base(options) { }

    public DbSet<Todo> Todos => Set<Todo>();
}
```

The preceding code defines the *database context*, which is the main class that coordinates Entity Framework functionality for a data model. This class derives from the Microsoft.EntityFrameworkCore.DbContext class.

Add the API code

- Replace the contents of the `Program.cs` file with the following code:

C#

```
using Microsoft.EntityFrameworkCore;

var builder = WebApplication.CreateBuilder(args);
builder.Services.AddDbContext<TodoDb>(opt =>
opt.UseInMemoryDatabase("TodoList"));
builder.Services.AddDatabaseDeveloperPageExceptionFilter();
var app = builder.Build();

app.MapGet("/todoitems", async (TodoDb db) =>
    await db.Todos.ToListAsync());

app.MapGet("/todoitems/complete", async (TodoDb db) =>
    await db.Todos.Where(t => t.IsComplete).ToListAsync());

app.MapGet("/todoitems/{id}", async (int id, TodoDb db) =>
    await db.Todos.FindAsync(id)
        is Todo todo
            ? Results.Ok(todo)
            : Results.NotFound());

app.MapPost("/todoitems", async (Todo todo, TodoDb db) =>
{
    db.Todos.Add(todo);
    await db.SaveChangesAsync();

    return Results.Created($"/todoitems/{todo.Id}", todo);
});

app.MapPut("/todoitems/{id}", async (int id, Todo inputTodo, TodoDb db) =>
{
    var todo = await db.Todos.FindAsync(id);

    if (todo is null) return Results.NotFound();

    todo.Name = inputTodo.Name;
    todo.IsComplete = inputTodo.IsComplete;

    await db.SaveChangesAsync();

    return Results.NoContent();
});

app.MapDelete("/todoitems/{id}", async (int id, TodoDb db) =>
{
    if (await db.Todos.FindAsync(id) is Todo todo)
    {
        db.Todos.Remove(todo);
        await db.SaveChangesAsync();
        return Results.NoContent();
    }

    return Results.NotFound();
});
```

```
app.Run();
```

The following highlighted code adds the database context to the dependency injection (DI) container and enables displaying database-related exceptions:

C#

```
var builder = WebApplication.CreateBuilder(args);
builder.Services.AddDbContext<TodoDb>(opt =>
opt.UseInMemoryDatabase("TodoList"));
builder.Services.AddDatabaseDeveloperPageExceptionFilter();
var app = builder.Build();
```

The DI container provides access to the database context and other services.

Visual Studio

This tutorial uses Endpoints Explorer and .http files to test the API.

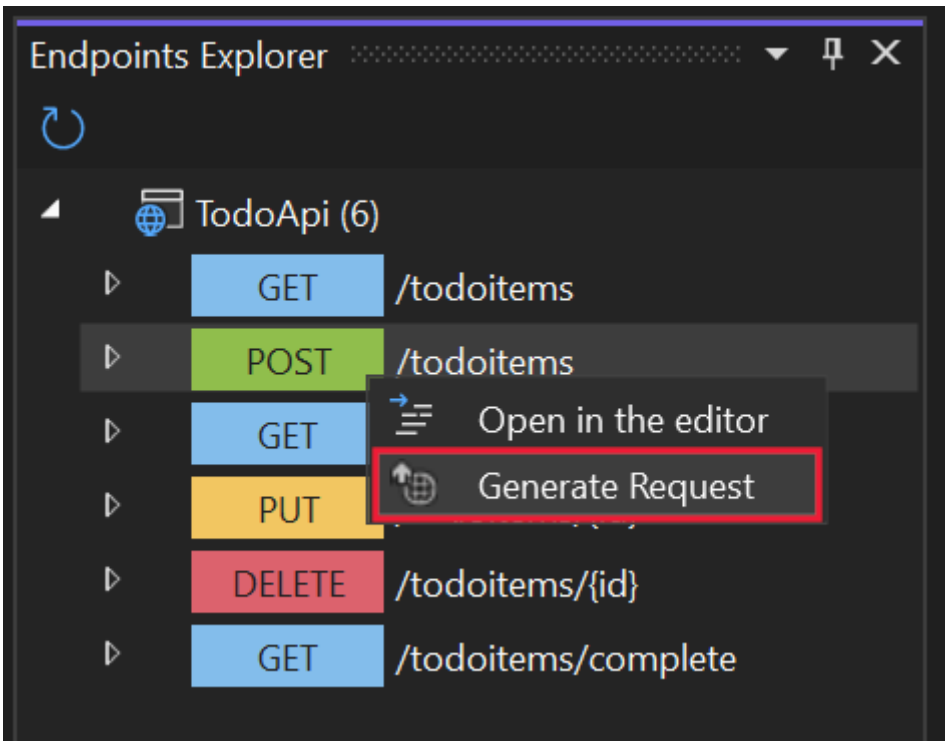
Test posting data

The following code in `Program.cs` creates an HTTP POST endpoint `/todoitems` that adds data to the in-memory database:

C#

```
app.MapPost("/todoitems", async (Todo todo, TodoDb db) =>
{
    db.Todos.Add(todo);
    await db.SaveChangesAsync();

    return Results.Created($"/todoitems/{todo.Id}", todo);
});
```



Run the app. The browser displays a 404 error because there's no longer a `/` endpoint.

The POST endpoint will be used to add data to the app.

Visual Studio

- Select **View** > **Other Windows** > **Endpoints Explorer**.

- Right-click the **POST** endpoint and select **Generate request**.

A new file is created in the project folder named `TodoApi.http`, with contents similar to the following example:

```
@TodoApi_HostAddress = https://localhost:7031

Post {{TodoApi_HostAddress}}/todoitems

###
```

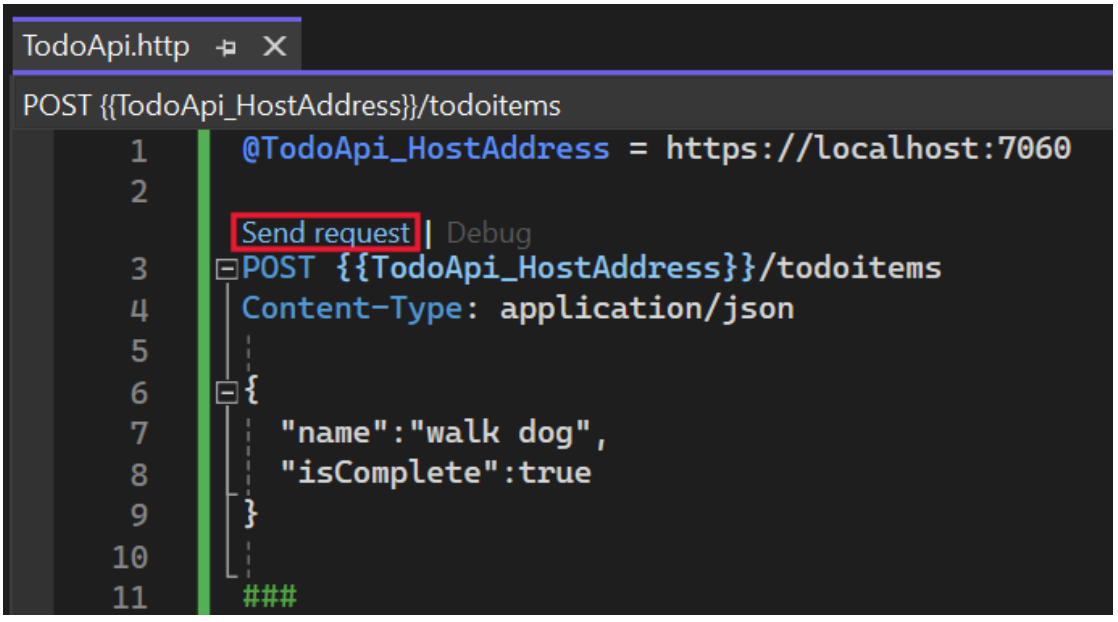
  - The first line creates a variable that is used for all of the endpoints.
  - The next line defines a POST request.
  - The triple hashtag (`###`) line is a request delimiter: what comes after it is for a different request.

- The POST request needs headers and a body. To define those parts of the request, add the following lines immediately after the POST request line:

```
Content-Type: application/json

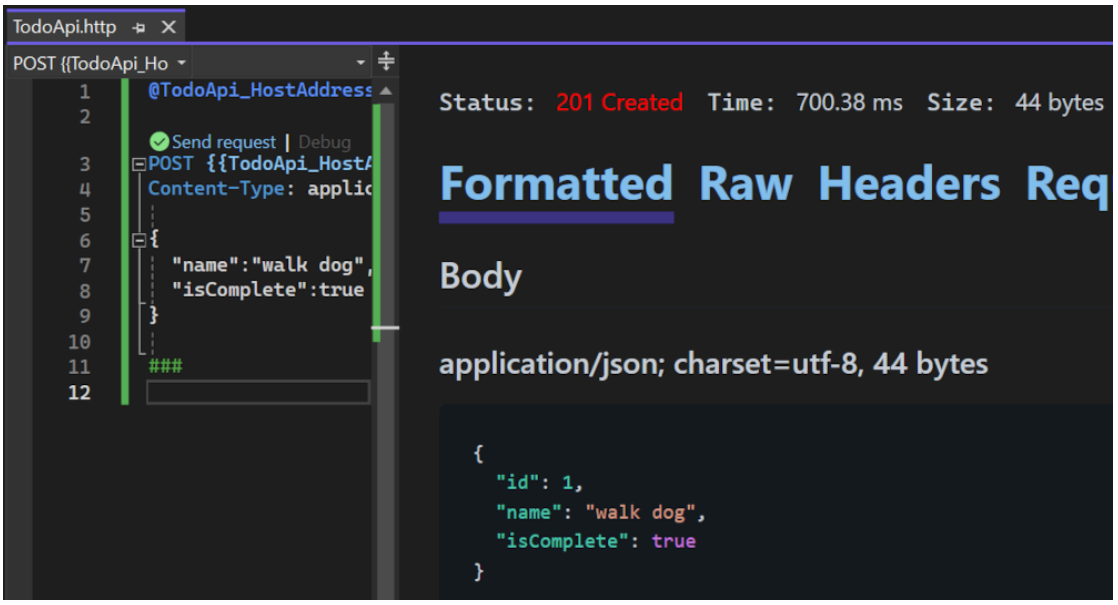
{
  "name":"walk dog",
  "isComplete":true
}
```

The preceding code adds a Content-Type header and a JSON request body. The TodoApi.http file should now look like the following example, but with your port number:



```
@TodoApi_HostAddress = https://localhost:7057

Post {{TodoApi_HostAddress}}/todoitems
Content-Type: application/json



{
  "name":"walk dog",
  "isComplete":true
}

###
```

- Run the app.
- Select the **Send request** link that is above the `POST` request line.

The POST request is sent to the app and the response is displayed in the **Response** pane.

Examine the GET endpoints

The sample app implements several GET endpoints by calling `MapGet`:

Expand table

API	Description	Request body	Response body
`GET /todoitems`	Get all to-do items	None	Array of to-do items
`GET /todoitems/complete`	Get all completed to-do items	None	Array of to-do items
`GET /todoitems/{id}`	Get an item by ID	None	To-do item

C#

```
app.MapGet("/todoitems", async (TodoDb db) =>
    await db.Todos.ToListAsync());

app.MapGet("/todoitems/complete", async (TodoDb db) =>
    await db.Todos.Where(t => t.IsComplete).ToListAsync());

app.MapGet("/todoitems/{id}", async (int id, TodoDb db) =>
    await db.Todos.FindAsync(id)
        is Todo todo
            ? Results.Ok(todo)
            : Results.NotFound());
```

Test the GET endpoints

Visual Studio

Test the app by calling the `GET` endpoints from a browser or by using **Endpoints Explorer**. The following steps are for **Endpoints Explorer**.

- In **Endpoints Explorer**, right-click the first **GET** endpoint, and select **Generate request**.

  The following content is added to the `TodoApi.http` file:

  ```
  Get {{TodoApi_HostAddress}}/todoitems

  ###
  ```

- Select the **Send request** link that is above the new `GET` request line.

  The GET request is sent to the app and the response is displayed in the **Response** pane.

- The response body is similar to the following JSON:

  JSON

  ```
  [
    {
      "id": 1,
      "name": "walk dog",
      "isComplete": true
    }
  ]
  ```

- In **Endpoints Explorer**, right-click the `/todoitems/{id}` **GET** endpoint and select **Generate request**. The following content is added to the `TodoApi.http` file:

  ```
  GET {{TodoApi_HostAddress}}/todoitems/{id}

  ###
  ```

- Replace `{id}` with `1`.

- Select the **Send request** link that is above the new GET request line.

  The GET request is sent to the app and the response is displayed in the **Response** pane.

- The response body is similar to the following JSON:

  ```
  JSON

  {
    "id": 1,
    "name": "walk dog",
    "isComplete": true
  }
  ```

This app uses an in-memory database. If the app is restarted, the GET request doesn't return any data. If no data is returned, POST data to the app and try the GET request again.

Return values

ASP.NET Core automatically serializes the object to JSON and writes the JSON into the body of the response message. The response code for this return type is 200 OK, assuming there are no unhandled exceptions. Unhandled exceptions are translated into 5xx errors.

The return types can represent a wide range of HTTP status codes. For example, `GET /todoitems/{id}` can return two different status values:

- If no item matches the requested ID, the method returns a 404 status NotFound error code.
- Otherwise, the method returns 200 with a JSON response body. Returning `item` results in an HTTP 200 response.

Examine the PUT endpoint

The sample app implements a single PUT endpoint using `MapPut`:

```
C#

app.MapPut("/todoitems/{id}", async (int id, Todo inputTodo, TodoDb db) =>
{
```

```
    var todo = await db.Todos.FindAsync(id);

    if (todo is null) return Results.NotFound();

    todo.Name = inputTodo.Name;
    todo.IsComplete = inputTodo.IsComplete;

    await db.SaveChangesAsync();

    return Results.NoContent();
});
```

This method is similar to the `MapPost` method, except it uses HTTP PUT. A successful response returns 204 (No Content). According to the HTTP specification, a PUT request requires the client to send the entire updated entity, not just the changes. To support partial updates, use HTTP PATCH.

Test the PUT endpoint

This sample uses an in-memory database that must be initialized each time the app is started. There must be an item in the database before you make a PUT call. Call GET to ensure there's an item in the database before making a PUT call.

Update the to-do item that has `Id = 1` and set its name to `"feed fish"`.

Visual Studio

- In **Endpoints Explorer**, right-click the **PUT** endpoint, and select **Generate request**.

  The following content is added to the `TodoApi.http` file:

  ```
  Put {{TodoApi_HostAddress}}/todoitems/{id}

  ###
  ```

- In the PUT request line, replace `{id}` with `1`.
- Add the following lines immediately after the PUT request line:

  ```
  ```

```
Content-Type: application/json

{
  "name": "feed fish",
  "isComplete": false
}
```

The preceding code adds a Content-Type header and a JSON request body.

- Select the **Send request** link that is above the new PUT request line.

  The PUT request is sent to the app and the response is displayed in the **Response** pane. The response body is empty, and the status code is 204.

Examine and test the DELETE endpoint

The sample app implements a single DELETE endpoint using `MapDelete`:

C#

```
app.MapDelete("/todoitems/{id}", async (int id, TodoDb db) =>
{
    if (await db.Todos.FindAsync(id) is Todo todo)
    {
        db.Todos.Remove(todo);
        await db.SaveChangesAsync();
        return Results.NoContent();
    }

    return Results.NotFound();
});
```

Visual Studio

- In **Endpoints Explorer**, right-click the **DELETE** endpoint and select **Generate request**.

  A DELETE request is added to `TodoApi.http`.

- Replace `{id}` in the DELETE request line with `1`. The DELETE request should look like the following example:

  ```
  
  ```

```
DELETE {{TodoApi_HostAddress}}/todoitems/1

###
```

- Select the **Send request** link for the DELETE request.

  The DELETE request is sent to the app and the response is displayed in the **Response** pane. The response body is empty, and the status code is 204.

Use the MapGroup API

The sample app code repeats the `todoitems` URL prefix each time it sets up an endpoint. APIs often have groups of endpoints with a common URL prefix, and the MapGroup method is available to help organize such groups. It reduces repetitive code and allows for customizing entire groups of endpoints with a single call to methods like RequireAuthorization and WithMetadata.

Replace the contents of `Program.cs` with the following code:

Visual Studio

C#

```
using Microsoft.EntityFrameworkCore;

var builder = WebApplication.CreateBuilder(args);
builder.Services.AddDbContext<TodoDb>(opt =>
opt.UseInMemoryDatabase("TodoList"));
builder.Services.AddDatabaseDeveloperPageExceptionFilter();
var app = builder.Build();

var todoItems = app.MapGroup("/todoitems");

todoItems.MapGet("/", async (TodoDb db) =>
    await db.Todos.ToListAsync());

todoItems.MapGet("/complete", async (TodoDb db) =>
    await db.Todos.Where(t => t.IsComplete).ToListAsync());

todoItems.MapGet("/{id}", async (int id, TodoDb db) =>
    await db.Todos.FindAsync(id)
        is Todo todo
            ? Results.Ok(todo)
            : Results.NotFound());
```

```
todoItems.MapPost("/", async (Todo todo, TodoDb db) =>
{
    db.Todos.Add(todo);
    await db.SaveChangesAsync();

    return Results.Created($"/todoitems/{todo.Id}", todo);
});

todoItems.MapPut("/{id}", async (int id, Todo inputTodo, TodoDb db) =>
{
    var todo = await db.Todos.FindAsync(id);

    if (todo is null) return Results.NotFound();

    todo.Name = inputTodo.Name;
    todo.IsComplete = inputTodo.IsComplete;

    await db.SaveChangesAsync();

    return Results.NoContent();
});

todoItems.MapDelete("/{id}", async (int id, TodoDb db) =>
{
    if (await db.Todos.FindAsync(id) is Todo todo)
    {
        db.Todos.Remove(todo);
        await db.SaveChangesAsync();
        return Results.NoContent();
    }

    return Results.NotFound();
});

app.Run();
```

The preceding code has the following changes:

- Adds `var todoItems = app.MapGroup("/todoitems");` to set up the group using the URL prefix `/todoitems`.
- Changes all the `app.Map<HttpVerb>` methods to `todoItems.Map<HttpVerb>`.
- Removes the URL prefix `/todoitems` from the `Map<HttpVerb>` method calls.

Test the endpoints to verify that they work the same.

Use the TypedResults API

Returning TypedResults rather than Results has several advantages, including testability and automatically returning the response type metadata for OpenAPI to describe the

endpoint. For more information, see TypedResults vs Results.

The `Map<HttpVerb>` methods can call route handler methods instead of using lambdas. To see an example, update *Program.cs* with the following code:

Visual Studio

C#

```
using Microsoft.EntityFrameworkCore;

var builder = WebApplication.CreateBuilder(args);
builder.Services.AddDbContext<TodoDb>(opt =>
opt.UseInMemoryDatabase("TodoList"));
builder.Services.AddDatabaseDeveloperPageExceptionFilter();
var app = builder.Build();

var todoItems = app.MapGroup("/todoitems");

todoItems.MapGet("/", GetAllTodos);
todoItems.MapGet("/complete", GetCompleteTodos);
todoItems.MapGet("/{id}", GetTodo);
todoItems.MapPost("/", CreateTodo);
todoItems.MapPut("/{id}", UpdateTodo);
todoItems.MapDelete("/{id}", DeleteTodo);

app.Run();

static async Task<IResult> GetAllTodos(TodoDb db)
{
    return TypedResults.Ok(await db.Todos.ToArrayAsync());
}

static async Task<IResult> GetCompleteTodos(TodoDb db)
{
    return TypedResults.Ok(await db.Todos.Where(t =>
t.IsComplete).ToListAsync());
}

static async Task<IResult> GetTodo(int id, TodoDb db)
{
    return await db.Todos.FindAsync(id)
        is Todo todo
            ? TypedResults.Ok(todo)
            : TypedResults.NotFound();
}

static async Task<IResult> CreateTodo(Todo todo, TodoDb db)
{
    db.Todos.Add(todo);
    await db.SaveChangesAsync();
```

```
    return TypedResults.Created($"/todoitems/{todo.Id}", todo);
}

static async Task<IResult> UpdateTodo(int id, Todo inputTodo, TodoDb db)
{
    var todo = await db.Todos.FindAsync(id);

    if (todo is null) return TypedResults.NotFound();

    todo.Name = inputTodo.Name;
    todo.IsComplete = inputTodo.IsComplete;

    await db.SaveChangesAsync();

    return TypedResults.NoContent();
}

static async Task<IResult> DeleteTodo(int id, TodoDb db)
{
    if (await db.Todos.FindAsync(id) is Todo todo)
    {
        db.Todos.Remove(todo);
        await db.SaveChangesAsync();
        return TypedResults.NoContent();
    }

    return TypedResults.NotFound();
}
```

The `Map<HttpVerb>` code now calls methods instead of lambdas:

C#

```
var todoItems = app.MapGroup("/todoitems");

todoItems.MapGet("/", GetAllTodos);
todoItems.MapGet("/complete", GetCompleteTodos);
todoItems.MapGet("/{id}", GetTodo);
todoItems.MapPost("/", CreateTodo);
todoItems.MapPut("/{id}", UpdateTodo);
todoItems.MapDelete("/{id}", DeleteTodo);
```

These methods return objects that implement IResult and are defined by TypedResults:

C#

```
static async Task<IResult> GetAllTodos(TodoDb db)
{
    return TypedResults.Ok(await db.Todos.ToArrayAsync());
}
```

```
static async Task<IResult> GetCompleteTodos(TodoDb db)
{
    return TypedResults.Ok(await db.Todos.Where(t =>
t.IsComplete).ToListAsync());
}

static async Task<IResult> GetTodo(int id, TodoDb db)
{
    return await db.Todos.FindAsync(id)
        is Todo todo
            ? TypedResults.Ok(todo)
            : TypedResults.NotFound();
}

static async Task<IResult> CreateTodo(Todo todo, TodoDb db)
{
    db.Todos.Add(todo);
    await db.SaveChangesAsync();

    return TypedResults.Created($"/todoitems/{todo.Id}", todo);
}

static async Task<IResult> UpdateTodo(int id, Todo inputTodo, TodoDb db)
{
    var todo = await db.Todos.FindAsync(id);

    if (todo is null) return TypedResults.NotFound();

    todo.Name = inputTodo.Name;
    todo.IsComplete = inputTodo.IsComplete;

    await db.SaveChangesAsync();

    return TypedResults.NoContent();
}

static async Task<IResult> DeleteTodo(int id, TodoDb db)
{
    if (await db.Todos.FindAsync(id) is Todo todo)
    {
        db.Todos.Remove(todo);
        await db.SaveChangesAsync();
        return TypedResults.NoContent();
    }

    return TypedResults.NotFound();
}
```

Unit tests can call these methods and test that they return the correct type. For example, if the method is `GetAllTodos`:

```
C#
```

```
static async Task<IResult> GetAllTodos(TodoDb db)
{
    return TypedResults.Ok(await db.Todos.ToArrayAsync());
}
```

Unit test code can verify that an object of type Ok<Todo[]> is returned from the handler method. For example:

C#

```
public async Task GetAllTodos_ReturnsOkOfTodosResult()
{
    // Arrange
    var db = CreateDbContext();

    // Act
    var result = await TodosApi.GetAllTodos(db);

    // Assert: Check for the correct returned type
    Assert.IsType<Ok<Todo[]>>(result);
}
```

Prevent over-posting

Currently the sample app exposes the entire `Todo` object. Production apps In production applications, a subset of the model is often used to restrict the data that can be input and returned. There are multiple reasons behind this and security is a major one. The subset of a model is usually referred to as a Data Transfer Object (DTO), input model, or view model. **DTO** is used in this article.

A DTO can be used to:

- Prevent over-posting.
- Hide properties that clients aren't supposed to view.
- Omit some properties to reduce payload size.
- Flatten object graphs that contain nested objects. Flattened object graphs can be more convenient for clients.

To demonstrate the DTO approach, update the `Todo` class to include a secret field:

C#

```
public class Todo
{
    public int Id { get; set; }
```

```
    public string? Name { get; set; }
    public bool IsComplete { get; set; }
    public string? Secret { get; set; }
}
```

The secret field needs to be hidden from this app, but an administrative app could choose to expose it.

Verify you can post and get the secret field.

Create a file named `TodoItemDTO.cs` with the following code:

C#

```
public class TodoItemDTO
{
    public int Id { get; set; }
    public string? Name { get; set; }
    public bool IsComplete { get; set; }

    public TodoItemDTO() { }
    public TodoItemDTO(Todo todoItem) =>
    (Id, Name, IsComplete) = (todoItem.Id, todoItem.Name,
todoItem.IsComplete);
}
```

Replace the contents of the `Program.cs` file with the following code to use this DTO model:

Visual Studio

C#

```
using Microsoft.EntityFrameworkCore;

var builder = WebApplication.CreateBuilder(args);
builder.Services.AddDbContext<TodoDb>(opt =>
opt.UseInMemoryDatabase("TodoList"));
builder.Services.AddDatabaseDeveloperPageExceptionFilter();
var app = builder.Build();

RouteGroupBuilder todoItems = app.MapGroup("/todoitems");

todoItems.MapGet("/", GetAllTodos);
todoItems.MapGet("/complete", GetCompleteTodos);
todoItems.MapGet("/{id}", GetTodo);
todoItems.MapPost("/", CreateTodo);
todoItems.MapPut("/{id}", UpdateTodo);
todoItems.MapDelete("/{id}", DeleteTodo);
```

```
app.Run();

static async Task<IResult> GetAllTodos(TodoDb db)
{
    return TypedResults.Ok(await db.Todos.Select(x => new
TodoItemDTO(x)).ToArrayAsync());
}

static async Task<IResult> GetCompleteTodos(TodoDb db) {
    return TypedResults.Ok(await db.Todos.Where(t =>
t.IsComplete).Select(x => new TodoItemDTO(x)).ToListAsync());
}

static async Task<IResult> GetTodo(int id, TodoDb db)
{
    return await db.Todos.FindAsync(id)
        is Todo todo
            ? TypedResults.Ok(new TodoItemDTO(todo))
            : TypedResults.NotFound();
}

static async Task<IResult> CreateTodo(TodoItemDTO todoItemDTO, TodoDb
db)
{
    var todoItem = new Todo
    {
        IsComplete = todoItemDTO.IsComplete,
        Name = todoItemDTO.Name
    };

    db.Todos.Add(todoItem);
    await db.SaveChangesAsync();

    todoItemDTO = new TodoItemDTO(todoItem);

    return TypedResults.Created($"/todoitems/{todoItem.Id}",
todoItemDTO);
}

static async Task<IResult> UpdateTodo(int id, TodoItemDTO todoItemDTO,
TodoDb db)
{
    var todo = await db.Todos.FindAsync(id);

    if (todo is null) return TypedResults.NotFound();

    todo.Name = todoItemDTO.Name;
    todo.IsComplete = todoItemDTO.IsComplete;

    await db.SaveChangesAsync();

    return TypedResults.NoContent();
}
```

```
static async Task<IResult> DeleteTodo(int id, TodoDb db)
{
    if (await db.Todos.FindAsync(id) is Todo todo)
    {
        db.Todos.Remove(todo);
        await db.SaveChangesAsync();
        return TypedResults.NoContent();
    }

    return TypedResults.NotFound();
}
```

Verify you can post and get all fields except the secret field.

Troubleshooting with the completed sample

If you run into a problem you can't resolve, compare your code to the completed project. View or download completed project (how to download).

Next steps

- Configure JSON serialization options.

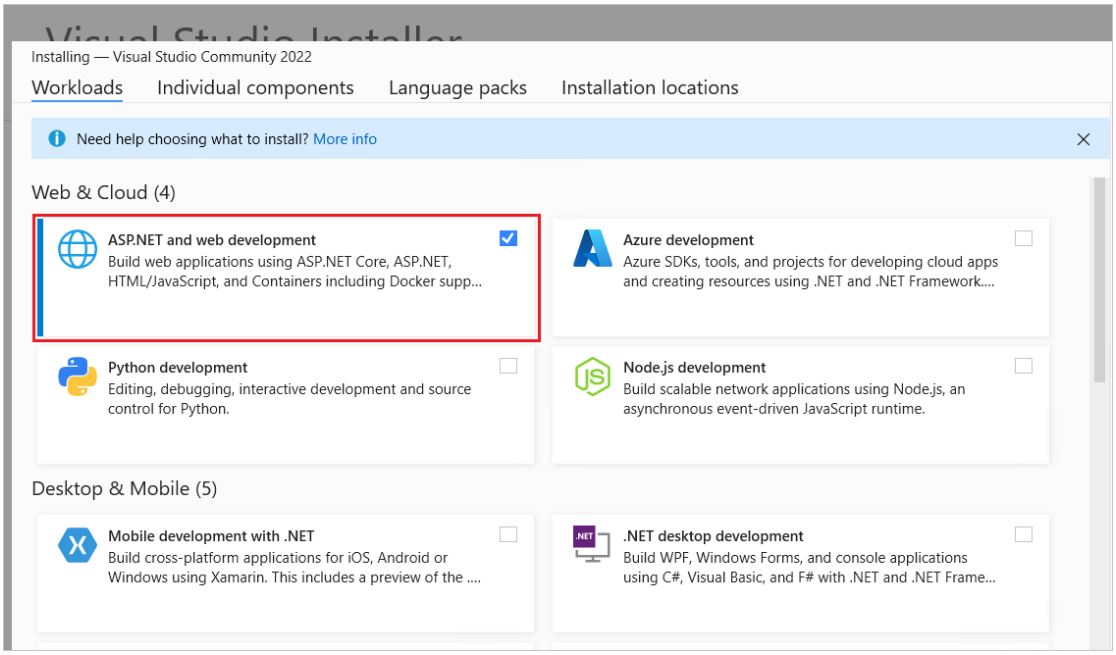
Tutorial: Get started with ASP.NET Core SignalR

Article • 11/16/2023

This tutorial teaches the basics of building a real-time app using SignalR. You learn how to:

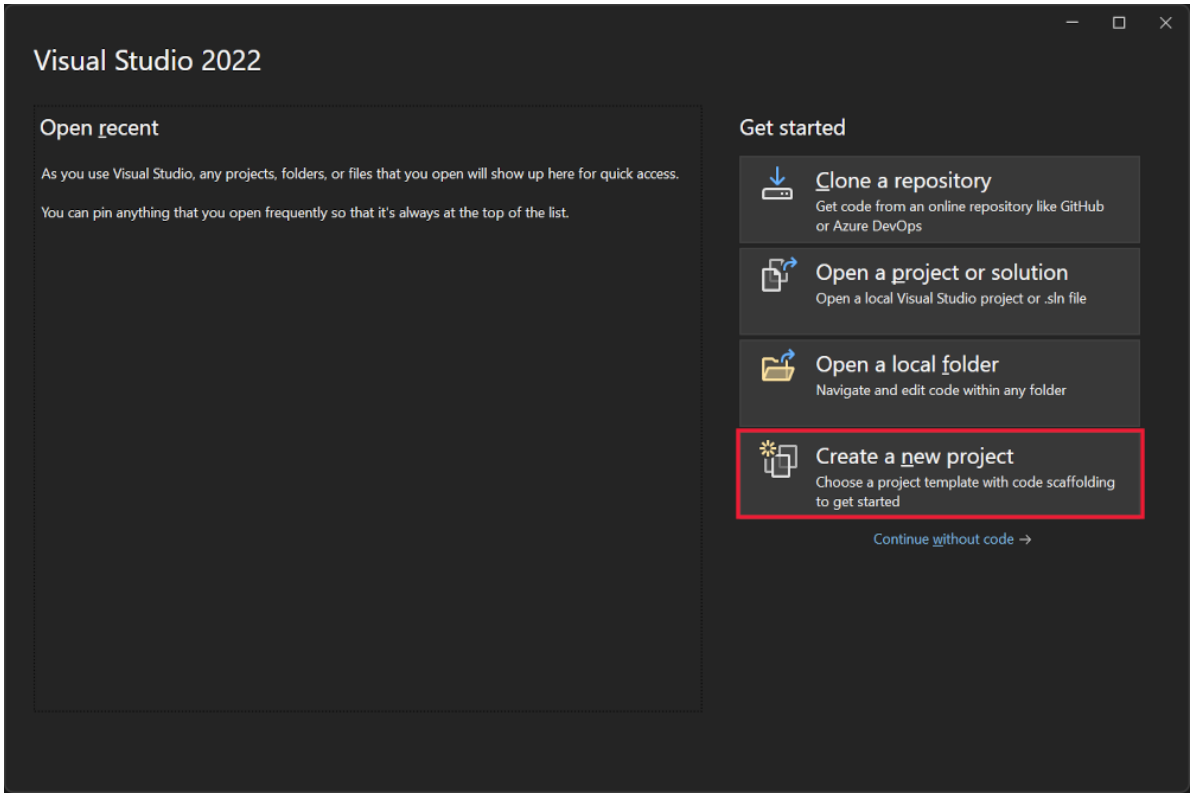
- ✓ Create a web project.
- ✓ Add the SignalR client library.
- ✓ Create a SignalR hub.
- ✓ Configure the project to use SignalR.
- ✓ Add code that sends messages from any client to all connected clients.



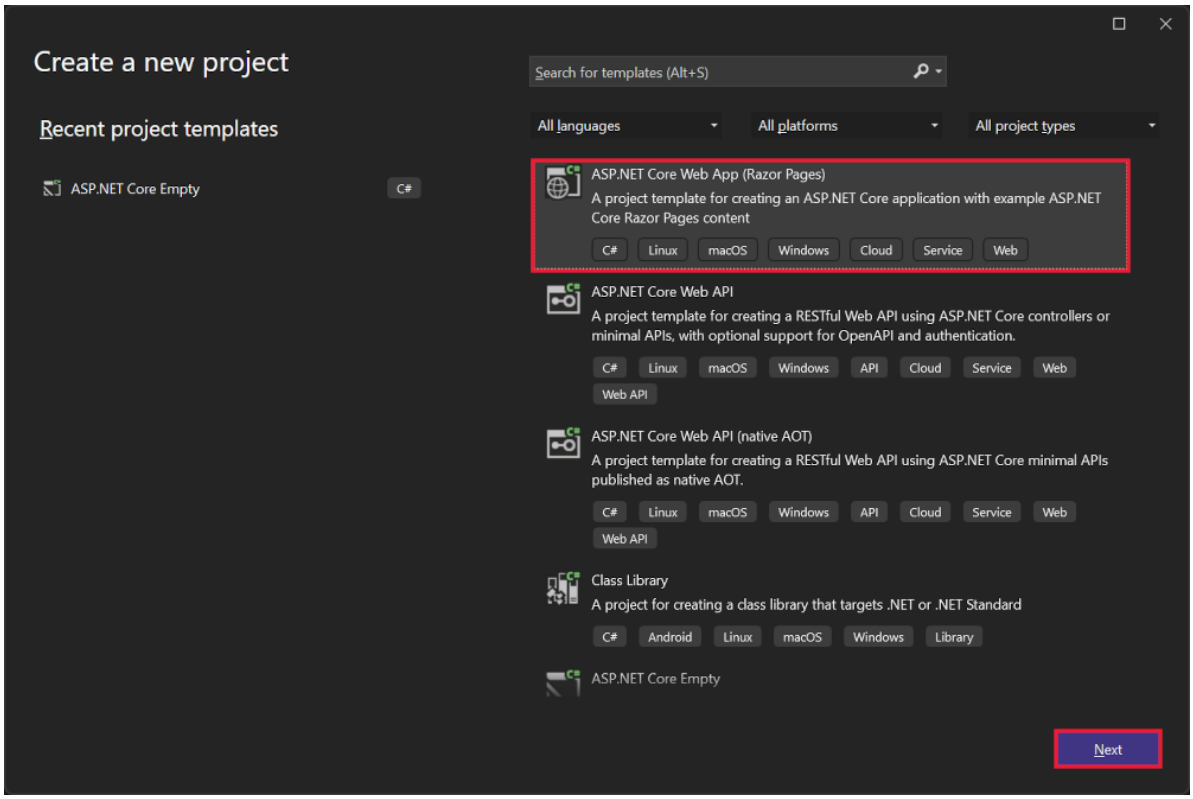
At the end, you'll have a working chat app:

Prerequisites

Visual Studio



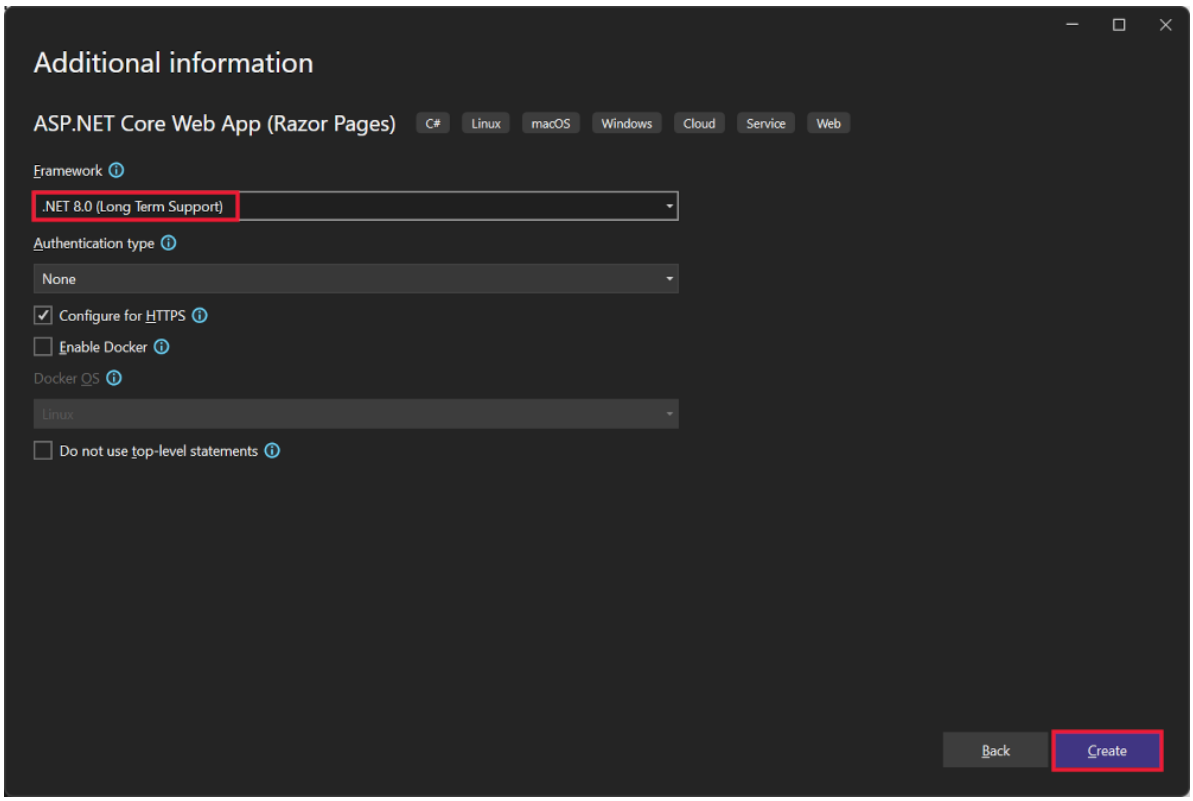
- Visual Studio 2022 Preview with the **ASP.NET and web development** workload.



Create a web app project

Visual Studio

Start Visual Studio 2022 and select **Create a new project**.



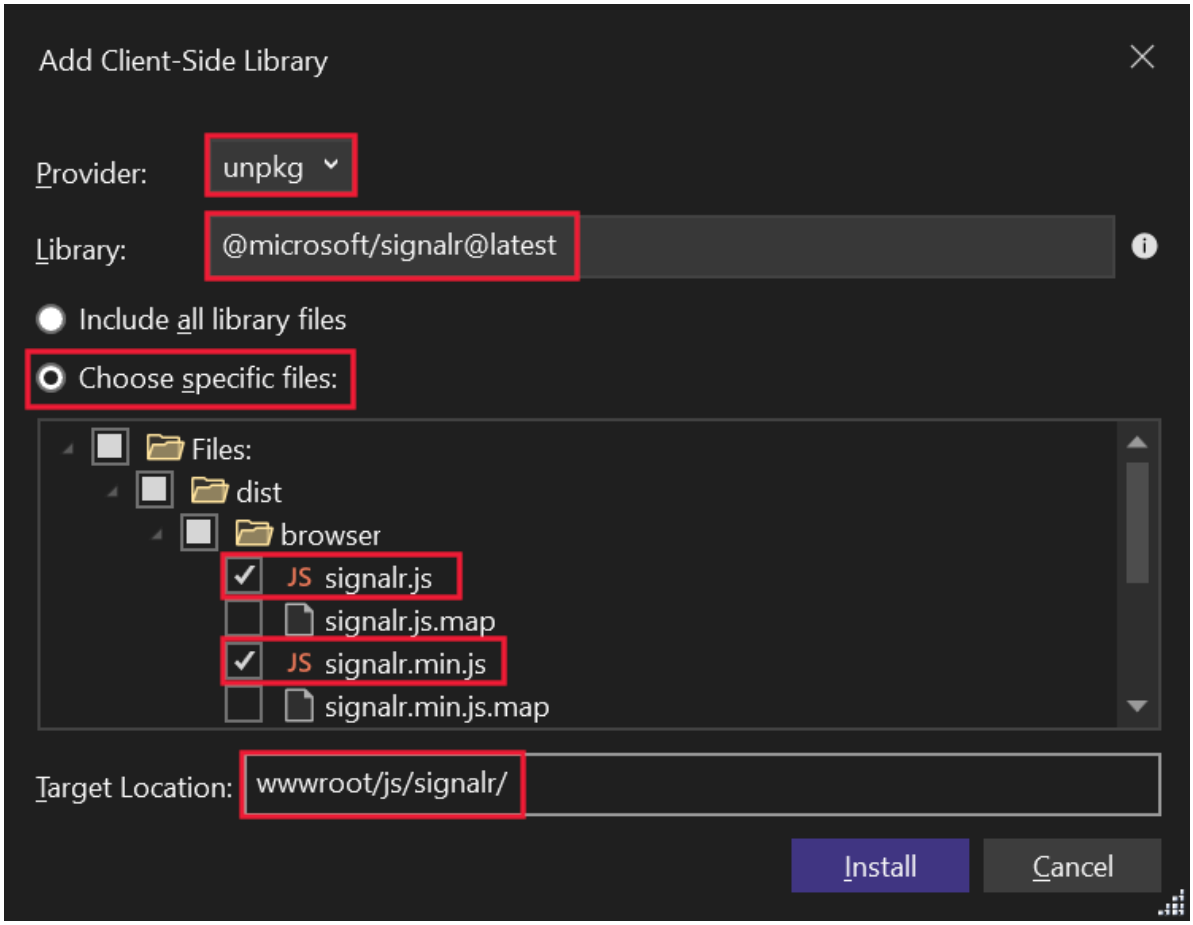
In the **Create a new project** dialog, select **ASP.NET Core Web App (Razor Pages)**, and then select **Next**.

In the **Configure your new project** dialog, enter `SignalRChat` for **Project name**. It's important to name the project `SignalRChat`, including matching the capitalization, so the namespaces match the code in the tutorial.

Select **Next**.

In the **Additional information** dialog, select **.NET 8.0 (Long Term Support)** and then select **Create**.

Add the SignalR client library



The SignalR server library is included in the ASP.NET Core shared framework. The JavaScript client library isn't automatically included in the project. For this tutorial, use Library Manager (LibMan) to get the client library from unpkg. `unpkg` is a fast, global content delivery network for everything on npm.

Visual Studio

In **Solution Explorer**, right-click the project, and select **Add** > **Client-Side Library**.

In the **Add Client-Side Library** dialog:

- Select **unpkg** for **Provider**
- Enter `@microsoft/signalr@latest` for **Library**.
- Select **Choose specific files**, expand the *dist/browser* folder, and select `signalr.js` and `signalr.min.js`.
- Set **Target Location** to `wwwroot/js/signalr/`.
- Select **Install**.

LibMan creates a `wwwroot/js/signalr` folder and copies the selected files to it.

Create a SignalR hub

A *hub* is a class that serves as a high-level pipeline that handles client-server communication.

In the SignalRChat project folder, create a `Hubs` folder.

In the `Hubs` folder, create the `ChatHub` class with the following code:

C#

```
using Microsoft.AspNetCore.SignalR;

namespace SignalRChat.Hubs
{
    public class ChatHub : Hub
    {
        public async Task SendMessage(string user, string message)
        {
            await Clients.All.SendAsync("ReceiveMessage", user, message);
        }
    }
}
```

The `ChatHub` class inherits from the SignalR Hub class. The `Hub` class manages connections, groups, and messaging.

The `SendMessage` method can be called by a connected client to send a message to all clients. JavaScript client code that calls the method is shown later in the tutorial. SignalR code is asynchronous to provide maximum scalability.

Configure SignalR

The SignalR server must be configured to pass SignalR requests to SignalR. Add the following highlighted code to the `Program.cs` file.

C#

```
using SignalRChat.Hubs;

var builder = WebApplication.CreateBuilder(args);

// Add services to the container.
builder.Services.AddRazorPages();
builder.Services.AddSignalR();

var app = builder.Build();
```

```
// Configure the HTTP request pipeline.
if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    // The default HSTS value is 30 days. You may want to change this for
production scenarios, see https://aka.ms/aspnetcore-hsts.
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseRouting();

app.UseAuthorization();

app.MapRazorPages();
app.MapHub<ChatHub>("/chatHub");

app.Run();
```

The preceding highlighted code adds SignalR to the ASP.NET Core dependency injection and routing systems.

Add SignalR client code

Replace the content in `Pages/Index.cshtml` with the following code:

CSHTML

```
@page
<div class="container">
    <div class="row p-1">
        <div class="col-1">User</div>
        <div class="col-5"><input type="text" id="userInput" /></div>
    </div>
    <div class="row p-1">
        <div class="col-1">Message</div>
        <div class="col-5"><input type="text" class="w-100"
id="messageInput" /></div>
    </div>
    <div class="row p-1">
        <div class="col-6 text-end">
            <input type="button" id="sendButton" value="Send Message" />
        </div>
    </div>
    <div class="row p-1">
        <div class="col-6">
            <hr />
        </div>
```

```
    </div>
    <div class="row p-1">
        <div class="col-6">
            <ul id="messagesList"></ul>
        </div>
    </div>
</div>
<script src="~/js/signalr/dist/browser/signalr.js"></script>
<script src="~/js/chat.js"></script>
```

The preceding markup:

- Creates text boxes and a submit button.
- Creates a list with `id="messagesList"` for displaying messages that are received from the SignalR hub.
- Includes script references to SignalR and the `chat.js` app code is created in the next step.

In the `wwwroot/js` folder, create a `chat.js` file with the following code:

JavaScript

```
"use strict";

var connection = new
signalR.HubConnectionBuilder().withUrl("/chatHub").build();

//Disable the send button until connection is established.
document.getElementById("sendButton").disabled = true;

connection.on("ReceiveMessage", function (user, message) {
    var li = document.createElement("li");
    document.getElementById("messagesList").appendChild(li);
    // We can assign user-supplied strings to an element's textContent
because it
    // is not interpreted as markup. If you're assigning in any other way,
you
    // should be aware of possible script injection concerns.
    li.textContent = `${user} says ${message}`;
});

connection.start().then(function () {
    document.getElementById("sendButton").disabled = false;
}).catch(function (err) {
    return console.error(err.toString());
});

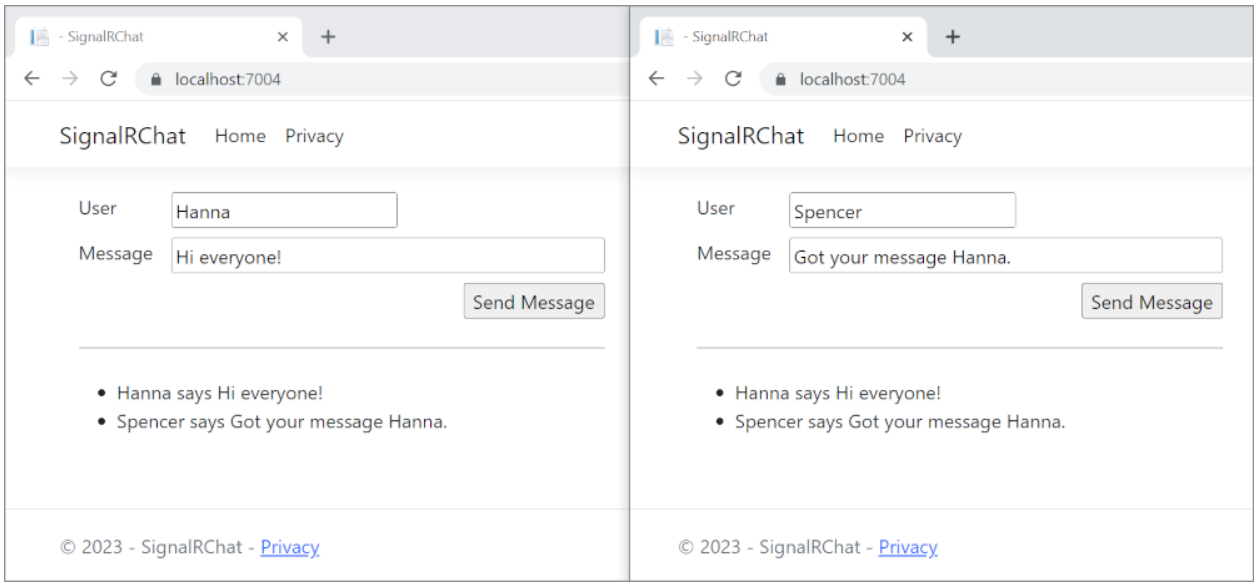
document.getElementById("sendButton").addEventListener("click", function
(event) {
    var user = document.getElementById("userInput").value;
    var message = document.getElementById("messageInput").value;
```

```
    connection.invoke("SendMessage", user, message).catch(function (err) {
        return console.error(err.toString());
    });
    event.preventDefault();
});
```

The preceding JavaScript:

- Creates and starts a connection.
- Adds to the submit button a handler that sends messages to the hub.
- Adds to the connection object a handler that receives messages from the hub and adds them to the list.

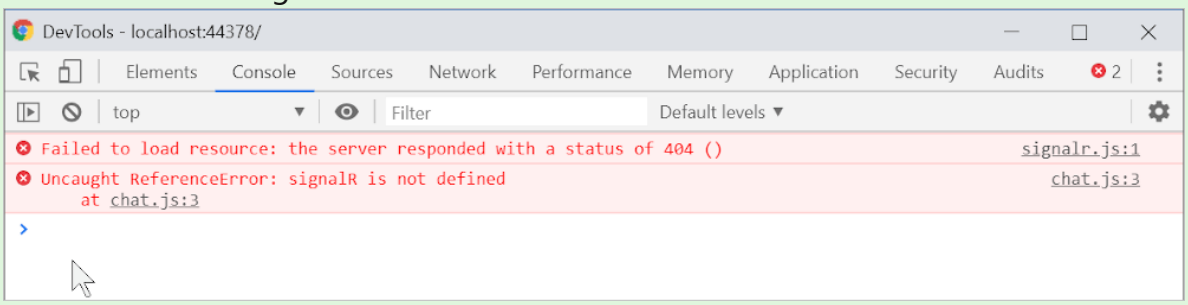
Run the app



Visual Studio

Select `Ctrl`+`F5` to run the app without debugging.

Copy the URL from the address bar, open another browser instance or tab, and paste the URL in the address bar.



Choose either browser, enter a name and message, and select the **Send Message** button.

The name and message are displayed on both pages instantly.

Tip

If the app doesn't work, open the browser developer tools (F12) and go to the console. Look for possible errors related to HTML and JavaScript code. For example, if `signalr.js` was put in a different folder than directed, the reference to that file won't work resulting in a 404 error in the console.

If an `ERR_SPDY_INADEQUATE_TRANSPORT_SECURITY` error has occurred in Chrome, run the following commands to update the development certificate:

.NET CLI

```
dotnet dev-certs https --clean
dotnet dev-certs https --trust
```

Publish to Azure

For information on deploying to Azure, see Quickstart: Deploy an ASP.NET web app. For more information on Azure SignalR Service, see What is Azure SignalR Service?.

Tutorial: Get started with ASP.NET Core SignalR using TypeScript and Webpack

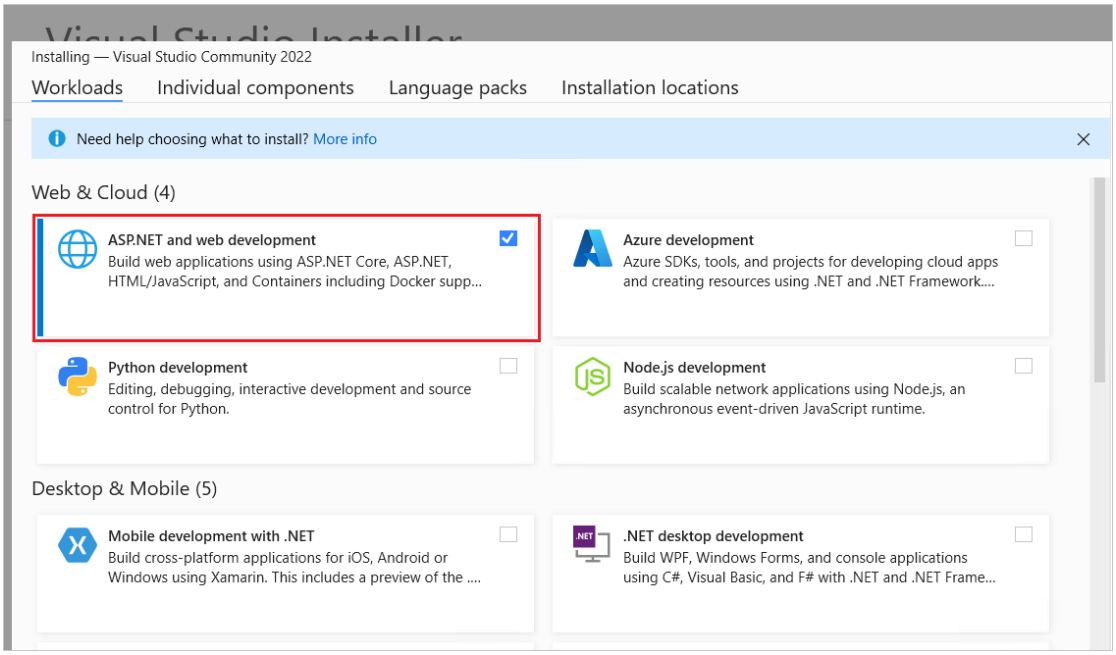
Article • 11/16/2023

By Sébastien Sougnez

This tutorial demonstrates using Webpack in an ASP.NET Core SignalR web app to bundle and build a client written in TypeScript. Webpack enables developers to bundle and build the client-side resources of a web app.

In this tutorial, you learn how to:

- ✓ Create an ASP.NET Core SignalR app
- ✓ Configure the SignalR server
- ✓ Configure a build pipeline using Webpack
- ✓ Configure the SignalR TypeScript client
- ✓ Enable communication between the client and the server



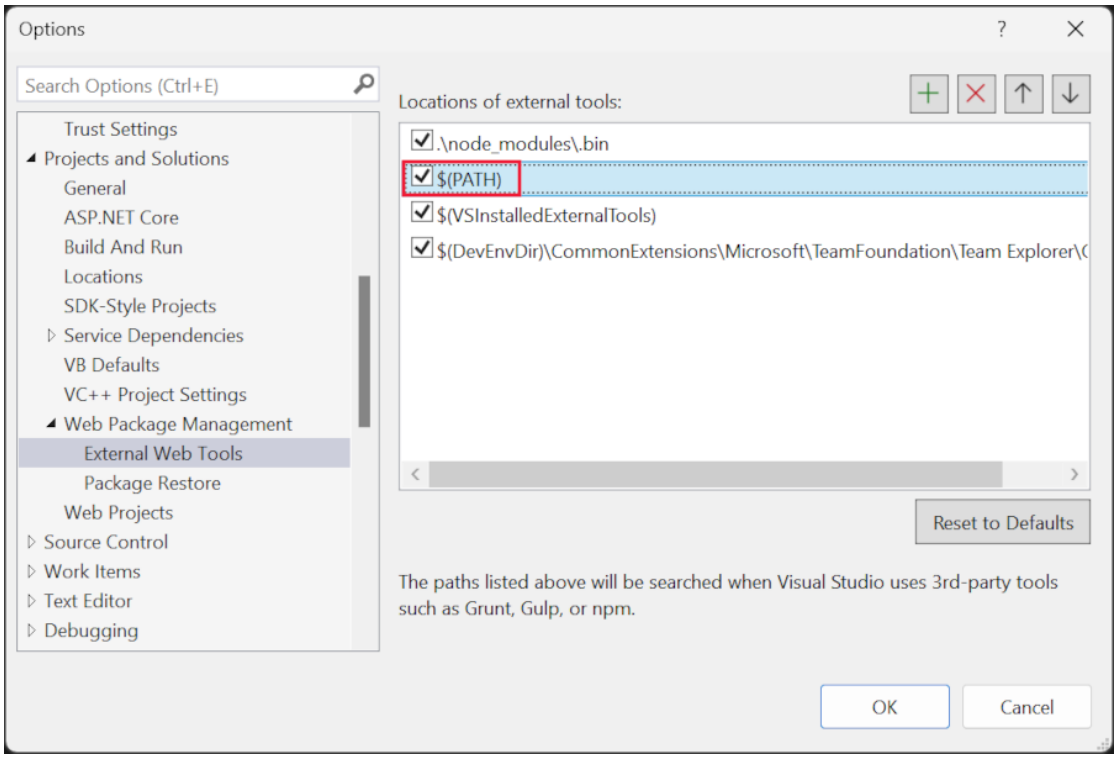
View or download sample code (how to download)

Prerequisites

- Node.js with npm

Visual Studio

- Visual Studio 2022 Preview with the **ASP.NET and web development** workload.



Create the ASP.NET Core web app

Visual Studio

By default, Visual Studio uses the version of npm found in its installation directory. To configure Visual Studio to look for npm in the `PATH` environment variable:

Launch Visual Studio. At the start window, select **Continue without code**.

1. Navigate to **Tools** > **Options** > **Projects and Solutions** > **Web Package Management** > **External Web Tools**.
2. Select the `$(PATH)` entry from the list. Select the up arrow to move the entry to the second position in the list, and select **OK**:

.

To create a new ASP.NET Core web app:

1. Use the **File** > **New** > **Project** menu option and choose the **ASP.NET Core Empty** template. Select **Next**.
2. Name the project `SignalRWebpack`, and select **Create**.
3. Select **.NET 8.0 (Long Term Support)** from the **Framework** drop-down. Select **Create**.

Add the Microsoft.TypeScript.MSBuild NuGet package to the project:

1. In **Solution Explorer**, right-click the project node and select **Manage NuGet Packages**. In the **Browse** tab, search for `Microsoft.TypeScript.MSBuild` and then select **Install** on the right to install the package.

Visual Studio adds the NuGet package under the **Dependencies** node in **Solution Explorer**, enabling TypeScript compilation in the project.

Configure the server

In this section, you configure the ASP.NET Core web app to send and receive SignalR messages.

1. In `Program.cs`, call AddSignalR:

```
C#
```

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddSignalR();
```

2. Again, in `Program.cs`, call UseDefaultFiles and UseStaticFiles:

```
C#

var app = builder.Build();

app.UseDefaultFiles();
app.UseStaticFiles();
```

   The preceding code allows the server to locate and serve the `index.html` file. The file is served whether the user enters its full URL or the root URL of the web app.

3. Create a new directory named `Hubs` in the project root, `SignalRWebpack/`, for the SignalR hub class.

4. Create a new file, `Hubs/ChatHub.cs`, with the following code:

```
C#

using Microsoft.AspNetCore.SignalR;

namespace SignalRWebpack.Hubs;

public class ChatHub : Hub
{
    public async Task NewMessage(long username, string message) =>
        await Clients.All.SendAsync("messageReceived", username,
message);
}
```

   The preceding code broadcasts received messages to all connected users once the server receives them. It's unnecessary to have a generic `on` method to receive all the messages. A method named after the message name is enough.

   In this example:

   - The TypeScript client sends a message identified as `newMessage`.
   - The C# `NewMessage` method expects the data sent by the client.
   - A call is made to SendAsync on Clients.All.
   - The received messages are sent to all clients connected to the hub.

5. Add the following `using` statement at the top of `Program.cs` to resolve the `ChatHub` reference:

```C#
using SignalRWebpack.Hubs;
```

6. In `Program.cs`, map the `/hub` route to the `ChatHub` hub. Replace the code that displays `Hello World!` with the following code:

```C#
app.MapHub<ChatHub>("/hub");
```

Configure the client

In this section, you create a Node.js project to convert TypeScript to JavaScript and bundle client-side resources, including HTML and CSS, using Webpack.

1. Run the following command in the project root to create a `package.json` file:

```Console
npm init -y
```

2. Add the highlighted property to the `package.json` file and save the file changes:

```JSON
{
  "name": "SignalRWebpack",
  "version": "1.0.0",
  "private": true,
  "description": "",
  "main": "index.js",
  "scripts": {
    "test": "echo \"Error: no test specified\" && exit 1"
  },
  "keywords": [],
  "author": "",
  "license": "ISC"
}
```

Setting the `private` property to `true` prevents package installation warnings in the next step.

3. Install the required npm packages. Run the following command from the project root:

```
Console

npm i -D -E clean-webpack-plugin css-loader html-webpack-plugin mini-
css-extract-plugin ts-loader typescript webpack webpack-cli
```

The `-E` option disables npm's default behavior of writing semantic versioning range operators to `package.json`. For example, `"webpack": "5.76.1"` is used instead of `"webpack": "^5.76.1"`. This option prevents unintended upgrades to newer package versions.

For more information, see the npm-install documentation.

4. Replace the `scripts` property of `package.json` file with the following code:

```
JSON

"scripts": {
  "build": "webpack --mode=development --watch",
  "release": "webpack --mode=production",
  "publish": "npm run release && dotnet publish -c Release"
},
```

The following scripts are defined:

- `build`: Bundles the client-side resources in development mode and watches for file changes. The file watcher causes the bundle to regenerate each time a project file changes. The `mode` option disables production optimizations, such as tree shaking and minification. use `build` in development only.
- `release`: Bundles the client-side resources in production mode.
- `publish`: Runs the `release` script to bundle the client-side resources in production mode. It calls the .NET CLI's publish command to publish the app.

5. Create a file named `webpack.config.js` in the project root, with the following code:

```
JavaScript

const path = require("path");
const HtmlWebpackPlugin = require("html-webpack-plugin");
const { CleanWebpackPlugin } = require("clean-webpack-plugin");
```

```
const MiniCssExtractPlugin = require("mini-css-extract-plugin");

module.exports = {
    entry: "./src/index.ts",
    output: {
        path: path.resolve(__dirname, "wwwroot"),
        filename: "[name].[chunkhash].js",
        publicPath: "/",
    },
    resolve: {
        extensions: [".js", ".ts"],
    },
    module: {
        rules: [
            {
                test: /\.ts$/,
                use: "ts-loader",
            },
            {
                test: /\.css$/,
                use: [MiniCssExtractPlugin.loader, "css-loader"],
            },
        ],
    },
    plugins: [
        new CleanWebpackPlugin(),
        new HtmlWebpackPlugin({
            template: "./src/index.html",
        }),
        new MiniCssExtractPlugin({
            filename: "css/[name].[chunkhash].css",
        }),
    ],
};
```

The preceding file configures the Webpack compilation process:

- The `output` property overrides the default value of `dist`. The bundle is instead emitted in the `wwwroot` directory.
- The `resolve.extensions` array includes `.js` to import the SignalR client JavaScript.

6. Create a new directory named `src` in the project root, `SignalRWebpack/`, for the client code.

7. Copy the `src` directory and its contents from the sample project into the project root. The `src` directory contains the following files:

    - `index.html`, which defines the homepage's boilerplate markup:

HTML

```
<!DOCTYPE html>
<html lang="en">
  <head>
    <meta charset="utf-8" />
    <title>ASP.NET Core SignalR with TypeScript and
Webpack</title>
  </head>
  <body>
    <div id="divMessages" class="messages"></div>
    <div class="input-zone">
      <label id="lblMessage" for="tbMessage">Message:</label>
      <input id="tbMessage" class="input-zone-input" type="text"
/>
      <button id="btnSend">Send</button>
    </div>
  </body>
</html>
```

- `css/main.css`, which provides CSS styles for the homepage:

CSS

```
*,
*::before,
*::after {
  box-sizing: border-box;
}

html,
body {
  margin: 0;
  padding: 0;
}

.input-zone {
  align-items: center;
  display: flex;
  flex-direction: row;
  margin: 10px;
}

.input-zone-input {
  flex: 1;
  margin-right: 10px;
}

.message-author {
  font-weight: bold;
}

.messages {
```

```
  border: 1px solid #000;
  margin: 10px;
  max-height: 300px;
  min-height: 300px;
  overflow-y: auto;
  padding: 5px;
}
```

- `tsconfig.json`, which configures the TypeScript compiler to produce ECMAScript 5-compatible JavaScript:

JSON

```
{
  "compilerOptions": {
    "target": "es5"
  }
}
```

- `index.ts`:

TypeScript

```
import * as signalR from "@microsoft/signalr";
import "./css/main.css";

const divMessages: HTMLDivElement =
document.querySelector("#divMessages");
const tbMessage: HTMLInputElement =
document.querySelector("#tbMessage");
const btnSend: HTMLButtonElement =
document.querySelector("#btnSend");
const username = new Date().getTime();

const connection = new signalR.HubConnectionBuilder()
    .withUrl("/hub")
    .build();

connection.on("messageReceived", (username: string, message:
string) => {
  const m = document.createElement("div");

  m.innerHTML = `<div class="message-author">${username}</div>
<div>${message}</div>`;

  divMessages.appendChild(m);
  divMessages.scrollTop = divMessages.scrollHeight;
});

connection.start().catch((err) => document.write(err));
```

```
tbMessage.addEventListener("keyup", (e: KeyboardEvent) => {
  if (e.key === "Enter") {
    send();
  }
});

btnSend.addEventListener("click", send);

function send() {
  connection.send("newMessage", username, tbMessage.value)
    .then(() => (tbMessage.value = ""));
}
```

The preceding code retrieves references to DOM elements and attaches two event handlers:

- `keyup`: Fires when the user types in the `tbMessage` textbox and calls the `send` function when the user presses the **Enter** key.
- `click`: Fires when the user selects the **Send** button and calls `send` function is called.

The `HubConnectionBuilder` class creates a new builder for configuring the server connection. The `withUrl` function configures the hub URL.

SignalR enables the exchange of messages between a client and a server. Each message has a specific name. For example, messages with the name `messageReceived` can run the logic responsible for displaying the new message in the messages zone. Listening to a specific message can be done via the `on` function. Any number of message names can be listened to. It's also possible to pass parameters to the message, such as the author's name and the content of the message received. Once the client receives a message, a new `div` element is created with the author's name and the message content in its `innerHTML` attribute. It's added to the main `div` element displaying the messages.

Sending a message through the WebSockets connection requires calling the `send` method. The method's first parameter is the message name. The message data inhabits the other parameters. In this example, a message identified as `newMessage` is sent to the server. The message consists of the username and the user input from a text box. If the send works, the text box value is cleared.

8. Run the following command at the project root:

```
Console
```

```
npm i @microsoft/signalr @types/node
```

The preceding command installs:

- The SignalR TypeScript client, which allows the client to send messages to the server.
- The TypeScript type definitions for Node.js, which enables compile-time checking of Node.js types.

Test the app

Confirm that the app works with the following steps:

Visual Studio

1. Run Webpack in `release` mode. Using the **Package Manager Console** window, run the following command in the project root.

   Console

   ```
   npm run release
   ```

   This command generates the client-side assets to be served when running the app. The assets are placed in the `wwwroot` folder.

   Webpack completed the following tasks:

   - Purged the contents of the `wwwroot` directory.
   - Converted the TypeScript to JavaScript in a process known as *transpilation*.
   - Mangled the generated JavaScript to reduce file size in a process known as *minification*.
   - Copied the processed JavaScript, CSS, and HTML files from `src` to the `wwwroot` directory.
   - Injected the following elements into the `wwwroot/index.html` file:
     - A `<link>` tag, referencing the `wwwroot/main.<hash>.css` file. This tag is placed immediately before the closing `</head>` tag.
     - A `<script>` tag, referencing the minified `wwwroot/main.<hash>.js` file. This tag is placed immediately after the closing `</title>` tag.

2. Select **Debug** > **Start without debugging** to launch the app in a browser without attaching the debugger. The `wwwroot/index.html` file is served at `https://localhost:<port>`.

   If there are compile errors, try closing and reopening the solution.

3. Open another browser instance (any browser) and paste the URL in the address bar.

4. Choose either browser, type something in the **Message** text box, and select the **Send** button. The unique user name and message are displayed on both pages instantly.

Use ASP.NET Core SignalR with Blazor

Article • 06/19/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

This tutorial provides a basic working experience for building a real-time app using SignalR with Blazor. This article is useful for developers who are already familiar with SignalR and are seeking to understand how to use SignalR in a Blazor app. For detailed guidance on the SignalR and Blazor frameworks, see the following reference documentation sets and the API documentation:

- Overview of ASP.NET Core SignalR
- ASP.NET Core Blazor
- .NET API browser

Learn how to:

- ✓ Create a Blazor app
- ✓ Add the SignalR client library
- ✓ Add a SignalR hub
- ✓ Add SignalR services and an endpoint for the SignalR hub
- ✓ Add a Razor component code for chat

At the end of this tutorial, you'll have a working chat app.

Prerequisites

Visual Studio

Visual Studio (latest release) with the **ASP.NET and web development** workload

Sample app

Downloading the tutorial's sample chat app isn't required for this tutorial. The sample app is the final, working app produced by following the steps of this tutorial. When you open the samples repository, open the version folder that you plan to target and find the sample named `BlazorSignalRApp`.

View or download sample code (how to download)

Create a Blazor Web App

Follow the guidance for your choice of tooling:

Visual Studio

> **Note**
>
> Visual Studio 2022 or later and .NET Core SDK 8.0.0 or later are required.

In Visual Studio:

- Select **Create a new project** from the **Start Window** or select **File** > **New** > **Project** from the menu bar.
- In the **Create a new project** dialog, select **Blazor Web App** from the list of project templates. Select the **Next** button.
- In the **Configure your new project** dialog, name the project `BlazorSignalRApp` in the **Project name** field, including matching the capitalization. Using this exact project name is important to ensure that the namespaces match for code that you copy from the tutorial into the app that you're building.
- Confirm that the **Location** for the app is suitable. Leave the **Place solution and project in the same directory** checkbox selected. Select the **Next** button.
- In the **Additional information** dialog, use the following settings:
  - **Framework**: Confirm that the latest framework is selected. If Visual Studio's **Framework** dropdown list doesn't include the latest available .NET framework, update Visual Studio and restart the tutorial.
  - **Authentication type**: **None**
  - **Configure for HTTPS**: Selected
  - **Interactive render mode**: **WebAssembly**
  - **Interactivity location**: **Per page/component**
  - **Include sample pages**: Selected
  - **Do not use top-level statements**: Not selected

- Select **Create**.

The guidance in this article uses a WebAssembly component for the SignalR client because it doesn't make sense to use SignalR to connect to a hub from an Interactive Server component in the same app, as that can lead to server port exhaustion.

Add the SignalR client library

Visual Studio

In **Solution Explorer**, right-click the `BlazorSignalRApp.Client` project and select **Manage NuGet Packages**.

In the **Manage NuGet Packages** dialog, confirm that the **Package source** is set to `nuget.org`.

With **Browse** selected, type `Microsoft.AspNetCore.SignalR.Client` in the search box.

In the search results, select the latest release of the Microsoft.AspNetCore.SignalR.Client package. Select **Install**.

If the **Preview Changes** dialog appears, select **OK**.

If the **License Acceptance** dialog appears, select **I Accept** if you agree with the license terms.

Add a SignalR hub

In the server `BlazorSignalRApp` project, create a `Hubs` (plural) folder and add the following `ChatHub` class (`Hubs/ChatHub.cs`):

C#

```
using Microsoft.AspNetCore.SignalR;

namespace BlazorSignalRApp.Hubs;

public class ChatHub : Hub
{
    public async Task SendMessage(string user, string message)
    {
        await Clients.All.SendAsync("ReceiveMessage", user, message);
```

```
    }
}
```

Add services and an endpoint for the SignalR hub

Open the `Program` file of the server `BlazorSignalRApp` project.

Add the namespaces for Microsoft.AspNetCore.ResponseCompression and the `ChatHub` class to the top of the file:

C#

```
using Microsoft.AspNetCore.ResponseCompression;
using BlazorSignalRApp.Hubs;
```

Add SignalR and Response Compression Middleware services:

C#

```
builder.Services.AddSignalR();

builder.Services.AddResponseCompression(opts =>
{
   opts.MimeTypes = ResponseCompressionDefaults.MimeTypes.Concat(
       ["application/octet-stream"]);
});
```

Use Response Compression Middleware at the top of the processing pipeline's configuration. Place the following line of code immediately after the line that builds the app (`var app = builder.Build();`):

C#

```
app.UseResponseCompression();
```

Add an endpoint for the hub immediately before the line that runs the app (`app.Run();`):

C#

```
app.MapHub<ChatHub>("/chathub");
```

Add Razor component code for chat

Add the following `Pages/Chat.razor` file to the `BlazorSignalRApp.Client` project:

razor

```razor
@page "/chat"
@rendermode InteractiveWebAssembly
@using Microsoft.AspNetCore.SignalR.Client
@inject NavigationManager Navigation
@implements IAsyncDisposable

<PageTitle>Chat</PageTitle>

<div class="form-group">
    <label>
        User:
        <input @bind="userInput" />
    </label>
</div>
<div class="form-group">
    <label>
        Message:
        <input @bind="messageInput" size="50" />
    </label>
</div>
<button @onclick="Send" disabled="@(!IsConnected)">Send</button>

<hr>

<ul id="messagesList">
    @foreach (var message in messages)
    {
        <li>@message</li>
    }
</ul>

@code {
    private HubConnection? hubConnection;
    private List<string> messages = new List<string>();
    private string? userInput;
    private string? messageInput;

    protected override async Task OnInitializedAsync()
    {
        hubConnection = new HubConnectionBuilder()
            .WithUrl(Navigation.ToAbsoluteUri("/chathub"))
            .Build();

        hubConnection.On<string, string>("ReceiveMessage", (user, message)
=>
        {
            var encodedMsg = $"{user}: {message}";
```

```
            messages.Add(encodedMsg);
            InvokeAsync(StateHasChanged);
        });

        await hubConnection.StartAsync();
    }

    private async Task Send()
    {
        if (hubConnection is not null)
        {
            await hubConnection.SendAsync("SendMessage", userInput,
messageInput);
        }
    }

    public bool IsConnected =>
        hubConnection?.State == HubConnectionState.Connected;

    public async ValueTask DisposeAsync()
    {
        if (hubConnection is not null)
        {
            await hubConnection.DisposeAsync();
        }
    }
}
```

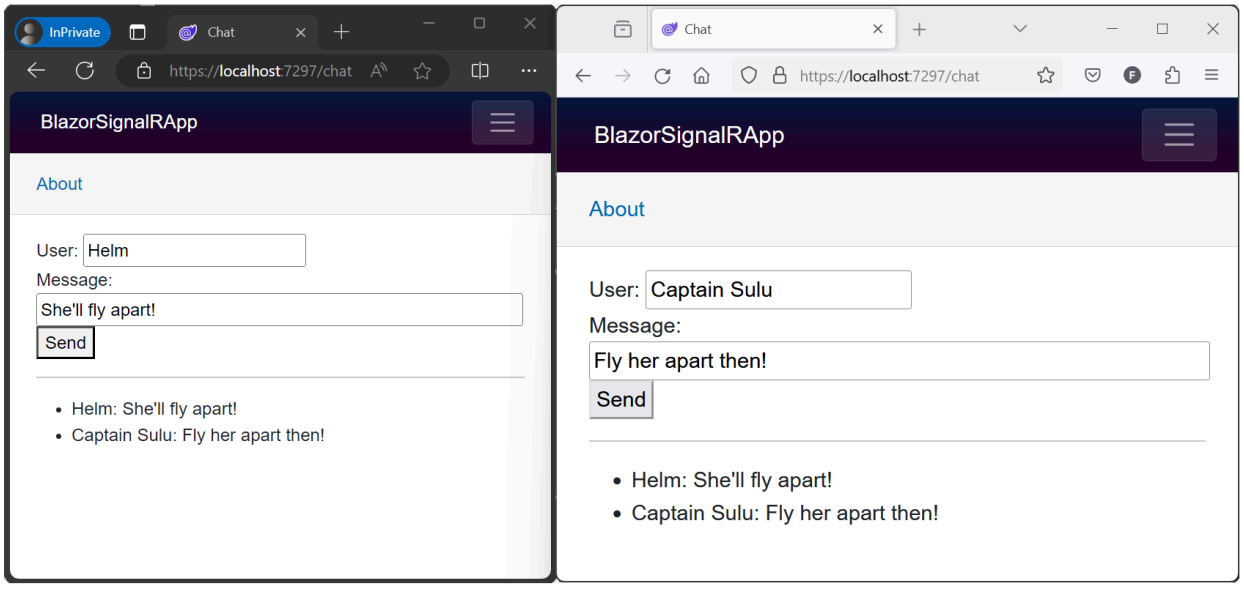
Add an entry to the `NavMenu` component to reach the chat page. In `Components/Layout/NavMenu.razor` immediately after the `<div>` block for the `Weather` component, add the following `<div>` block:

razor

```
<div class="nav-item px-3">
    <NavLink class="nav-link" href="chat">
        <span class="bi bi-list-nested-nav-menu" aria-hidden="true"></span>
Chat
    </NavLink>
</div>
```

> ⓘ Note
>
> Disable Response Compression Middleware in the `Development` environment when using Hot Reload. For more information, see ASP.NET Core Blazor SignalR guidance.

Run the app



Follow the guidance for your tooling:

Visual Studio

With the server `BlazorSignalRApp` project selected in **Solution Explorer**, press `F5` to run the app with debugging or `Ctrl`+`F5` (Windows)/`⌘`+`F5` (macOS) to run the app without debugging.

Copy the URL from the address bar, open another browser instance or tab, and paste the URL in the address bar.

Choose either browser, enter a name and message, and select the button to send the message. The name and message are displayed on both pages instantly:

Quotes: *Star Trek VI: The Undiscovered Country* ©1991 Paramount

Next steps

In this tutorial, you learned how to:

- ✓ Create a Blazor app
- ✓ Add the SignalR client library
- ✓ Add a SignalR hub
- ✓ Add SignalR services and an endpoint for the SignalR hub
- ✓ Add a Razor component code for chat

For detailed guidance on the SignalR and Blazor frameworks, see the following reference documentation sets:

Overview of ASP.NET Core SignalR | ASP.NET Core Blazor

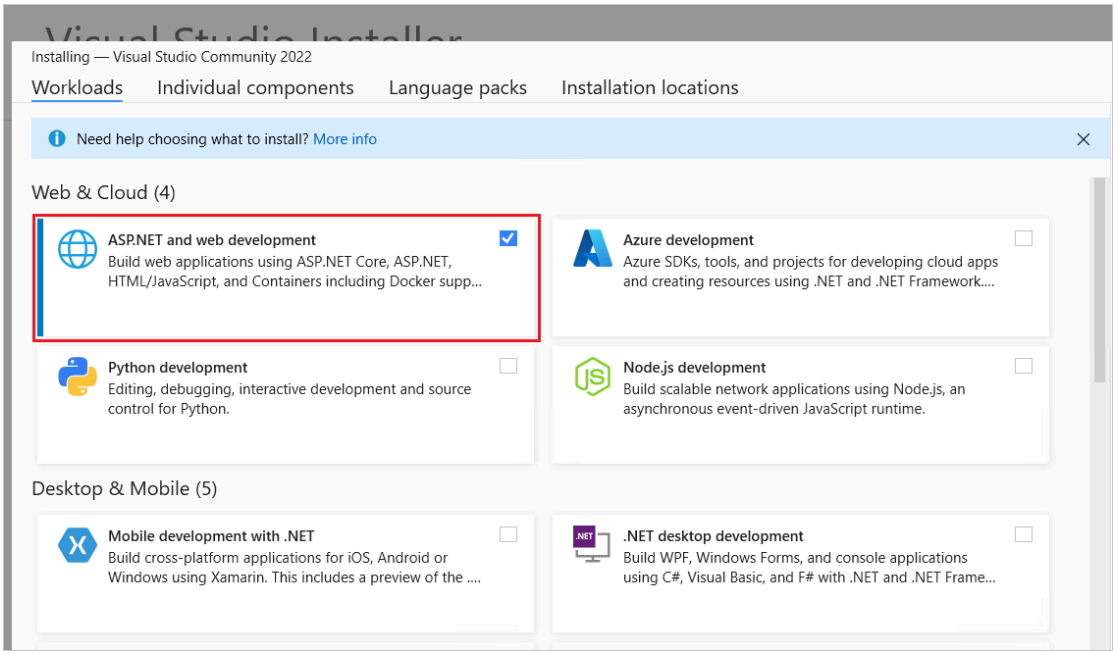
Provide product feedback

Tutorial: Create a gRPC client and server in ASP.NET Core

Article • 06/18/2024

This tutorial shows how to create a .NET Core gRPC client and an ASP.NET Core gRPC Server. At the end, you'll have a gRPC client that communicates with the gRPC Greeter service.



In this tutorial, you:

- ✓ Create a gRPC Server.
- ✓ Create a gRPC client.
- ✓ Test the gRPC client with the gRPC Greeter service.

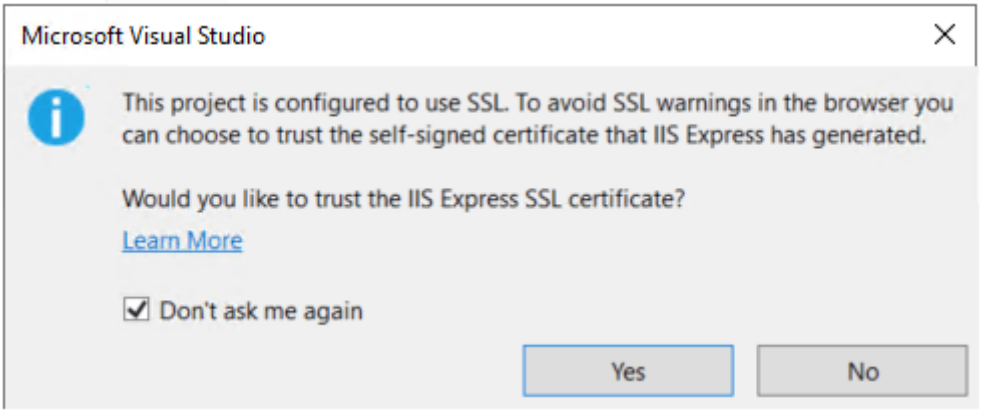
Prerequisites

Visual Studio

- Visual Studio 2022 with the **ASP.NET and web development** workload.

Create a gRPC service

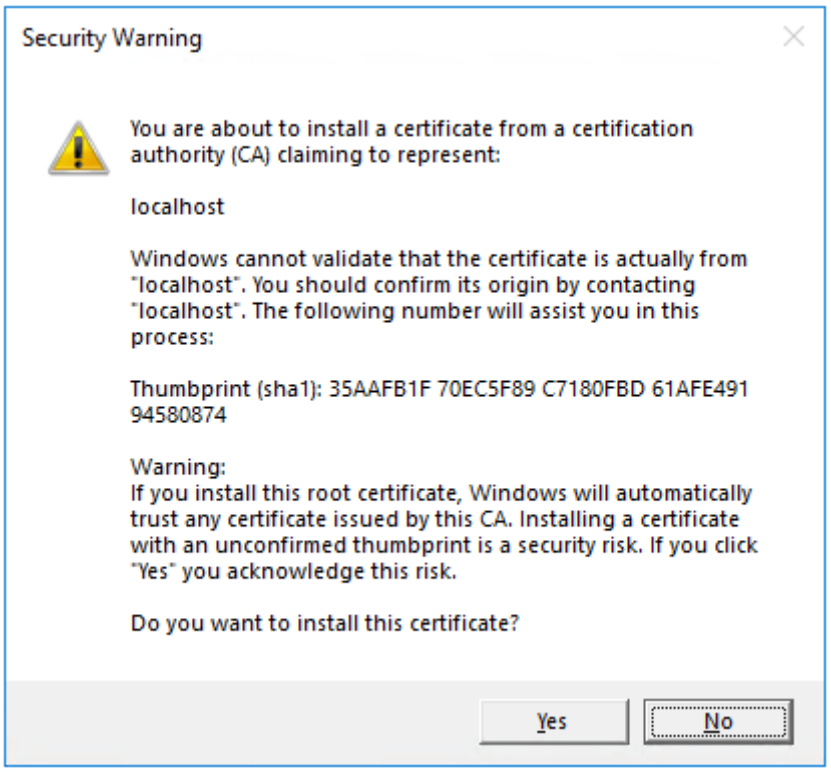
Visual Studio



- Start Visual Studio 2022 and select **New Project**.
- In the **Create a new project** dialog, search for `gRPC`. Select **ASP.NET Core gRPC Service** and select **Next**.
- In the **Configure your new project** dialog, enter `GrpcGreeter` for **Project name**. It's important to name the project *GrpcGreeter* so the namespaces match when you copy and paste code.
- Select **Next**.
- In the **Additional information** dialog, select **.NET 8.0 (Long Term Support)** and then select **Create**.

Run the service

Visual Studio



- Press Ctrl+F5 to run without the debugger.

  Visual Studio displays the following dialog when a project is not yet configured to use SSL:

  Select **Yes** if you trust the IIS Express SSL certificate.

  The following dialog is displayed:

Select **Yes** if you agree to trust the development certificate.

For information on trusting the Firefox browser, see Firefox SEC_ERROR_INADEQUATE_KEY_USAGE certificate error.

Visual Studio:

- Starts Kestrel server.
- Launches a browser.
- Navigates to `http://localhost:port`, such as `http://localhost:7042`.
  - *port*: A randomly assigned port number for the app.
  - `localhost`: The standard hostname for the local computer. Localhost only serves web requests from the local computer.

The logs show the service listening on `https://localhost:<port>`, where `<port>` is the localhost port number randomly assigned when the project is created and set in `Properties/launchSettings.json`.

Console

```
info: Microsoft.Hosting.Lifetime[0]
      Now listening on: https://localhost:<port>
info: Microsoft.Hosting.Lifetime[0]
      Application started. Press Ctrl+C to shut down.
info: Microsoft.Hosting.Lifetime[0]
      Hosting environment: Development
```

> **Note**
>
> The gRPC template is configured to use Transport Layer Security (TLS). gRPC clients need to use HTTPS to call the server. The gRPC service localhost port number is randomly assigned when the project is created and set in the *Properties\launchSettings.json* file of the gRPC service project.

Examine the project files

GrpcGreeter project files:

- `Protos/greet.proto`: defines the `Greeter` gRPC and is used to generate the gRPC server assets. For more information, see Introduction to gRPC.
- `Services` folder: Contains the implementation of the `Greeter` service.
- `appSettings.json`: Contains configuration data such as the protocol used by Kestrel. For more information, see Configuration in ASP.NET Core.
- `Program.cs`, which contains:
  - The entry point for the gRPC service. For more information, see .NET Generic Host in ASP.NET Core.
  - Code that configures app behavior. For more information, see App startup.

Create the gRPC client in a .NET console app

Visual Studio

- Open a second instance of Visual Studio and select **New Project**.
- In the **Create a new project** dialog, select **Console App**, and select **Next**.
- In the **Project name** text box, enter **GrpcGreeterClient** and select **Next**.
- In the **Additional information** dialog, select **.NET 8.0 (Long Term Support)** and then select **Create**.

Add required NuGet packages

The gRPC client project requires the following NuGet packages:

- Grpc.Net.Client, which contains the .NET Core client.
- Google.Protobuf, which contains protobuf message APIs for C#.

- Grpc.Tools, which contain C# tooling support for protobuf files. The tooling package isn't required at runtime, so the dependency is marked with `PrivateAssets="All"`.

Visual Studio

Install the packages using either the Package Manager Console (PMC) or Manage NuGet Packages.

PMC option to install packages

- From Visual Studio, select **Tools** > **NuGet Package Manager** > **Package Manager Console**
- From the **Package Manager Console** window, run `cd GrpcGreeterClient` to change directories to the folder containing the `GrpcGreeterClient.csproj` files.
- Run the following commands:

PowerShell

```
Install-Package Grpc.Net.Client
Install-Package Google.Protobuf
Install-Package Grpc.Tools
```

Manage NuGet Packages option to install packages

- Right-click the project in **Solution Explorer** > **Manage NuGet Packages**.
- Select the **Browse** tab.
- Enter **Grpc.Net.Client** in the search box.
- Select the **Grpc.Net.Client** package from the **Browse** tab and select **Install**.
- Repeat for `Google.Protobuf` and `Grpc.Tools`.

Add greet.proto

- Create a *Protos* folder in the gRPC client project.
- Copy the *Protos\greet.proto* file from the gRPC Greeter service to the *Protos* folder in the gRPC client project.
- Update the namespace inside the `greet.proto` file to the project's namespace:

JSON

```
option csharp_namespace = "GrpcGreeterClient";
```

- Edit the `GrpcGreeterClient.csproj` project file:

Visual Studio

Right-click the project and select **Edit Project File**.

- Add an item group with a `<Protobuf>` element that refers to the *greet.proto* file:

XML

```
<ItemGroup>
  <Protobuf Include="Protos\greet.proto" GrpcServices="Client" />
</ItemGroup>
```

Create the Greeter client

- Build the client project to create the types in the `GrpcGreeterClient` namespace.

> **Note**
>
> The `GrpcGreeterClient` types are generated automatically by the build process. The tooling package Grpc.Tools generates the following files based on the *greet.proto* file:
>
> - `GrpcGreeterClient\obj\Debug\[TARGET_FRAMEWORK]\Protos\Greet.cs`: The protocol buffer code which populates, serializes and retrieves the request and response message types.
> - `GrpcGreeterClient\obj\Debug\[TARGET_FRAMEWORK]\Protos\GreetGrpc.cs`: Contains the generated client classes.
>
> For more information on the C# assets automatically generated by Grpc.Tools, see gRPC services with C#: Generated C# assets.

- Update the gRPC client `Program.cs` file with the following code.

C#

```
using System.Threading.Tasks;
using Grpc.Net.Client;
using GrpcGreeterClient;

// The port number must match the port of the gRPC server.
using var channel = GrpcChannel.ForAddress("https://localhost:7042");
var client = new Greeter.GreeterClient(channel);
var reply = await client.SayHelloAsync(
                  new HelloRequest { Name = "GreeterClient" });
Console.WriteLine("Greeting: " + reply.Message);
Console.WriteLine("Press any key to exit...");
Console.ReadKey();
```

- In the preceding highlighted code, replace the localhost port number `7042` with the `HTTPS` port number specified in `Properties/launchSettings.json` within the `GrpcGreeter` service project.

`Program.cs` contains the entry point and logic for the gRPC client.

The Greeter client is created by:

- Instantiating a `GrpcChannel` containing the information for creating the connection to the gRPC service.
- Using the `GrpcChannel` to construct the Greeter client:

C#

```
// The port number must match the port of the gRPC server.
using var channel = GrpcChannel.ForAddress("https://localhost:7042");
var client = new Greeter.GreeterClient(channel);
var reply = await client.SayHelloAsync(
                  new HelloRequest { Name = "GreeterClient" });
Console.WriteLine("Greeting: " + reply.Message);
Console.WriteLine("Press any key to exit...");
Console.ReadKey();
```

The Greeter client calls the asynchronous `SayHello` method. The result of the `SayHello` call is displayed:

C#

```
// The port number must match the port of the gRPC server.
using var channel = GrpcChannel.ForAddress("https://localhost:7042");
var client = new Greeter.GreeterClient(channel);
```

```
var reply = await client.SayHelloAsync(
                  new HelloRequest { Name = "GreeterClient" });
Console.WriteLine("Greeting: " + reply.Message);
Console.WriteLine("Press any key to exit...");
Console.ReadKey();
```

Test the gRPC client with the gRPC Greeter service

Update the `appsettings.Development.json` file by adding the following highlighted lines:

C#

```
{
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "Microsoft.AspNetCore": "Warning"
      ,"Microsoft.AspNetCore.Hosting": "Information",
      "Microsoft.AspNetCore.Routing.EndpointMiddleware": "Information"
    }
  }
}
```

Visual Studio

- In the Greeter service, press `Ctrl+F5` to start the server without the debugger.
- In the `GrpcGreeterClient` project, press `Ctrl+F5` to start the client without the debugger.

The client sends a greeting to the service with a message containing its name, *GreeterClient*. The service sends the message "Hello GreeterClient" as a response. The "Hello GreeterClient" response is displayed in the command prompt:

Console

```
Greeting: Hello GreeterClient
Press any key to exit...
```

The gRPC service records the details of the successful call in the logs written to the command prompt:

Console

```
info: Microsoft.Hosting.Lifetime[0]
      Now listening on: https://localhost:<port>
info: Microsoft.Hosting.Lifetime[0]
      Application started. Press Ctrl+C to shut down.
info: Microsoft.Hosting.Lifetime[0]
      Hosting environment: Development
info: Microsoft.Hosting.Lifetime[0]
      Content root path:
C:\GH\aspnet\docs\4\Docs\aspnetcore\tutorials\grpc\grpc-
start\sample\GrpcGreeter
info: Microsoft.AspNetCore.Hosting.Diagnostics[1]
      Request starting HTTP/2 POST https://localhost:
<port>/Greet.Greeter/SayHello application/grpc
info: Microsoft.AspNetCore.Routing.EndpointMiddleware[0]
      Executing endpoint 'gRPC - /Greet.Greeter/SayHello'
info: Microsoft.AspNetCore.Routing.EndpointMiddleware[1]
      Executed endpoint 'gRPC - /Greet.Greeter/SayHello'
info: Microsoft.AspNetCore.Hosting.Diagnostics[2]
      Request finished in 78.32260000000001ms 200 application/grpc
```

> **Note**
>
> The code in this article requires the ASP.NET Core HTTPS development certificate to secure the gRPC service. If the .NET gRPC client fails with the message `The remote certificate is invalid according to the validation procedure.` or `The SSL connection could not be established.`, the development certificate isn't trusted. To fix this issue, see Call a gRPC service with an untrusted/invalid certificate.

Next steps

- View or download the completed sample code for this tutorial (how to download).
- Overview for gRPC on .NET
- gRPC services with C#
- Migrate gRPC from C-core to gRPC for .NET

Razor Pages with Entity Framework Core in ASP.NET Core - Tutorial 1 of 8

Article • 09/27/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

By Tom Dykstra, Jeremy Likness, and Jon P Smith

This is the first in a series of tutorials that show how to use Entity Framework (EF) Core in an ASP.NET Core Razor Pages app. The tutorials build a web site for a fictional Contoso University. The site includes functionality such as student admission, course creation, and instructor assignments. The tutorial uses the code first approach. For information on following this tutorial using the database first approach, see this Github issue.

Download or view the completed app. Download instructions.

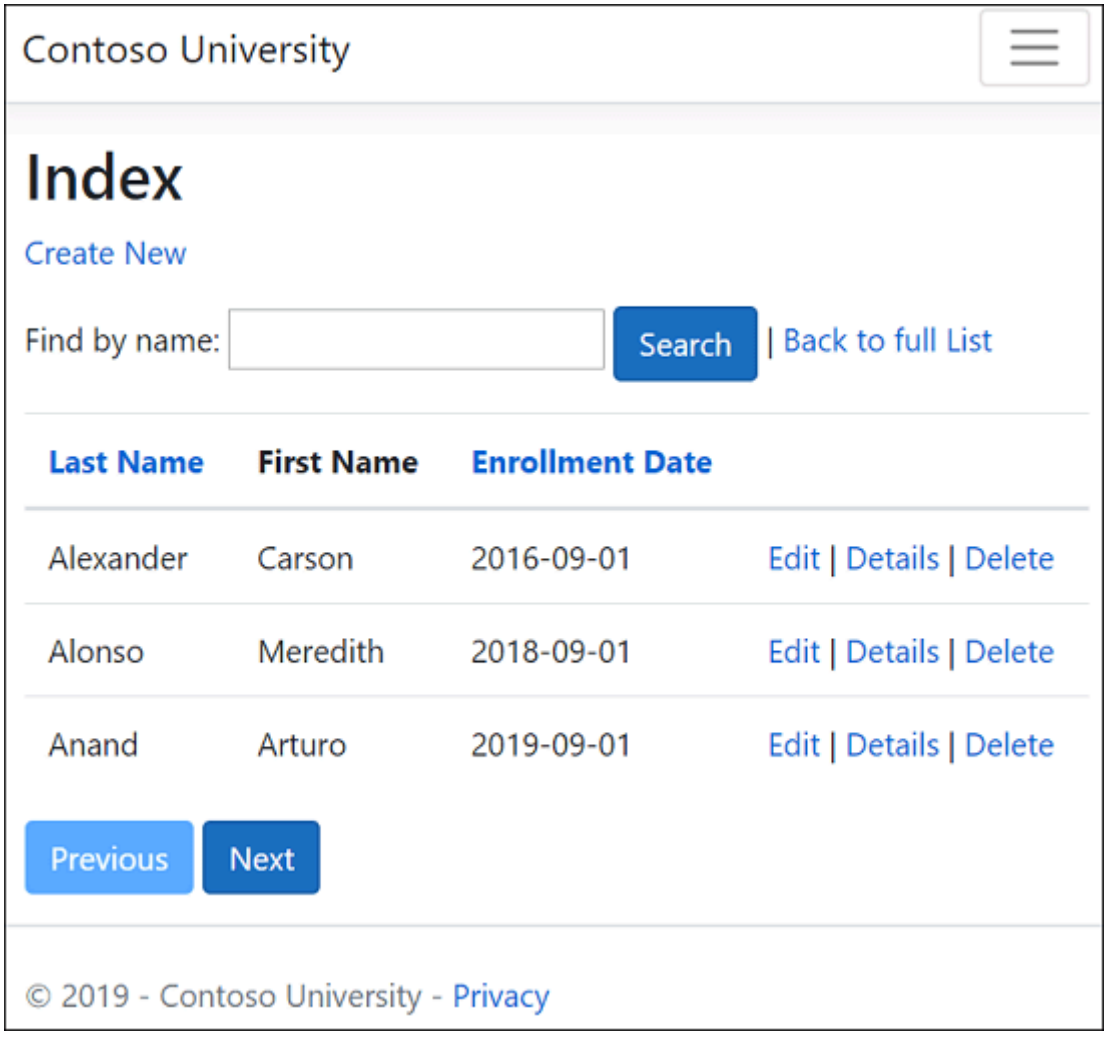
Prerequisites

- If you're new to Razor Pages, go through the Get started with Razor Pages tutorial series before starting this one.

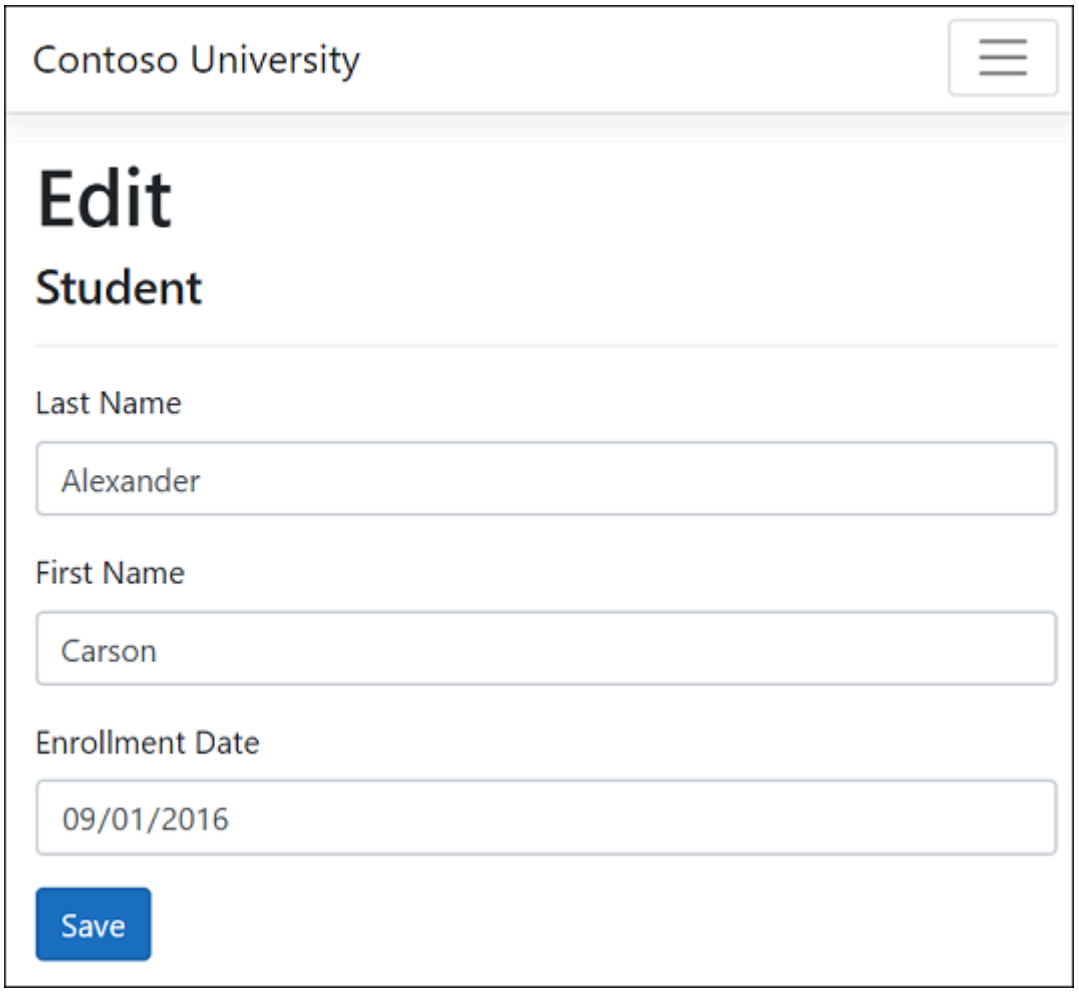
Visual Studio

- Visual Studio 2022 with the **ASP.NET and web development** workload.
- .NET 6.0 SDK

Database engines



The Visual Studio instructions use SQL Server LocalDB, a version of SQL Server Express that runs only on Windows.



Troubleshooting

If you run into a problem you can't resolve, compare your code to the completed project. A good way to get help is by posting a question to StackOverflow.com, using the ASP.NET Core tag or the EF Core tag.

The sample app

The app built in these tutorials is a basic university web site. Users can view and update student, course, and instructor information. Here are a few of the screens created in the tutorial.

The UI style of this site is based on the built-in project templates. The tutorial's focus is on how to use EF Core with ASP.NET Core, not how to customize the UI.

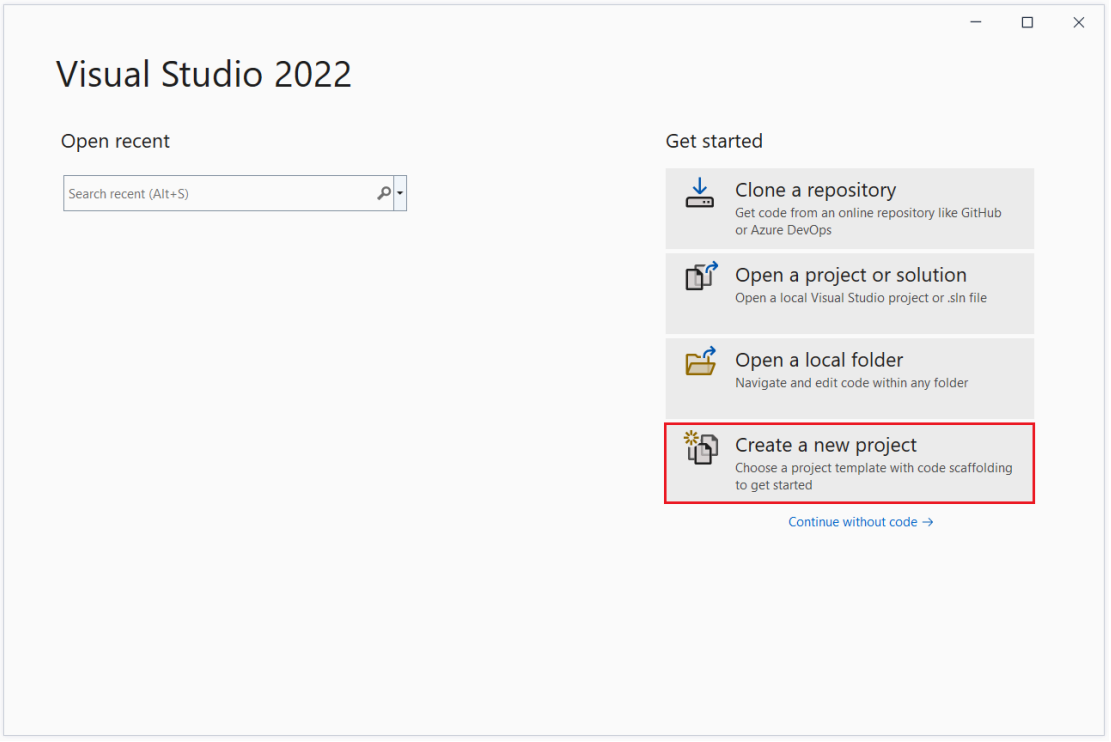
Optional: Build the sample download

This step is optional. Building the completed app is recommended when you have problems you can't solve. If you run into a problem you can't resolve, compare your code to the completed project. Download instructions.

Visual Studio

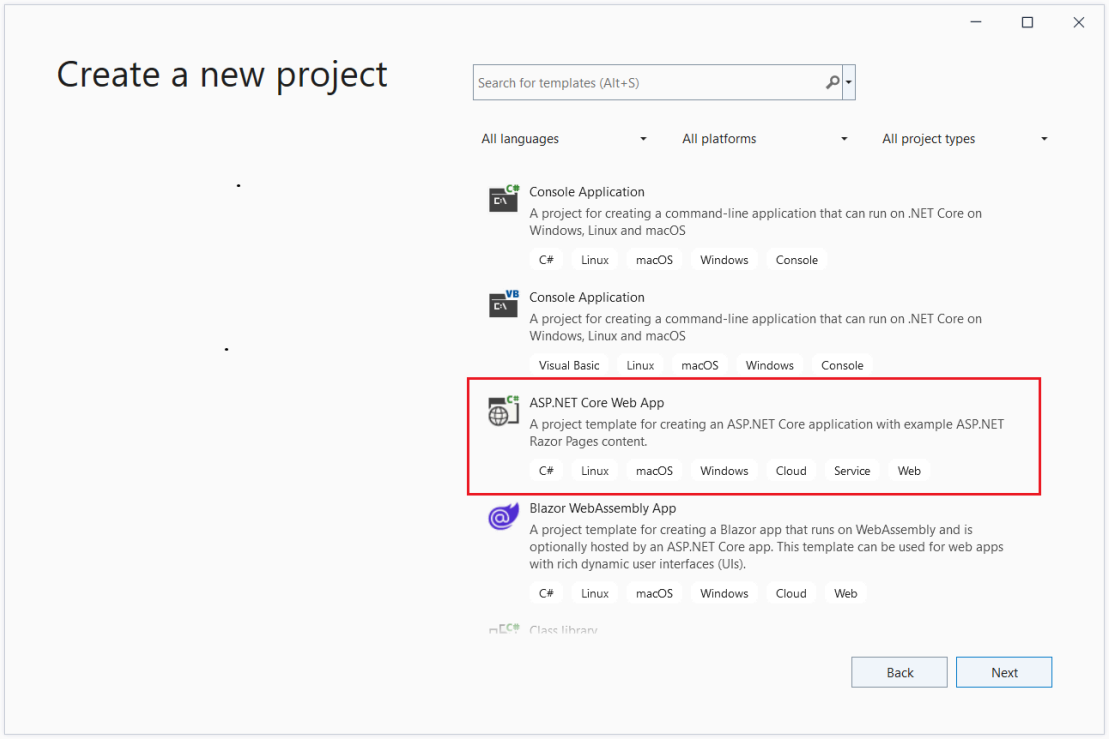
Select `ContosoUniversity.csproj` to open the project.

- Build the project.
- In Package Manager Console (PMC) run the following command:



```
PowerShell
Update-Database
```

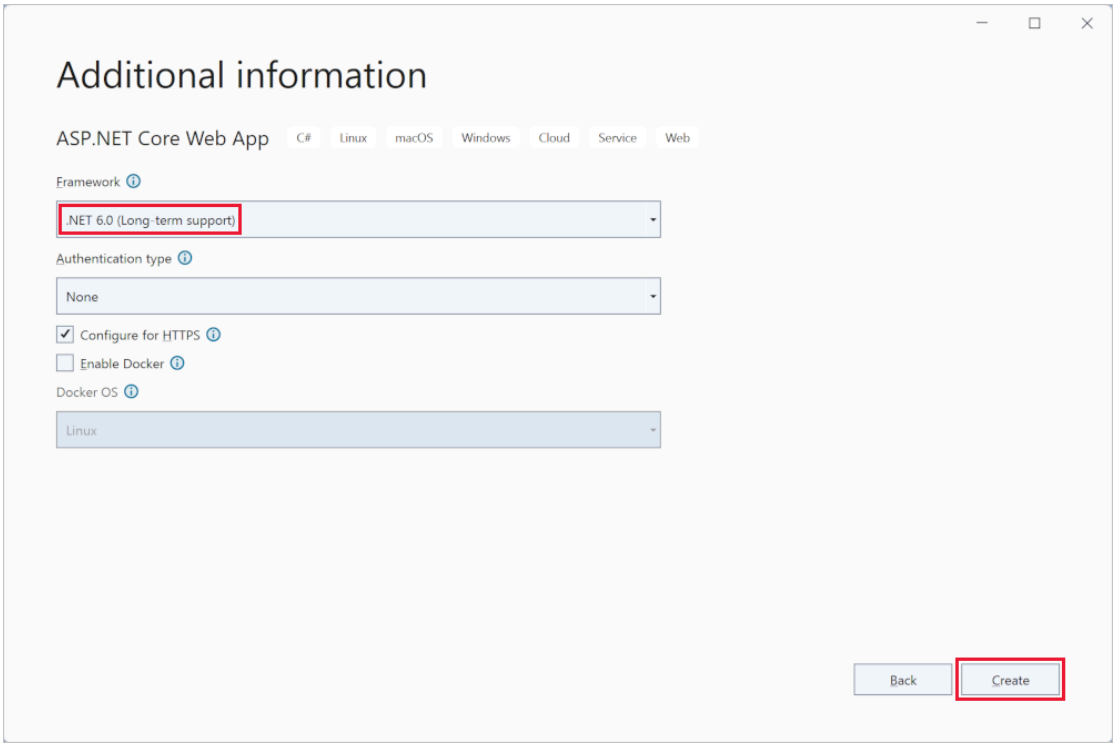
Run the project to seed the database.



Create the web app project

Visual Studio

1. Start Visual Studio 2022 and select **Create a new project**.



2. In the **Create a new project** dialog, select **ASP.NET Core Web App**, and then select **Next**.

3. In the **Configure your new project** dialog, enter `ContosoUniversity` for **Project name**. It's important to name the project *ContosoUniversity*, including matching the capitalization, so the namespaces will match when you copy and paste example code.

4. Select **Next**.

5. In the **Additional information** dialog, select **.NET 6.0 (Long-term support)** and then select **Create**.

Set up the site style

Copy and paste the following code into the `Pages/Shared/_Layout.cshtml` file:

CSHTML

```
<!DOCTYPE html>
<html lang="en">
<head>
    <meta charset="utf-8" />
    <meta name="viewport" content="width=device-width, initial-scale=1.0" />
    <title>@ViewData["Title"] - Contoso University</title>
    <link rel="stylesheet" href="~/lib/bootstrap/dist/css/bootstrap.css" />
    <link rel="stylesheet" href="~/css/site.css" asp-append-version="true"
/>
    <link rel="stylesheet" href="~/ContosoUniversity.styles.css" asp-append-
version="true" />
</head>
<body>
    <header>
        <nav class="navbar navbar-expand-sm navbar-toggleable-sm navbar-
light bg-white border-bottom box-shadow mb-3">
            <div class="container">
                <a class="navbar-brand" asp-area="" asp-
page="/Index">Contoso University</a>
                <button class="navbar-toggler" type="button" data-bs-
toggle="collapse" data-bs-target=".navbar-collapse" aria-
controls="navbarSupportedContent"
                        aria-expanded="false" aria-label="Toggle
navigation">
                    <span class="navbar-toggler-icon"></span>
                </button>
                <div class="navbar-collapse collapse d-sm-inline-flex
justify-content-between">
                    <ul class="navbar-nav flex-grow-1">
```

```
                        <li class="nav-item">
                            <a class="nav-link text-dark" asp-area="" asp-
page="/About">About</a>
                        </li>
                        <li class="nav-item">
                            <a class="nav-link text-dark" asp-area="" asp-
page="/Students/Index">Students</a>
                        </li>
                        <li class="nav-item">
                            <a class="nav-link text-dark" asp-area="" asp-
page="/Courses/Index">Courses</a>
                        </li>
                        <li class="nav-item">
                            <a class="nav-link text-dark" asp-area="" asp-
page="/Instructors/Index">Instructors</a>
                        </li>
                        <li class="nav-item">
                            <a class="nav-link text-dark" asp-area="" asp-
page="/Departments/Index">Departments</a>
                        </li>
                    </ul>
                </div>
            </div>
        </nav>
    </header>
    <div class="container">
        <main role="main" class="pb-3">
            @RenderBody()
        </main>
    </div>

    <footer class="border-top footer text-muted">
        <div class="container">
            &copy; 2021 - Contoso University - <a asp-area="" asp-
page="/Privacy">Privacy</a>
        </div>
    </footer>

    <script src="~/lib/jquery/dist/jquery.js"></script>
    <script src="~/lib/bootstrap/dist/js/bootstrap.bundle.js"></script>
    <script src="~/js/site.js" asp-append-version="true"></script>

    @await RenderSectionAsync("Scripts", required: false)
</body>
</html>
```

The layout file sets the site header, footer, and menu. The preceding code makes the following changes:

- Each occurrence of "ContosoUniversity" to "Contoso University". There are three occurrences.
- The **Home** and **Privacy** menu entries are deleted.

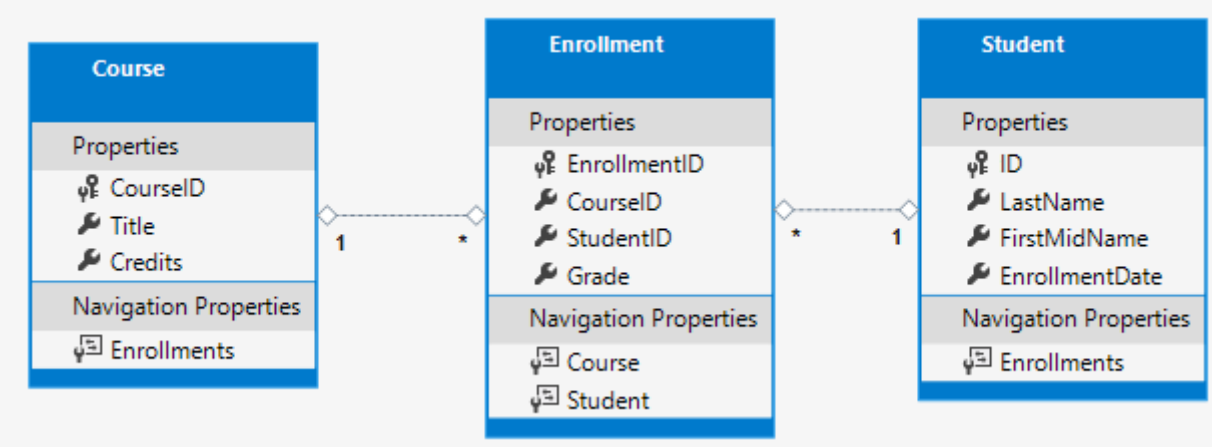
- Entries are added for **About**, **Students**, **Courses**, **Instructors**, and **Departments**.

In `Pages/Index.cshtml`, replace the contents of the file with the following code:

CSHTML

```
@page
@model IndexModel
@{
    ViewData["Title"] = "Home page";
}

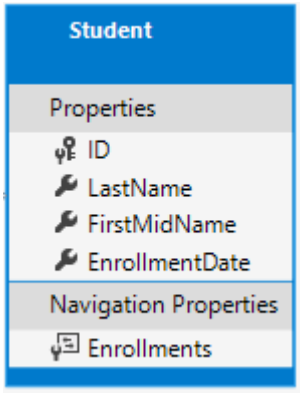
<div class="row mb-auto">
    <div class="col-md-4">
        <div class="row no-gutters border mb-4">
            <div class="col p-4 mb-4 ">
                <p class="card-text">
                    Contoso University is a sample application that
                    demonstrates how to use Entity Framework Core in an
                    ASP.NET Core Razor Pages web app.
                </p>
            </div>
        </div>
    </div>
    <div class="col-md-4">
        <div class="row no-gutters border mb-4">
            <div class="col p-4 d-flex flex-column position-static">
                <p class="card-text mb-auto">
                    You can build the application by following the steps in
a series of tutorials.
                </p>
                <p>
@*                      <a
href="https://docs.microsoft.com/aspnet/core/data/ef-rp/intro"
class="stretched-link">See the tutorial</a>
*@                  </p>
            </div>
        </div>
    </div>
    <div class="col-md-4">
        <div class="row no-gutters border mb-4">
            <div class="col p-4 d-flex flex-column">
                <p class="card-text mb-auto">
                    You can download the completed project from GitHub.
                </p>
                <p>
@*                      <a
href="https://github.com/dotnet/AspNetCore.Docs/tree/main/aspnetcore/data/ef
-rp/intro/samples" class="stretched-link">See project source code</a>
*@                  </p>
            </div>
        </div>
```



```
    </div>
</div>
```

The preceding code replaces the text about ASP.NET Core with text about this app.

Run the app to verify that the home page appears.



The data model

The following sections create a data model:

A student can enroll in any number of courses, and a course can have any number of students enrolled in it.

The Student entity

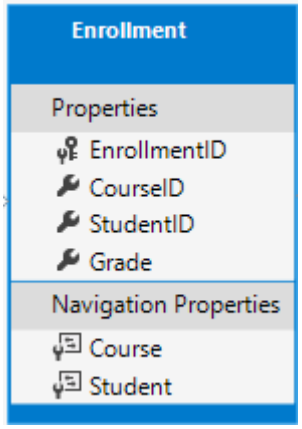
- Create a *Models* folder in the project folder.
- Create `Models/Student.cs` with the following code:

```
C#

namespace ContosoUniversity.Models
{
    public class Student
```

```
    {
        public int ID { get; set; }
        public string LastName { get; set; }
        public string FirstMidName { get; set; }
        public DateTime EnrollmentDate { get; set; }

        public ICollection<Enrollment> Enrollments { get; set; }
    }
}
```



The `ID` property becomes the primary key column of the database table that corresponds to this class. By default, EF Core interprets a property that's named `ID` or `classnameID` as the primary key. So the alternative automatically recognized name for the `Student` class primary key is `StudentID`. For more information, see EF Core - Keys.

The `Enrollments` property is a navigation property. Navigation properties hold other entities that are related to this entity. In this case, the `Enrollments` property of a `Student` entity holds all of the `Enrollment` entities that are related to that Student. For example, if a Student row in the database has two related Enrollment rows, the `Enrollments` navigation property contains those two Enrollment entities.

In the database, an Enrollment row is related to a Student row if its `StudentID` column contains the student's ID value. For example, suppose a Student row has ID=1. Related Enrollment rows will have `StudentID` = 1. `StudentID` is a *foreign key* in the Enrollment table.

The `Enrollments` property is defined as `ICollection<Enrollment>` because there may be multiple related Enrollment entities. Other collection types can be used, such as `List<Enrollment>` or `HashSet<Enrollment>`. When `ICollection<Enrollment>` is used, EF Core creates a `HashSet<Enrollment>` collection by default.

The Enrollment entity

Create `Models/Enrollment.cs` with the following code:

```
C#

using System.ComponentModel.DataAnnotations;

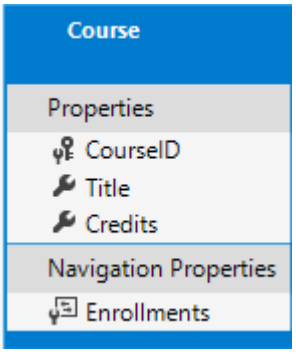
namespace ContosoUniversity.Models
{
    public enum Grade
    {
        A, B, C, D, F
    }

    public class Enrollment
    {
        public int EnrollmentID { get; set; }
        public int CourseID { get; set; }
        public int StudentID { get; set; }
        [DisplayFormat(NullDisplayText = "No grade")]
        public Grade? Grade { get; set; }

        public Course Course { get; set; }
        public Student Student { get; set; }
    }
}
```

The `EnrollmentID` property is the primary key; this entity uses the `classnameID` pattern instead of `ID` by itself. For a production data model, many developers choose one pattern and use it consistently. This tutorial uses both just to illustrate that both work. Using `ID` without `classname` makes it easier to implement some kinds of data model changes.

The `Grade` property is an `enum`. The question mark after the `Grade` type declaration indicates that the `Grade` property is nullable. A grade that's null is different from a zero grade—null means a grade isn't known or hasn't been assigned yet.



The `StudentID` property is a foreign key, and the corresponding navigation property is `Student`. An `Enrollment` entity is associated with one `Student` entity, so the property contains a single `Student` entity.

The `CourseID` property is a foreign key, and the corresponding navigation property is `Course`. An `Enrollment` entity is associated with one `Course` entity.

EF Core interprets a property as a foreign key if it's named `<navigation property name><primary key property name>`. For example, `StudentID` is the foreign key for the `Student` navigation property, since the `Student` entity's primary key is `ID`. Foreign key properties

can also be named `<primary key property name>`. For example, `CourseID` since the `Course` entity's primary key is `CourseID`.

The Course entity

Create `Models/Course.cs` with the following code:

C#

```
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Course
    {
        [DatabaseGenerated(DatabaseGeneratedOption.None)]
        public int CourseID { get; set; }
        public string Title { get; set; }
        public int Credits { get; set; }

        public ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

The `Enrollments` property is a navigation property. A `Course` entity can be related to any number of `Enrollment` entities.

The `DatabaseGenerated` attribute allows the app to specify the primary key rather than having the database generate it.

Build the app. The compiler generates several warnings about how `null` values are handled. See this GitHub issue, Nullable reference types, and Tutorial: Express your design intent more clearly with nullable and non-nullable reference types for more information.

To eliminate the warnings from nullable reference types, remove the following line from the `ContosoUniversity.csproj` file:

XML

```
<Nullable>enable</Nullable>
```

The scaffolding engine currently does not support nullable reference types, therefore the models used in scaffold can't either.

Remove the `?` nullable reference type annotation from `public string? RequestId { get; set; }` in `Pages/Error.cshtml.cs` so the project builds without compiler warnings.

Scaffold Student pages

In this section, the ASP.NET Core scaffolding tool is used to generate:

- An EF Core `DbContext` class. The context is the main class that coordinates Entity Framework functionality for a given data model. It derives from the Microsoft.EntityFrameworkCore.DbContext class.
- Razor pages that handle Create, Read, Update, and Delete (CRUD) operations for the `Student` entity.

Visual Studio

- Create a *Pages/Students* folder.
- In **Solution Explorer**, right-click the *Pages/Students* folder and select **Add** > **New Scaffolded Item**.
- In the **Add New Scaffold Item** dialog:
  - In the left tab, select **Installed** > **Common** > **Razor Pages**
  - Select **Razor Pages using Entity Framework (CRUD)** > **ADD**.
- In the **Add Razor Pages using Entity Framework (CRUD)** dialog:
  - In the **Model class** drop-down, select **Student (ContosoUniversity.Models)**.
  - In the **Data context class** row, select the + (plus) sign.
    - Change the data context name to end in `SchoolContext` rather than `ContosoUniversityContext`. The updated context name: `ContosoUniversity.Data.SchoolContext`
    - Select **Add** to finish adding the data context class.
    - Select **Add** to finish the **Add Razor Pages** dialog.

The following packages are automatically installed:

- `Microsoft.EntityFrameworkCore.SqlServer`
- `Microsoft.EntityFrameworkCore.Tools`

- `Microsoft.VisualStudio.Web.CodeGeneration.Design`

If the preceding step fails, build the project and retry the scaffold step.

The scaffolding process:

- Creates Razor pages in the *Pages/Students* folder:
  - `Create.cshtml` and `Create.cshtml.cs`
  - `Delete.cshtml` and `Delete.cshtml.cs`
  - `Details.cshtml` and `Details.cshtml.cs`
  - `Edit.cshtml` and `Edit.cshtml.cs`
  - `Index.cshtml` and `Index.cshtml.cs`
- Creates `Data/SchoolContext.cs`.
- Adds the context to dependency injection in `Program.cs`.
- Adds a database connection string to `appsettings.json`.

Database connection string

The scaffolding tool generates a connection string in the `appsettings.json` file.

Visual Studio

The connection string specifies SQL Server LocalDB:

JSON

```
{
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "Microsoft.AspNetCore": "Warning"
    }
  },
  "AllowedHosts": "*",
  "ConnectionStrings": {
    "SchoolContext": "Server=
(localdb)\\mssqllocaldb;Database=SchoolContext-
0e9;Trusted_Connection=True;MultipleActiveResultSets=true"
  }
}
```

LocalDB is a lightweight version of the SQL Server Express Database Engine and is intended for app development, not production use. By default, LocalDB creates *.mdf*

files in the `C:/Users/<user>` directory.

Update the database context class

The main class that coordinates EF Core functionality for a given data model is the database context class. The context is derived from Microsoft.EntityFrameworkCore.DbContext. The context specifies which entities are included in the data model. In this project, the class is named `SchoolContext`.

Update `Data/SchoolContext.cs` with the following code:

C#

```
using Microsoft.EntityFrameworkCore;
using ContosoUniversity.Models;

namespace ContosoUniversity.Data
{
    public class SchoolContext : DbContext
    {
        public SchoolContext (DbContextOptions<SchoolContext> options)
            : base(options)
        {
        }

        public DbSet<Student> Students { get; set; }
        public DbSet<Enrollment> Enrollments { get; set; }
        public DbSet<Course> Courses { get; set; }

        protected override void OnModelCreating(ModelBuilder modelBuilder)
        {
            modelBuilder.Entity<Course>().ToTable("Course");
            modelBuilder.Entity<Enrollment>().ToTable("Enrollment");
            modelBuilder.Entity<Student>().ToTable("Student");
        }
    }
}
```

The preceding code changes from the singular `DbSet<Student> Student` to the plural `DbSet<Student> Students`. To make the Razor Pages code match the new `DBSet` name, make a global change from: `_context.Student.` to: `_context.Students.`

There are 8 occurrences.

Because an entity set contains multiple entities, many developers prefer the `DBSet` property names should be plural.

The highlighted code:

- Creates a DbSet<TEntity> property for each entity set. In EF Core terminology:
  - An entity set typically corresponds to a database table.
  - An entity corresponds to a row in the table.
- Calls OnModelCreating. `OnModelCreating`:
  - Is called when `SchoolContext` has been initialized but before the model has been secured and used to initialize the context.
  - Is required because later in the tutorial the `Student` entity will have references to the other entities.

We hope to fix this issue in a future release.

Program.cs

ASP.NET Core is built with dependency injection. Services such as the `SchoolContext` are registered with dependency injection during app startup. Components that require these services, such as Razor Pages, are provided these services via constructor parameters. The constructor code that gets a database context instance is shown later in the tutorial.

The scaffolding tool automatically registered the context class with the dependency injection container.

Visual Studio

The following highlighted lines were added by the scaffolder:

C#

```
using ContosoUniversity.Data;
using Microsoft.EntityFrameworkCore;
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();

builder.Services.AddDbContext<SchoolContext>(options =>

options.UseSqlServer(builder.Configuration.GetConnectionString("SchoolCo
ntext")));
```

The name of the connection string is passed in to the context by calling a method on a DbContextOptions object. For local development, the ASP.NET Core configuration

system reads the connection string from the `appsettings.json` or the `appsettings.Development.json` file.

Add the database exception filter

Add AddDatabaseDeveloperPageExceptionFilter and UseMigrationsEndPoint as shown in the following code:

Visual Studio

C#

```
using ContosoUniversity.Data;
using Microsoft.EntityFrameworkCore;
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();

builder.Services.AddDbContext<SchoolContext>(options =>

options.UseSqlServer(builder.Configuration.GetConnectionString("SchoolCo
ntext")));

builder.Services.AddDatabaseDeveloperPageExceptionFilter();

var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}
else
{
    app.UseDeveloperExceptionPage();
    app.UseMigrationsEndPoint();
}
```

Add the Microsoft.AspNetCore.Diagnostics.EntityFrameworkCore NuGet package.

In the Package Manager Console, enter the following to add the NuGet package:

PowerShell

```
Install-Package Microsoft.AspNetCore.Diagnostics.EntityFrameworkCore
```

The `Microsoft.AspNetCore.Diagnostics.EntityFrameworkCore` NuGet package provides ASP.NET Core middleware for Entity Framework Core error pages. This middleware helps to detect and diagnose errors with Entity Framework Core migrations.

The `AddDatabaseDeveloperPageExceptionFilter` provides helpful error information in the development environment for EF migrations errors.

Create the database

Update `Program.cs` to create the database if it doesn't exist:

Visual Studio

C#

```
using ContosoUniversity.Data;
using Microsoft.EntityFrameworkCore;
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();

builder.Services.AddDbContext<SchoolContext>(options =>

options.UseSqlServer(builder.Configuration.GetConnectionString("SchoolCo
ntext")));

builder.Services.AddDatabaseDeveloperPageExceptionFilter();

var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}
else
{
    app.UseDeveloperExceptionPage();
    app.UseMigrationsEndPoint();
}

using (var scope = app.Services.CreateScope())
{
    var services = scope.ServiceProvider;

    var context = services.GetRequiredService<SchoolContext>();
    context.Database.EnsureCreated();
    // DbInitializer.Initialize(context);
}
```

```
app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseRouting();

app.UseAuthorization();

app.MapRazorPages();

app.Run();
```

The EnsureCreated method takes no action if a database for the context exists. If no database exists, it creates the database and schema. `EnsureCreated` enables the following workflow for handling data model changes:

- Delete the database. Any existing data is lost.
- Change the data model. For example, add an `EmailAddress` field.
- Run the app.
- `EnsureCreated` creates a database with the new schema.

This workflow works early in development when the schema is rapidly evolving, as long as data doesn't need to be preserved. The situation is different when data that has been entered into the database needs to be preserved. When that is the case, use migrations.

Later in the tutorial series, the database is deleted that was created by `EnsureCreated` and migrations is used. A database that is created by `EnsureCreated` can't be updated by using migrations.

Test the app

- Run the app.
- Select the **Students** link and then **Create New**.
- Test the Edit, Details, and Delete links.

Seed the database

The `EnsureCreated` method creates an empty database. This section adds code that populates the database with test data.

Create `Data/DbInitializer.cs` with the following code:

```
C#
```

```
using ContosoUniversity.Models;

namespace ContosoUniversity.Data
{
    public static class DbInitializer
    {
        public static void Initialize(SchoolContext context)
        {
            // Look for any students.
            if (context.Students.Any())
            {
                return;   // DB has been seeded
            }

            var students = new Student[]
            {
                new
Student{FirstMidName="Carson",LastName="Alexander",EnrollmentDate=DateTime.P
arse("2019-09-01")},
                new
Student{FirstMidName="Meredith",LastName="Alonso",EnrollmentDate=DateTime.Pa
rse("2017-09-01")},
                new
Student{FirstMidName="Arturo",LastName="Anand",EnrollmentDate=DateTime.Parse
("2018-09-01")},
                new
Student{FirstMidName="Gytis",LastName="Barzdukas",EnrollmentDate=DateTime.Pa
rse("2017-09-01")},
                new
Student{FirstMidName="Yan",LastName="Li",EnrollmentDate=DateTime.Parse("2017
-09-01")},
                new
Student{FirstMidName="Peggy",LastName="Justice",EnrollmentDate=DateTime.Pars
e("2016-09-01")},
                new
Student{FirstMidName="Laura",LastName="Norman",EnrollmentDate=DateTime.Parse
("2018-09-01")},
                new
Student{FirstMidName="Nino",LastName="Olivetto",EnrollmentDate=DateTime.Pars
e("2019-09-01")}
            };

            context.Students.AddRange(students);
            context.SaveChanges();

            var courses = new Course[]
            {
                new Course{CourseID=1050,Title="Chemistry",Credits=3},
                new Course{CourseID=4022,Title="Microeconomics",Credits=3},
                new Course{CourseID=4041,Title="Macroeconomics",Credits=3},
                new Course{CourseID=1045,Title="Calculus",Credits=4},
                new Course{CourseID=3141,Title="Trigonometry",Credits=4},
                new Course{CourseID=2021,Title="Composition",Credits=3},
                new Course{CourseID=2042,Title="Literature",Credits=4}
```

```
            };

            context.Courses.AddRange(courses);
            context.SaveChanges();

            var enrollments = new Enrollment[]
            {
                new Enrollment{StudentID=1,CourseID=1050,Grade=Grade.A},
                new Enrollment{StudentID=1,CourseID=4022,Grade=Grade.C},
                new Enrollment{StudentID=1,CourseID=4041,Grade=Grade.B},
                new Enrollment{StudentID=2,CourseID=1045,Grade=Grade.B},
                new Enrollment{StudentID=2,CourseID=3141,Grade=Grade.F},
                new Enrollment{StudentID=2,CourseID=2021,Grade=Grade.F},
                new Enrollment{StudentID=3,CourseID=1050},
                new Enrollment{StudentID=4,CourseID=1050},
                new Enrollment{StudentID=4,CourseID=4022,Grade=Grade.F},
                new Enrollment{StudentID=5,CourseID=4041,Grade=Grade.C},
                new Enrollment{StudentID=6,CourseID=1045},
                new Enrollment{StudentID=7,CourseID=3141,Grade=Grade.A},
            };

            context.Enrollments.AddRange(enrollments);
            context.SaveChanges();
        }
    }
}
```

The code checks if there are any students in the database. If there are no students, it adds test data to the database. It creates the test data in arrays rather than `List<T>` collections to optimize performance.

- In `Program.cs`, remove `//` from the `DbInitializer.Initialize` line:

C#

```
using (var scope = app.Services.CreateScope())
{
    var services = scope.ServiceProvider;

    var context = services.GetRequiredService<SchoolContext>();
    context.Database.EnsureCreated();
    DbInitializer.Initialize(context);
}
```

Visual Studio

- Stop the app if it's running, and run the following command in the **Package Manager Console** (PMC):

PowerShell

```
Drop-Database -Confirm
```

- Respond with `Y` to delete the database.

- Restart the app.
- Select the Students page to see the seeded data.

View the database

Visual Studio

- Open **SQL Server Object Explorer** (SSOX) from the **View** menu in Visual Studio.
- In SSOX, select **(localdb)\MSSQLLocalDB** > **Databases** > **SchoolContext-{GUID}**. The database name is generated from the context name provided earlier plus a dash and a GUID.
- Expand the **Tables** node.
- Right-click the **Student** table and click **View Data** to see the columns created and the rows inserted into the table.
- Right-click the **Student** table and click **View Code** to see how the `Student` model maps to the `Student` table schema.

Asynchronous EF methods in ASP.NET Core web apps

Asynchronous programming is the default mode for ASP.NET Core and EF Core.

A web server has a limited number of threads available, and in high load situations all of the available threads might be in use. When that happens, the server can't process new requests until the threads are freed up. With synchronous code, many threads may be tied up while they aren't doing work because they're waiting for I/O to complete. With asynchronous code, when a process is waiting for I/O to complete, its thread is freed up for the server to use for processing other requests. As a result, asynchronous code enables server resources to be used more efficiently, and the server can handle more traffic without delays.

Asynchronous code does introduce a small amount of overhead at run time. For low traffic situations, the performance hit is negligible, while for high traffic situations, the potential performance improvement is substantial.

In the following code, the async keyword, `Task` return value, `await` keyword, and `ToListAsync` method make the code execute asynchronously.

```
C#

public async Task OnGetAsync()
{
    Students = await _context.Students.ToListAsync();
}
```

- The `async` keyword tells the compiler to:
  - Generate callbacks for parts of the method body.
  - Create the Task object that's returned.
- The `Task` return type represents ongoing work.
- The `await` keyword causes the compiler to split the method into two parts. The first part ends with the operation that's started asynchronously. The second part is put into a callback method that's called when the operation completes.
- `ToListAsync` is the asynchronous version of the `ToList` extension method.

Some things to be aware of when writing asynchronous code that uses EF Core:

- Only statements that cause queries or commands to be sent to the database are executed asynchronously. That includes `ToListAsync`, `SingleOrDefaultAsync`, `FirstOrDefaultAsync`, and `SaveChangesAsync`. It doesn't include statements that just change an `IQueryable`, such as `var students = context.Students.Where(s => s.LastName == "Davolio")`.
- An EF Core context isn't thread safe: don't try to do multiple operations in parallel.
- To take advantage of the performance benefits of async code, verify that library packages (such as for paging) use async if they call EF Core methods that send queries to the database.

For more information about asynchronous programming in .NET, see Async Overview and Asynchronous programming with async and await.

> ⚠ **Warning**
>
> The async implementation of Microsoft.Data.SqlClient has some known issues (#593, #601, and others). If you're seeing unexpected performance problems,

try using sync command execution instead, especially when dealing with large text or binary values.

Performance considerations

In general, a web page shouldn't be loading an arbitrary number of rows. A query should use paging or a limiting approach. For example, the preceding query could use `Take` to limit the rows returned:

C#

```
public async Task OnGetAsync()
{
    Student = await _context.Students.Take(10).ToListAsync();
}
```

Enumerating a large table in a view could return a partially constructed HTTP 200 response if a database exception occurs part way through the enumeration.

Paging is covered later in the tutorial.

For more information, see Performance considerations (EF).

By Tom Dykstra, Jeremy Likness, and Jon P Smith

The Contoso University web app demonstrates how to create Razor Pages web apps using EF Core and Visual Studio. For information about the tutorial series, see the first tutorial.

If you run into problems you can't solve, download the completed app and compare that code to what you created by following the tutorial.

In this tutorial, the scaffolded CRUD (create, read, update, delete) code is reviewed and customized.

No repository

Some developers use a service layer or repository pattern to create an abstraction layer between the UI (Razor Pages) and the data access layer. This tutorial doesn't do that. To minimize complexity and keep the tutorial focused on EF Core, EF Core code is added directly to the page model classes.

Update the Details page

The scaffolded code for the Students pages doesn't include enrollment data. In this section, enrollments are added to the `Details` page.

Read enrollments

To display a student's enrollment data on the page, the enrollment data must be read. The scaffolded code in `Pages/Students/Details.cshtml.cs` reads only the `Student` data, without the `Enrollment` data:

C#

```
public async Task<IActionResult> OnGetAsync(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    Student = await _context.Students.FirstOrDefaultAsync(m => m.ID == id);

    if (Student == null)
    {
        return NotFound();
    }
    return Page();
}
```

Replace the `OnGetAsync` method with the following code to read enrollment data for the selected student. The changes are highlighted.

C#

```
public async Task<IActionResult> OnGetAsync(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    Student = await _context.Students
        .Include(s => s.Enrollments)
        .ThenInclude(e => e.Course)
        .AsNoTracking()
        .FirstOrDefaultAsync(m => m.ID == id);

    if (Student == null)
    {
        return NotFound();
    }
    return Page();
}
```

The Include and ThenInclude methods cause the context to load the `Student.Enrollments` navigation property, and within each enrollment the

`Enrollment.Course` navigation property. These methods are examined in detail in the Read related data tutorial.

The AsNoTracking method improves performance in scenarios where the entities returned are not updated in the current context. `AsNoTracking` is discussed later in this tutorial.

Display enrollments

Replace the code in `Pages/Students/Details.cshtml` with the following code to display a list of enrollments. The changes are highlighted.

CSHTML

```
@page
@model ContosoUniversity.Pages.Students.DetailsModel

@{
    ViewData["Title"] = "Details";
}

<h1>Details</h1>

<div>
    <h4>Student</h4>
    <hr />
    <dl class="row">
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Student.LastName)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Student.LastName)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Student.FirstMidName)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Student.FirstMidName)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Student.EnrollmentDate)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Student.EnrollmentDate)
        </dd>
```

```
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Student.Enrollments)
        </dt>
        <dd class="col-sm-10">
            <table class="table">
                <tr>
                    <th>Course Title</th>
                    <th>Grade</th>
                </tr>
                @foreach (var item in Model.Student.Enrollments)
                {
                    <tr>
                        <td>
                            @Html.DisplayFor(modelItem => item.Course.Title)
                        </td>
                        <td>
                            @Html.DisplayFor(modelItem => item.Grade)
                        </td>
                    </tr>
                }
            </table>
        </dd>
    </dl>
</div>
<div>
    <a asp-page="./Edit" asp-route-id="@Model.Student.ID">Edit</a> |
    <a asp-page="./Index">Back to List</a>
</div>
```

The preceding code loops through the entities in the `Enrollments` navigation property. For each enrollment, it displays the course title and the grade. The course title is retrieved from the `Course` entity that's stored in the `Course` navigation property of the Enrollments entity.

Run the app, select the **Students** tab, and click the **Details** link for a student. The list of courses and grades for the selected student is displayed.

Ways to read one entity

The generated code uses FirstOrDefaultAsync to read one entity. This method returns null if nothing is found; otherwise, it returns the first row found that satisfies the query filter criteria. `FirstOrDefaultAsync` is generally a better choice than the following alternatives:

- SingleOrDefaultAsync - Throws an exception if there's more than one entity that satisfies the query filter. To determine if more than one row could be returned by the query, `SingleOrDefaultAsync` tries to fetch multiple rows. This extra work is

unnecessary if the query can only return one entity, as when it searches on a unique key.

- FindAsync - Finds an entity with the primary key (PK). If an entity with the PK is being tracked by the context, it's returned without a request to the database. This method is optimized to look up a single entity, but you can't call `Include` with `FindAsync`. So if related data is needed, `FirstOrDefaultAsync` is the better choice.

Route data vs. query string

The URL for the Details page is `https://localhost:<port>/Students/Details?id=1`. The entity's primary key value is in the query string. Some developers prefer to pass the key value in route data: `https://localhost:<port>/Students/Details/1`. For more information, see Update the generated code.

Update the Create page

The scaffolded `OnPostAsync` code for the Create page is vulnerable to overposting. Replace the `OnPostAsync` method in `Pages/Students/Create.cshtml.cs` with the following code.

C#

```
public async Task<IActionResult> OnPostAsync()
{
    var emptyStudent = new Student();

    if (await TryUpdateModelAsync<Student>(
        emptyStudent,
        "student",   // Prefix for form value.
        s => s.FirstMidName, s => s.LastName, s => s.EnrollmentDate))
    {
        _context.Students.Add(emptyStudent);
        await _context.SaveChangesAsync();
        return RedirectToPage("./Index");
    }

    return Page();
}
```

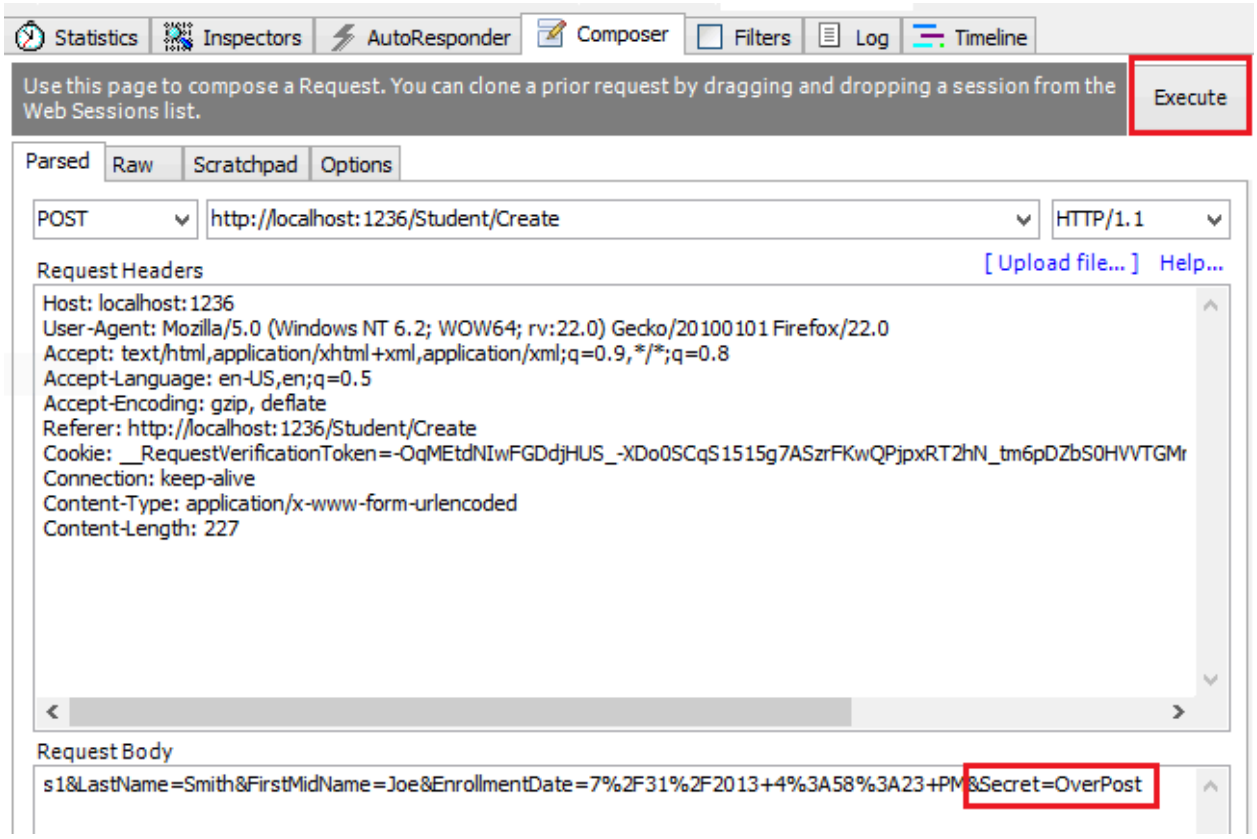
TryUpdateModelAsync

The preceding code creates a Student object and then uses posted form fields to update the Student object's properties. The TryUpdateModelAsync method:

- Uses the posted form values from the PageContext property in the PageModel.
- Updates only the properties listed (`s => s.FirstMidName, s => s.LastName, s => s.EnrollmentDate`).
- Looks for form fields with a "student" prefix. For example, `Student.FirstMidName`. It's not case sensitive.
- Uses the model binding system to convert form values from strings to the types in the `Student` model. For example, `EnrollmentDate` is converted to `DateTime`.

Run the app, and create a student entity to test the Create page.

Overposting



Using `TryUpdateModel` to update fields with posted values is a security best practice because it prevents overposting. For example, suppose the Student entity includes a `Secret` property that this web page shouldn't update or add:

C#

```
public class Student
{
    public int ID { get; set; }
    public string LastName { get; set; }
    public string FirstMidName { get; set; }
    public DateTime EnrollmentDate { get; set; }
    public string Secret { get; set; }
}
```

Even if the app doesn't have a `Secret` field on the create or update Razor Page, a hacker could set the `Secret` value by overposting. A hacker could use a tool such as Fiddler, or write some JavaScript, to post a `Secret` form value. The original code doesn't limit the fields that the model binder uses when it creates a Student instance.

Whatever value the hacker specified for the `Secret` form field is updated in the database. The following image shows the Fiddler tool adding the `Secret` field, with the value "OverPost", to the posted form values.

The value "OverPost" is successfully added to the `Secret` property of the inserted row. That happens even though the app designer never intended the `Secret` property to be set with the Create page.

View model

View models provide an alternative way to prevent overposting.

The application model is often called the domain model. The domain model typically contains all the properties required by the corresponding entity in the database. The view model contains only the properties needed for the UI page, for example, the Create page.

In addition to the view model, some apps use a binding model or input model to pass data between the Razor Pages page model class and the browser.

Consider the following `StudentVM` view model:

C#

```
public class StudentVM
{
    public int ID { get; set; }
    public string LastName { get; set; }
    public string FirstMidName { get; set; }
```

```
    public DateTime EnrollmentDate { get; set; }
}
```

The following code uses the `StudentVM` view model to create a new student:

C#

```
[BindProperty]
public StudentVM StudentVM { get; set; }

public async Task<IActionResult> OnPostAsync()
{
    if (!ModelState.IsValid)
    {
        return Page();
    }

    var entry = _context.Add(new Student());
    entry.CurrentValues.SetValues(StudentVM);
    await _context.SaveChangesAsync();
    return RedirectToPage("./Index");
}
```

The SetValues method sets the values of this object by reading values from another PropertyValues object. `SetValues` uses property name matching. The view model type:

- Doesn't need to be related to the model type.
- Needs to have properties that match.

Using `StudentVM` requires the Create page use `StudentVM` rather than `Student`:

CSHTML

```
@page
@model CreateVMModel

@{
    ViewData["Title"] = "Create";
}

<h1>Create</h1>

<h4>Student</h4>
<hr />
<div class="row">
    <div class="col-md-4">
        <form method="post">
            <div asp-validation-summary="ModelOnly" class="text-danger">
</div>
            <div class="form-group">
```

```
                <label asp-for="StudentVM.LastName" class="control-label">
</label>
                <input asp-for="StudentVM.LastName" class="form-control" />
                <span asp-validation-for="StudentVM.LastName" class="text-
danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="StudentVM.FirstMidName" class="control-
label"></label>
                <input asp-for="StudentVM.FirstMidName" class="form-control"
/>
                <span asp-validation-for="StudentVM.FirstMidName"
class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="StudentVM.EnrollmentDate" class="control-
label"></label>
                <input asp-for="StudentVM.EnrollmentDate" class="form-
control" />
                <span asp-validation-for="StudentVM.EnrollmentDate"
class="text-danger"></span>
            </div>
            <div class="form-group">
                <input type="submit" value="Create" class="btn btn-primary"
/>
            </div>
        </form>
    </div>
</div>

<div>
    <a asp-page="Index">Back to List</a>
</div>

@section Scripts {
    @{await Html.RenderPartialAsync("_ValidationScriptsPartial");}
}
```

Update the Edit page

In `Pages/Students/Edit.cshtml.cs`, replace the `OnGetAsync` and `OnPostAsync` methods with the following code.

C#

```
public async Task<IActionResult> OnGetAsync(int? id)
{
    if (id == null)
    {
        return NotFound();
    }
```

```
    Student = await _context.Students.FindAsync(id);

    if (Student == null)
    {
        return NotFound();
    }
    return Page();
}

public async Task<IActionResult> OnPostAsync(int id)
{
    var studentToUpdate = await _context.Students.FindAsync(id);

    if (studentToUpdate == null)
    {
        return NotFound();
    }

    if (await TryUpdateModelAsync<Student>(
        studentToUpdate,
        "student",
        s => s.FirstMidName, s => s.LastName, s => s.EnrollmentDate))
    {
        await _context.SaveChangesAsync();
        return RedirectToPage("./Index");
    }

    return Page();
}
```

The code changes are similar to the Create page with a few exceptions:

- `FirstOrDefaultAsync` has been replaced with FindAsync. When you don't have to include related data, `FindAsync` is more efficient.
- `OnPostAsync` has an `id` parameter.
- The current student is fetched from the database, rather than creating an empty student.

Run the app, and test it by creating and editing a student.

Entity States

The database context keeps track of whether entities in memory are in sync with their corresponding rows in the database. This tracking information determines what happens when SaveChangesAsync is called. For example, when a new entity is passed to the AddAsync method, that entity's state is set to Added. When `SaveChangesAsync` is called, the database context issues a SQL `INSERT` command.

An entity may be in one of the following states:

- `Added`: The entity doesn't yet exist in the database. The `SaveChanges` method issues an `INSERT` statement.
- `Unchanged`: No changes need to be saved with this entity. An entity has this status when it's read from the database.
- `Modified`: Some or all of the entity's property values have been modified. The `SaveChanges` method issues an `UPDATE` statement.
- `Deleted`: The entity has been marked for deletion. The `SaveChanges` method issues a `DELETE` statement.
- `Detached`: The entity isn't being tracked by the database context.

In a desktop app, state changes are typically set automatically. An entity is read, changes are made, and the entity state is automatically changed to `Modified`. Calling `SaveChanges` generates a SQL `UPDATE` statement that updates only the changed properties.

In a web app, the `DbContext` that reads an entity and displays the data is disposed after a page is rendered. When a page's `OnPostAsync` method is called, a new web request is made and with a new instance of the `DbContext`. Rereading the entity in that new context simulates desktop processing.

Update the Delete page

In this section, a custom error message is implemented when the call to `SaveChanges` fails.

Replace the code in `Pages/Students/Delete.cshtml.cs` with the following code:

C#

```
using ContosoUniversity.Models;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.EntityFrameworkCore;
using Microsoft.Extensions.Logging;
using System;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Students
{
```

```
    public class DeleteModel : PageModel
    {
        private readonly ContosoUniversity.Data.SchoolContext _context;
        private readonly ILogger<DeleteModel> _logger;

        public DeleteModel(ContosoUniversity.Data.SchoolContext context,
                           ILogger<DeleteModel> logger)
        {
            _context = context;
            _logger = logger;
        }

        [BindProperty]
        public Student Student { get; set; }
        public string ErrorMessage { get; set; }

        public async Task<IActionResult> OnGetAsync(int? id, bool?
saveChangesError = false)
        {
            if (id == null)
            {
                return NotFound();
            }

            Student = await _context.Students
                .AsNoTracking()
                .FirstOrDefaultAsync(m => m.ID == id);

            if (Student == null)
            {
                return NotFound();
            }

            if (saveChangesError.GetValueOrDefault())
            {
                ErrorMessage = String.Format("Delete {ID} failed. Try
again", id);
            }

            return Page();
        }

        public async Task<IActionResult> OnPostAsync(int? id)
        {
            if (id == null)
            {
                return NotFound();
            }

            var student = await _context.Students.FindAsync(id);

            if (student == null)
            {
                return NotFound();
            }
```

```
            try
            {
                _context.Students.Remove(student);
                await _context.SaveChangesAsync();
                return RedirectToPage("./Index");
            }
            catch (DbUpdateException ex)
            {
                _logger.LogError(ex, ErrorMessage);

                return RedirectToAction("./Delete",
                                        new { id, saveChangesError = true });
            }
        }
    }
}
```

The preceding code:

- Adds Logging.
- Adds the optional parameter `saveChangesError` to the `OnGetAsync` method signature. `saveChangesError` indicates whether the method was called after a failure to delete the student object.

The delete operation might fail because of transient network problems. Transient network errors are more likely when the database is in the cloud. The `saveChangesError` parameter is `false` when the Delete page `OnGetAsync` is called from the UI. When `OnGetAsync` is called by `OnPostAsync` because the delete operation failed, the `saveChangesError` parameter is `true`.

The `OnPostAsync` method retrieves the selected entity, then calls the Remove method to set the entity's status to `Deleted`. When `SaveChanges` is called, a SQL `DELETE` command is generated. If `Remove` fails:

- The database exception is caught.
- The Delete pages `OnGetAsync` method is called with `saveChangesError=true`.

Add an error message to `Pages/Students/Delete.cshtml`:

CSHTML

```
@page
@model ContosoUniversity.Pages.Students.DeleteModel

@{
    ViewData["Title"] = "Delete";
}
```

```
<h1>Delete</h1>

<p class="text-danger">@Model.ErrorMessage</p>

<h3>Are you sure you want to delete this?</h3>
<div>
    <h4>Student</h4>
    <hr />
    <dl class="row">
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Student.LastName)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Student.LastName)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Student.FirstMidName)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Student.FirstMidName)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Student.EnrollmentDate)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Student.EnrollmentDate)
        </dd>
    </dl>

    <form method="post">
        <input type="hidden" asp-for="Student.ID" />
        <input type="submit" value="Delete" class="btn btn-danger" /> |
        <a asp-page="./Index">Back to List</a>
    </form>
</div>
```

Run the app and delete a student to test the Delete page.

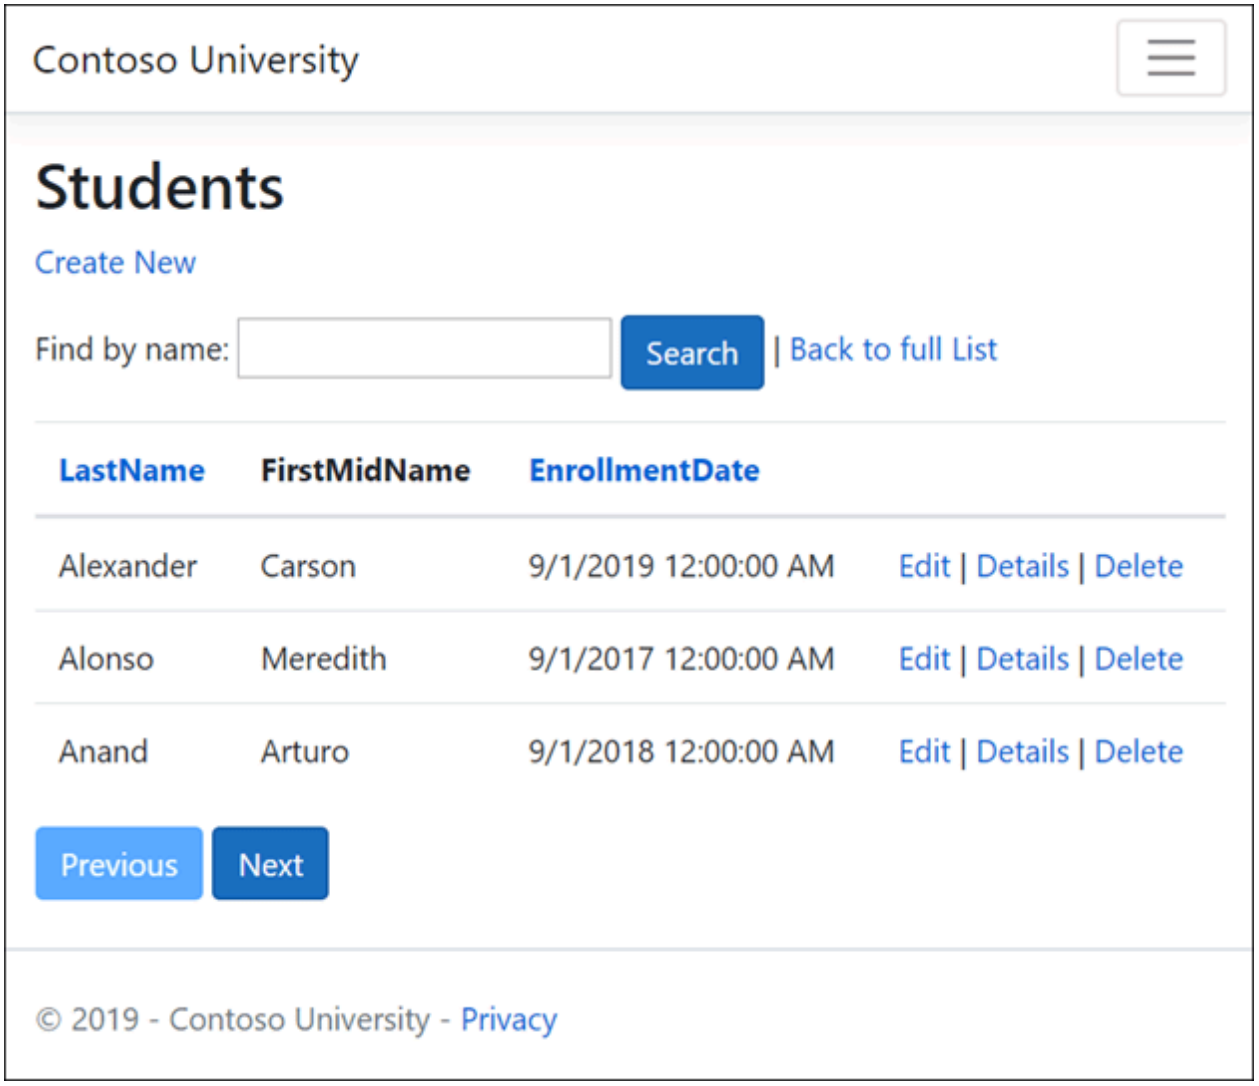
Part 3, Razor Pages with EF Core in ASP.NET Core - Sort, Filter, Paging

Article • 04/10/2024



By Tom Dykstra, Jeremy Likness, and Jon P Smith

The Contoso University web app demonstrates how to create Razor Pages web apps using EF Core and Visual Studio. For information about the tutorial series, see the first tutorial.

If you run into problems you can't solve, download the completed app and compare that code to what you created by following the tutorial.

This tutorial adds sorting, filtering, and paging functionality to the Students pages.

The following illustration shows a completed page. The column headings are clickable links to sort the column. Click a column heading repeatedly to switch between ascending and descending sort order.

Add sorting

Replace the code in `Pages/Students/Index.cshtml.cs` with the following code to add sorting.

C#

```
public class IndexModel : PageModel
{
    private readonly SchoolContext _context;
    public IndexModel(SchoolContext context)
    {
        _context = context;
    }

    public string NameSort { get; set; }
    public string DateSort { get; set; }
    public string CurrentFilter { get; set; }
    public string CurrentSort { get; set; }

    public IList<Student> Students { get; set; }

    public async Task OnGetAsync(string sortOrder)
    {
        // using System;
        NameSort = String.IsNullOrEmpty(sortOrder) ? "name_desc" : "";
        DateSort = sortOrder == "Date" ? "date_desc" : "Date";

        IQueryable<Student> studentsIQ = from s in _context.Students
                                         select s;

        switch (sortOrder)
        {
            case "name_desc":
                studentsIQ = studentsIQ.OrderByDescending(s => s.LastName);
                break;
            case "Date":
                studentsIQ = studentsIQ.OrderBy(s => s.EnrollmentDate);
                break;
            case "date_desc":
                studentsIQ = studentsIQ.OrderByDescending(s =>
s.EnrollmentDate);
                break;
            default:
                studentsIQ = studentsIQ.OrderBy(s => s.LastName);
                break;
        }

        Students = await studentsIQ.AsNoTracking().ToListAsync();
    }
}
```

The preceding code:

- Requires adding `using System;`.
- Adds properties to contain the sorting parameters.
- Changes the name of the `Student` property to `Students`.
- Replaces the code in the `OnGetAsync` method.

The `OnGetAsync` method receives a `sortOrder` parameter from the query string in the URL. The URL and query string is generated by the Anchor Tag Helper.

The `sortOrder` parameter is either `Name` or `Date`. The `sortOrder` parameter is optionally followed by `_desc` to specify descending order. The default sort order is ascending.

When the Index page is requested from the **Students** link, there's no query string. The students are displayed in ascending order by last name. Ascending order by last name is the `default` in the `switch` statement. When the user clicks a column heading link, the appropriate `sortOrder` value is provided in the query string value.

`NameSort` and `DateSort` are used by the Razor Page to configure the column heading hyperlinks with the appropriate query string values:

```
C#
```

```
NameSort = String.IsNullOrEmpty(sortOrder) ? "name_desc" : "";
DateSort = sortOrder == "Date" ? "date_desc" : "Date";
```

The code uses the C# conditional operator ?:. The `?:` operator is a ternary operator, it takes three operands. The first line specifies that when `sortOrder` is null or empty, `NameSort` is set to `name_desc`. If `sortOrder` is ***not*** null or empty, `NameSort` is set to an empty string.

These two statements enable the page to set the column heading hyperlinks as follows:

Expand table

Current sort order	Last Name Hyperlink	Date Hyperlink
Last Name ascending	descending	ascending
Last Name descending	ascending	ascending
Date ascending	ascending	descending
Date descending	ascending	ascending

The method uses LINQ to Entities to specify the column to sort by. The code initializes an `IQueryable<Student>` before the switch statement, and modifies it in the switch statement:

C#

```
IQueryable<Student> studentsIQ = from s in _context.Students
                                 select s;

switch (sortOrder)
{
    case "name_desc":
        studentsIQ = studentsIQ.OrderByDescending(s => s.LastName);
        break;
    case "Date":
        studentsIQ = studentsIQ.OrderBy(s => s.EnrollmentDate);
        break;
    case "date_desc":
        studentsIQ = studentsIQ.OrderByDescending(s => s.EnrollmentDate);
        break;
    default:
        studentsIQ = studentsIQ.OrderBy(s => s.LastName);
        break;
}

Students = await studentsIQ.AsNoTracking().ToListAsync();
```

When an `IQueryable` is created or modified, no query is sent to the database. The query isn't executed until the `IQueryable` object is converted into a collection. `IQueryable` are converted to a collection by calling a method such as `ToListAsync`. Therefore, the `IQueryable` code results in a single query that's not executed until the following statement:

C#

```
Students = await studentsIQ.AsNoTracking().ToListAsync();
```

`OnGetAsync` could get verbose with a large number of sortable columns. For information about an alternative way to code this functionality, see Use dynamic LINQ to simplify code in the MVC version of this tutorial series.

Add column heading hyperlinks to the Student Index page

Replace the code in `Students/Index.cshtml`, with the following code. The changes are highlighted.

CSHTML

```
@page
@model ContosoUniversity.Pages.Students.IndexModel

@{
    ViewData["Title"] = "Students";
}

<h2>Students</h2>
<p>
    <a asp-page="Create">Create New</a>
</p>

<table class="table">
    <thead>
        <tr>
            <th>
                <a asp-page="./Index" asp-route-sortOrder="@Model.NameSort">
                    @Html.DisplayNameFor(model =>
model.Students[0].LastName)
                </a>
            </th>
            <th>
                @Html.DisplayNameFor(model =>
model.Students[0].FirstMidName)
            </th>
            <th>
                <a asp-page="./Index" asp-route-sortOrder="@Model.DateSort">
                    @Html.DisplayNameFor(model =>
model.Students[0].EnrollmentDate)
                </a>
            </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
        @foreach (var item in Model.Students)
        {
            <tr>
                <td>
                    @Html.DisplayFor(modelItem => item.LastName)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.FirstMidName)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.EnrollmentDate)
                </td>
                <td>
                    <a asp-page="./Edit" asp-route-id="@item.ID">Edit</a> |
```

```
                    <a asp-page="./Details" asp-route-
id="@item.ID">Details</a> |
                    <a asp-page="./Delete" asp-route-
id="@item.ID">Delete</a>
                </td>
            </tr>
        }
    </tbody>
</table>
```

The preceding code:

- Adds hyperlinks to the `LastName` and `EnrollmentDate` column headings.
- Uses the information in `NameSort` and `DateSort` to set up hyperlinks with the current sort order values.
- Changes the page heading from Index to Students.
- Changes `Model.Student` to `Model.Students`.

To verify that sorting works:

- Run the app and select the **Students** tab.
- Click the column headings.

Add filtering

To add filtering to the Students Index page:

- A text box and a submit button is added to the Razor Page. The text box supplies a search string on the first or last name.
- The page model is updated to use the text box value.

Update the OnGetAsync method

Replace the code in `Students/Index.cshtml.cs` with the following code to add filtering:

C#

```
public class IndexModel : PageModel
{
    private readonly SchoolContext _context;

    public IndexModel(SchoolContext context)
    {
        _context = context;
    }
```

```
    public string NameSort { get; set; }
    public string DateSort { get; set; }
    public string CurrentFilter { get; set; }
    public string CurrentSort { get; set; }

    public IList<Student> Students { get; set; }

    public async Task OnGetAsync(string sortOrder, string searchString)
    {
        NameSort = String.IsNullOrEmpty(sortOrder) ? "name_desc" : "";
        DateSort = sortOrder == "Date" ? "date_desc" : "Date";

        CurrentFilter = searchString;

        IQueryable<Student> studentsIQ = from s in _context.Students
                                         select s;
        if (!String.IsNullOrEmpty(searchString))
        {
            studentsIQ = studentsIQ.Where(s =>
s.LastName.Contains(searchString)
                                   ||
s.FirstMidName.Contains(searchString));
        }

        switch (sortOrder)
        {
            case "name_desc":
                studentsIQ = studentsIQ.OrderByDescending(s => s.LastName);
                break;
            case "Date":
                studentsIQ = studentsIQ.OrderBy(s => s.EnrollmentDate);
                break;
            case "date_desc":
                studentsIQ = studentsIQ.OrderByDescending(s =>
s.EnrollmentDate);
                break;
            default:
                studentsIQ = studentsIQ.OrderBy(s => s.LastName);
                break;
        }

        Students = await studentsIQ.AsNoTracking().ToListAsync();
    }
}
```

The preceding code:

- Adds the `searchString` parameter to the `OnGetAsync` method, and saves the parameter value in the `CurrentFilter` property. The search string value is received from a text box that's added in the next section.
- Adds to the LINQ statement a `Where` clause. The `Where` clause selects only students whose first name or last name contains the search string. The LINQ statement is

executed only if there's a value to search for.

IQueryable vs. IEnumerable

The code calls the Where method on an `IQueryable` object, and the filter is processed on the server. In some scenarios, the app might be calling the `Where` method as an extension method on an in-memory collection. For example, suppose `_context.Students` changes from EF Core `DbSet` to a repository method that returns an `IEnumerable` collection. The result would normally be the same but in some cases may be different.

For example, the .NET Framework implementation of `Contains` performs a case-sensitive comparison by default. In SQL Server, `Contains` case-sensitivity is determined by the collation setting of the SQL Server instance. SQL Server defaults to case-insensitive. SQLite defaults to case-sensitive. `ToUpper` could be called to make the test explicitly case-insensitive:

```
C#

Where(s => s.LastName.ToUpper().Contains(searchString.ToUpper())`
```

The preceding code would ensure that the filter is case-insensitive even if the `Where` method is called on an `IEnumerable` or runs on SQLite.

When `Contains` is called on an `IEnumerable` collection, the .NET Core implementation is used. When `Contains` is called on an `IQueryable` object, the database implementation is used.

Calling `Contains` on an `IQueryable` is usually preferable for performance reasons. With `IQueryable`, the filtering is done by the database server. If an `IEnumerable` is created first, all the rows have to be returned from the database server.

There's a performance penalty for calling `ToUpper`. The `ToUpper` code adds a function in the WHERE clause of the TSQL SELECT statement. The added function prevents the optimizer from using an index. Given that SQL is installed as case-insensitive, it's best to avoid the `ToUpper` call when it's not needed.

For more information, see How to use case-insensitive query with Sqlite provider.

Update the Razor page

Replace the code in `Pages/Students/Index.cshtml` to add a **Search** button.

CSHTML

```
@page
@model ContosoUniversity.Pages.Students.IndexModel

@{
    ViewData["Title"] = "Students";
}

<h2>Students</h2>

<p>
    <a asp-page="Create">Create New</a>
</p>

<form asp-page="./Index" method="get">
    <div class="form-actions no-color">
        <p>
            Find by name:
            <input type="text" name="SearchString"
value="@Model.CurrentFilter" />
            <input type="submit" value="Search" class="btn btn-primary" /> |
            <a asp-page="./Index">Back to full List</a>
        </p>
    </div>
</form>

<table class="table">
    <thead>
        <tr>
            <th>
                <a asp-page="./Index" asp-route-sortOrder="@Model.NameSort">
                    @Html.DisplayNameFor(model =>
model.Students[0].LastName)
                </a>
            </th>
            <th>
                @Html.DisplayNameFor(model =>
model.Students[0].FirstMidName)
            </th>
            <th>
                <a asp-page="./Index" asp-route-sortOrder="@Model.DateSort">
                    @Html.DisplayNameFor(model =>
model.Students[0].EnrollmentDate)
                </a>
            </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
        @foreach (var item in Model.Students)
        {
```

```
            <tr>
                <td>
                    @Html.DisplayFor(modelItem => item.LastName)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.FirstMidName)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.EnrollmentDate)
                </td>
                <td>
                    <a asp-page="./Edit" asp-route-id="@item.ID">Edit</a> |
                    <a asp-page="./Details" asp-route-
id="@item.ID">Details</a> |
                    <a asp-page="./Delete" asp-route-
id="@item.ID">Delete</a>
                </td>
            </tr>
        }
    </tbody>
</table>
```

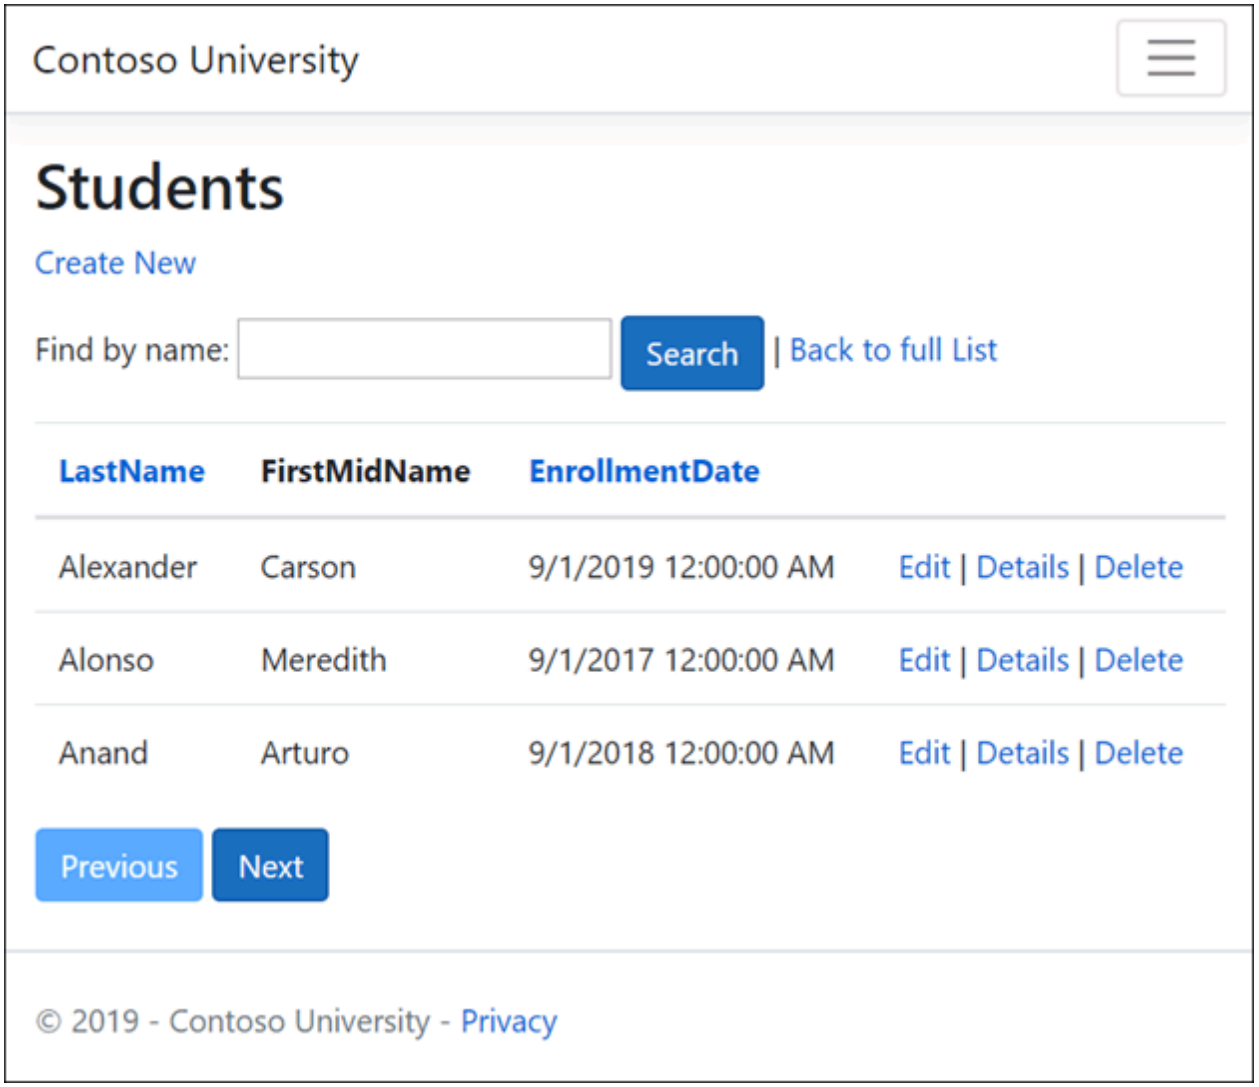
The preceding code uses the `<form>` tag helper to add the search text box and button. By default, the `<form>` tag helper submits form data with a POST. With POST, the parameters are passed in the HTTP message body and not in the URL. When HTTP GET is used, the form data is passed in the URL as query strings. Passing the data with query strings enables users to bookmark the URL. The W3C guidelines recommend that GET should be used when the action doesn't result in an update.

Test the app:

- Select the **Students** tab and enter a search string. If you're using SQLite, the filter is case-insensitive only if you implemented the optional `ToUpper` code shown earlier.
- Select **Search**.

Notice that the URL contains the search string. For example:

```
browser-address-bar
```



```
https://localhost:5001/Students?SearchString=an
```

If the page is bookmarked, the bookmark contains the URL to the page and the `SearchString` query string. The `method="get"` in the `form` tag is what caused the query string to be generated.

Currently, when a column heading sort link is selected, the filter value from the **Search** box is lost. The lost filter value is fixed in the next section.

Add paging

In this section, a `PaginatedList` class is created to support paging. The `PaginatedList` class uses `Skip` and `Take` statements to filter data on the server instead of retrieving all rows of the table. The following illustration shows the paging buttons.

Create the PaginatedList class

In the project folder, create `PaginatedList.cs` with the following code:

C#

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;
using Microsoft.EntityFrameworkCore;

namespace ContosoUniversity
{
    public class PaginatedList<T> : List<T>
```

```
    {
        public int PageIndex { get; private set; }
        public int TotalPages { get; private set; }

        public PaginatedList(List<T> items, int count, int pageIndex, int
pageSize)
        {
            PageIndex = pageIndex;
            TotalPages = (int)Math.Ceiling(count / (double)pageSize);

            this.AddRange(items);
        }

        public bool HasPreviousPage => PageIndex > 1;

        public bool HasNextPage => PageIndex < TotalPages;

        public static async Task<PaginatedList<T>> CreateAsync(
            IQueryable<T> source, int pageIndex, int pageSize)
        {
            var count = await source.CountAsync();
            var items = await source.Skip(
                (pageIndex - 1) * pageSize)
                .Take(pageSize).ToListAsync();
            return new PaginatedList<T>(items, count, pageIndex, pageSize);
        }
    }
}
```

The `CreateAsync` method in the preceding code takes page size and page number and applies the appropriate `Skip` and `Take` statements to the `IQueryable`. When `ToListAsync` is called on the `IQueryable`, it returns a List containing only the requested page. The properties `HasPreviousPage` and `HasNextPage` are used to enable or disable **Previous** and **Next** paging buttons.

The `CreateAsync` method is used to create the `PaginatedList<T>`. A constructor can't create the `PaginatedList<T>` object; constructors can't run asynchronous code.

Add page size to configuration

Add `PageSize` to the `appsettings.json` Configuration file:

JSON

```
{
  "PageSize": 3,
  "Logging": {
    "LogLevel": {
      "Default": "Information",
```

```
      "Microsoft": "Warning",
      "Microsoft.Hosting.Lifetime": "Information"
    }
  },
  "AllowedHosts": "*",
  "ConnectionStrings": {
    "SchoolContext": "Server=(localdb)\\mssqllocaldb;Database=CU-
1;Trusted_Connection=True;MultipleActiveResultSets=true"
  }
}
```

Add paging to IndexModel

Replace the code in `Students/Index.cshtml.cs` to add paging.

C#

```
using ContosoUniversity.Data;
using ContosoUniversity.Models;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.EntityFrameworkCore;
using Microsoft.Extensions.Configuration;
using System;
using System.Linq;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Students
{
    public class IndexModel : PageModel
    {
        private readonly SchoolContext _context;
        private readonly IConfiguration Configuration;

        public IndexModel(SchoolContext context, IConfiguration
configuration)
        {
            _context = context;
            Configuration = configuration;
        }

        public string NameSort { get; set; }
        public string DateSort { get; set; }
        public string CurrentFilter { get; set; }
        public string CurrentSort { get; set; }
```

```
        public PaginatedList<Student> Students { get; set; }

        public async Task OnGetAsync(string sortOrder,
            string currentFilter, string searchString, int? pageIndex)
        {
            CurrentSort = sortOrder;
            NameSort = String.IsNullOrEmpty(sortOrder) ? "name_desc" : "";
            DateSort = sortOrder == "Date" ? "date_desc" : "Date";
            if (searchString != null)
            {
                pageIndex = 1;
            }
            else
            {
                searchString = currentFilter;
            }

            CurrentFilter = searchString;

            IQueryable<Student> studentsIQ = from s in _context.Students
                                             select s;
            if (!String.IsNullOrEmpty(searchString))
            {
                studentsIQ = studentsIQ.Where(s =>
s.LastName.Contains(searchString)
                                       ||
s.FirstMidName.Contains(searchString));
            }
            switch (sortOrder)
            {
                case "name_desc":
                    studentsIQ = studentsIQ.OrderByDescending(s =>
s.LastName);
                    break;
                case "Date":
                    studentsIQ = studentsIQ.OrderBy(s => s.EnrollmentDate);
                    break;
                case "date_desc":
                    studentsIQ = studentsIQ.OrderByDescending(s =>
s.EnrollmentDate);
                    break;
                default:
                    studentsIQ = studentsIQ.OrderBy(s => s.LastName);
                    break;
            }

            var pageSize = Configuration.GetValue("PageSize", 4);
            Students = await PaginatedList<Student>.CreateAsync(
                studentsIQ.AsNoTracking(), pageIndex ?? 1, pageSize);
        }
    }
}
```

The preceding code:

- Changes the type of the `Students` property from `IList<Student>` to `PaginatedList<Student>`.
- Adds the page index, the current `sortOrder`, and the `currentFilter` to the `OnGetAsync` method signature.
- Saves the sort order in the `CurrentSort` property.
- Resets page index to 1 when there's a new search string.
- Uses the `PaginatedList` class to get Student entities.
- Sets `pageSize` to 3 from Configuration, 4 if configuration fails.

All the parameters that `OnGetAsync` receives are null when:

- The page is called from the **Students** link.
- The user hasn't clicked a paging or sorting link.

When a paging link is clicked, the page index variable contains the page number to display.

The `CurrentSort` property provides the Razor Page with the current sort order. The current sort order must be included in the paging links to keep the sort order while paging.

The `CurrentFilter` property provides the Razor Page with the current filter string. The `CurrentFilter` value:

- Must be included in the paging links in order to maintain the filter settings during paging.
- Must be restored to the text box when the page is redisplayed.

If the search string is changed while paging, the page is reset to 1. The page has to be reset to 1 because the new filter can result in different data to display. When a search value is entered and **Submit** is selected:

- The search string is changed.
- The `searchString` parameter isn't null.

The `PaginatedList.CreateAsync` method converts the student query to a single page of students in a collection type that supports paging. That single page of students is passed to the Razor Page.

The two question marks after `pageIndex` in the `PaginatedList.CreateAsync` call represent the null-coalescing operator. The null-coalescing operator defines a default value for a nullable type. The expression `pageIndex ?? 1` returns the value of `pageIndex` if it has a value, otherwise, it returns 1.

Add paging links

Replace the code in `Students/Index.cshtml` with the following code. The changes are highlighted:

CSHTML

```
@page
@model ContosoUniversity.Pages.Students.IndexModel

@{
    ViewData["Title"] = "Students";
}

<h2>Students</h2>

<p>
    <a asp-page="Create">Create New</a>
</p>

<form asp-page="./Index" method="get">
    <div class="form-actions no-color">
        <p>
            Find by name:
            <input type="text" name="SearchString"
value="@Model.CurrentFilter" />
            <input type="submit" value="Search" class="btn btn-primary" /> |
            <a asp-page="./Index">Back to full List</a>
        </p>
    </div>
</form>

<table class="table">
    <thead>
        <tr>
            <th>
                <a asp-page="./Index" asp-route-sortOrder="@Model.NameSort"
                   asp-route-currentFilter="@Model.CurrentFilter">
                    @Html.DisplayNameFor(model =>
model.Students[0].LastName)
                </a>
            </th>
            <th>
                @Html.DisplayNameFor(model =>
model.Students[0].FirstMidName)
            </th>
            <th>
                <a asp-page="./Index" asp-route-sortOrder="@Model.DateSort"
                   asp-route-currentFilter="@Model.CurrentFilter">
                    @Html.DisplayNameFor(model =>
model.Students[0].EnrollmentDate)
                </a>
            </th>
```

```
            <th></th>
        </tr>
    </thead>
    <tbody>
        @foreach (var item in Model.Students)
        {
            <tr>
                <td>
                    @Html.DisplayFor(modelItem => item.LastName)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.FirstMidName)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.EnrollmentDate)
                </td>
                <td>
                    <a asp-page="./Edit" asp-route-id="@item.ID">Edit</a> |
                    <a asp-page="./Details" asp-route-
id="@item.ID">Details</a> |
                    <a asp-page="./Delete" asp-route-
id="@item.ID">Delete</a>
                </td>
            </tr>
        }
    </tbody>
</table>
```

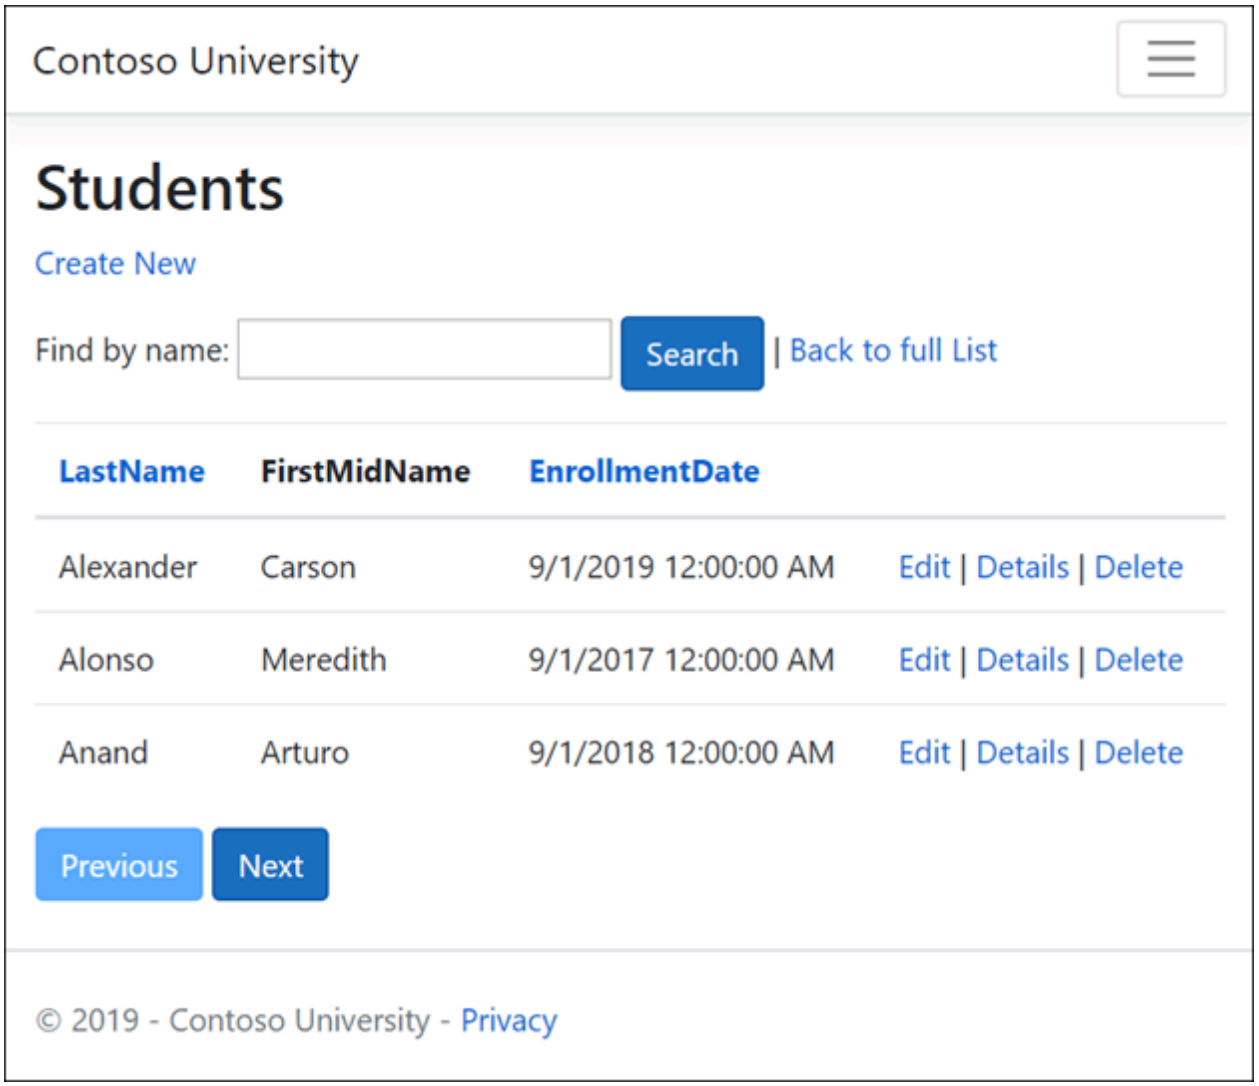
```
@{
    var prevDisabled = !Model.Students.HasPreviousPage ? "disabled" : "";
    var nextDisabled = !Model.Students.HasNextPage ? "disabled" : "";
}

<a asp-page="./Index"
   asp-route-sortOrder="@Model.CurrentSort"
   asp-route-pageIndex="@(Model.Students.PageIndex - 1)"
   asp-route-currentFilter="@Model.CurrentFilter"
   class="btn btn-primary @prevDisabled">
    Previous
</a>
<a asp-page="./Index"
   asp-route-sortOrder="@Model.CurrentSort"
   asp-route-pageIndex="@(Model.Students.PageIndex + 1)"
   asp-route-currentFilter="@Model.CurrentFilter"
   class="btn btn-primary @nextDisabled">
    Next
</a>
```

The column header links use the query string to pass the current search string to the `OnGetAsync` method:

CSHTML

```
<a asp-page="./Index" asp-route-sortOrder="@Model.NameSort"
   asp-route-currentFilter="@Model.CurrentFilter">
    @Html.DisplayNameFor(model => model.Students[0].LastName)
</a>
```



The paging buttons are displayed by tag helpers:

CSHTML

```
<a asp-page="./Index"
   asp-route-sortOrder="@Model.CurrentSort"
   asp-route-pageIndex="@(Model.Students.PageIndex - 1)"
   asp-route-currentFilter="@Model.CurrentFilter"
   class="btn btn-primary @prevDisabled">
    Previous
</a>
<a asp-page="./Index"
   asp-route-sortOrder="@Model.CurrentSort"
   asp-route-pageIndex="@(Model.Students.PageIndex + 1)"
   asp-route-currentFilter="@Model.CurrentFilter"
   class="btn btn-primary @nextDisabled">
    Next
</a>
```

Run the app and navigate to the students page.

- To make sure paging works, click the paging links in different sort orders.
- To verify that paging works correctly with sorting and filtering, enter a search string and try paging.

Grouping

This section creates an `About` page that displays how many students have enrolled for each enrollment date. The update uses grouping and includes the following steps:

- Create a view model for the data used by the `About` page.
- Update the `About` page to use the view model.

Create the view model

Create a *Models/SchoolViewModels* folder.

Create `SchoolViewModels/EnrollmentDateGroup.cs` with the following code:

C#

```
using System;
using System.ComponentModel.DataAnnotations;

namespace ContosoUniversity.Models.SchoolViewModels
```

```
{
    public class EnrollmentDateGroup
    {
        [DataType(DataType.Date)]
        public DateTime? EnrollmentDate { get; set; }

        public int StudentCount { get; set; }
    }
}
```

Create the Razor Page

Create a `Pages/About.cshtml` file with the following code:

CSHTML

```
@page
@model ContosoUniversity.Pages.AboutModel

@{
    ViewData["Title"] = "Student Body Statistics";
}

<h2>Student Body Statistics</h2>

<table>
    <tr>
        <th>
            Enrollment Date
        </th>
        <th>
            Students
        </th>
    </tr>

    @foreach (var item in Model.Students)
    {
        <tr>
            <td>
                @Html.DisplayFor(modelItem => item.EnrollmentDate)
            </td>
            <td>
                @item.StudentCount
            </td>
        </tr>
    }
</table>
```

Create the page model

Update the `Pages/About.cshtml.cs` file with the following code:

C#

```
using ContosoUniversity.Models.SchoolViewModels;
using ContosoUniversity.Data;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.EntityFrameworkCore;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;
using ContosoUniversity.Models;

namespace ContosoUniversity.Pages
{
    public class AboutModel : PageModel
    {
        private readonly SchoolContext _context;

        public AboutModel(SchoolContext context)
        {
            _context = context;
        }

        public IList<EnrollmentDateGroup> Students { get; set; }

        public async Task OnGetAsync()
        {
            IQueryable<EnrollmentDateGroup> data =
                from student in _context.Students
                group student by student.EnrollmentDate into dateGroup
                select new EnrollmentDateGroup()
                {
                    EnrollmentDate = dateGroup.Key,
                    StudentCount = dateGroup.Count()
                };

            Students = await data.AsNoTracking().ToListAsync();
        }
    }
}
```

The LINQ statement groups the student entities by enrollment date, calculates the number of entities in each group, and stores the results in a collection of `EnrollmentDateGroup` view model objects.

Run the app and navigate to the About page. The count of students for each enrollment date is displayed in a table.

Next steps

In the next tutorial, the app uses migrations to update the data model.

Previous tutorial | Next tutorial

Part 4, Razor Pages with EF Core migrations in ASP.NET Core

Article • 05/31/2024

By Tom Dykstra, Jon P Smith, and Rick Anderson

The Contoso University web app demonstrates how to create Razor Pages web apps using EF Core and Visual Studio. For information about the tutorial series, see the first tutorial.

If you run into problems you can't solve, download the completed app and compare that code to what you created by following the tutorial.

This tutorial introduces the EF Core migrations feature for managing data model changes.

When a new app is developed, the data model changes frequently. Each time the model changes, the model gets out of sync with the database. This tutorial series started by configuring the Entity Framework to create the database if it doesn't exist. Each time the data model changes, the database needs to be dropped. The next time the app runs, the call to `EnsureCreated` re-creates the database to match the new data model. The `DbInitializer` class then runs to seed the new database.

This approach to keeping the DB in sync with the data model works well until the app needs to be deployed to production. When the app is running in production, it's usually storing data that needs to be maintained. The app can't start with a test DB each time a change is made (such as adding a new column). The EF Core Migrations feature solves this problem by enabling EF Core to update the DB schema instead of creating a new database.

Rather than dropping and recreating the database when the data model changes, migrations updates the schema and retains existing data.

> **Note**
>
> **SQLite limitations**
>
> This tutorial uses the Entity Framework Core migrations feature where possible. Migrations updates the database schema to match changes in the data model. However, migrations only does the kinds of changes that the database engine supports, and SQLite's schema change capabilities are limited. For example, adding

a column is supported, but removing a column is not supported. If a migration is created to remove a column, the `ef migrations add` command succeeds but the `ef database update` command fails.

The workaround for the SQLite limitations is to manually write migrations code to perform a table rebuild when something in the table changes. The code goes in the `Up` and `Down` methods for a migration and involves:

- Creating a new table.
- Copying data from the old table to the new table.
- Dropping the old table.
- Renaming the new table.

Writing database-specific code of this type is outside the scope of this tutorial. Instead, this tutorial drops and re-creates the database whenever an attempt to apply a migration would fail. For more information, see the following resources:

- SQLite EF Core Database Provider Limitations
- Customize migration code
- Data seeding
- SQLite ALTER TABLE statement

Drop the database

Visual Studio

Use **SQL Server Object Explorer** (SSOX) to delete the database, or run the following command in the **Package Manager Console** (PMC):

PowerShell

```
Drop-Database
```

Create an initial migration

Visual Studio

Run the following commands in the PMC:

PowerShell

```
Add-Migration InitialCreate
Update-Database
```

Remove EnsureCreated

This tutorial series started by using EnsureCreated. `EnsureCreated` doesn't create a migrations history table and so can't be used with migrations. It's designed for testing or rapid prototyping where the database is dropped and re-created frequently.

From this point forward, the tutorials will use migrations.

In `Program.cs`, delete the following line:

C#

```
context.Database.EnsureCreated();
```

Run the app and verify that the database is seeded.

Up and Down methods

The EF Core `migrations add` command generated code to create the database. This migrations code is in the `Migrations\<timestamp>_InitialCreate.cs` file. The `Up` method of the `InitialCreate` class creates the database tables that correspond to the data model entity sets. The `Down` method deletes them, as shown in the following example:

C#

```
using System;
using Microsoft.EntityFrameworkCore.Metadata;
using Microsoft.EntityFrameworkCore.Migrations;

namespace ContosoUniversity.Migrations
{
    public partial class InitialCreate : Migration
    {
        protected override void Up(MigrationBuilder migrationBuilder)
        {
            migrationBuilder.CreateTable(
                name: "Course",
                columns: table => new
                {
```

```
                    CourseID = table.Column<int>(nullable: false),
                    Title = table.Column<string>(nullable: true),
                    Credits = table.Column<int>(nullable: false)
                },
                constraints: table =>
                {
                    table.PrimaryKey("PK_Course", x => x.CourseID);
                });

            migrationBuilder.CreateTable(
                name: "Student",
                columns: table => new
                {
                    ID = table.Column<int>(nullable: false)
                        .Annotation("SqlServer:ValueGenerationStrategy",
SqlServerValueGenerationStrategy.IdentityColumn),
                    LastName = table.Column<string>(nullable: true),
                    FirstMidName = table.Column<string>(nullable: true),
                    EnrollmentDate = table.Column<DateTime>(nullable: false)
                },
                constraints: table =>
                {
                    table.PrimaryKey("PK_Student", x => x.ID);
                });

            migrationBuilder.CreateTable(
                name: "Enrollment",
                columns: table => new
                {
                    EnrollmentID = table.Column<int>(nullable: false)
                        .Annotation("SqlServer:ValueGenerationStrategy",
SqlServerValueGenerationStrategy.IdentityColumn),
                    CourseID = table.Column<int>(nullable: false),
                    StudentID = table.Column<int>(nullable: false),
                    Grade = table.Column<int>(nullable: true)
                },
                constraints: table =>
                {
                    table.PrimaryKey("PK_Enrollment", x => x.EnrollmentID);
                    table.ForeignKey(
                        name: "FK_Enrollment_Course_CourseID",
                        column: x => x.CourseID,
                        principalTable: "Course",
                        principalColumn: "CourseID",
                        onDelete: ReferentialAction.Cascade);
                    table.ForeignKey(
                        name: "FK_Enrollment_Student_StudentID",
                        column: x => x.StudentID,
                        principalTable: "Student",
                        principalColumn: "ID",
                        onDelete: ReferentialAction.Cascade);
                });

            migrationBuilder.CreateIndex(
                name: "IX_Enrollment_CourseID",
```

```
                table: "Enrollment",
                column: "CourseID");

            migrationBuilder.CreateIndex(
                name: "IX_Enrollment_StudentID",
                table: "Enrollment",
                column: "StudentID");
        }

        protected override void Down(MigrationBuilder migrationBuilder)
        {
            migrationBuilder.DropTable(
                name: "Enrollment");

            migrationBuilder.DropTable(
                name: "Course");

            migrationBuilder.DropTable(
                name: "Student");
        }
    }
}
```

The preceding code is for the initial migration. The code:

- Was generated by the `migrations add InitialCreate` command.
- Is executed by the `database update` command.
- Creates a database for the data model specified by the database context class.

The migration name parameter (`InitialCreate` in the example) is used for the file name. The migration name can be any valid file name. It's best to choose a word or phrase that summarizes what is being done in the migration. For example, a migration that added a department table might be called "AddDepartmentTable."

The migrations history table

- Use SSOX or SQLite tool to inspect the database.
- Notice the addition of an `__EFMigrationsHistory` table. The `__EFMigrationsHistory` table keeps track of which migrations have been applied to the database.
- View the data in the `__EFMigrationsHistory` table. It shows one row for the first migration.

The data model snapshot

Migrations creates a *snapshot* of the current data model in `Migrations/SchoolContextModelSnapshot.cs`. When add a migration is added, EF determines what changed by comparing the current data model to the snapshot file.

Because the snapshot file tracks the state of the data model, a migration cannot be deleted by deleting the `<timestamp>_<migrationname>.cs` file. To back out the most recent migration, use the migrations remove command. `migrations remove` deletes the migration and ensures the snapshot is correctly reset. For more information, see dotnet ef migrations remove.

See Resetting all migrations to remove all migrations.

Applying migrations in production

We recommend that production apps **not** call Database.Migrate at application startup. `Migrate` shouldn't be called from an app that is deployed to a server farm. If the app is scaled out to multiple server instances, it's hard to ensure database schema updates don't happen from multiple servers or conflict with read/write access.

Database migration should be done as part of deployment, and in a controlled way. Production database migration approaches include:

- Using migrations to create SQL scripts and using the SQL scripts in deployment.
- Running `dotnet ef database update` from a controlled environment.

Troubleshooting

If the app uses SQL Server LocalDB and displays the following exception:

```text
SqlException: Cannot open database "ContosoUniversity" requested by the
login.
The login failed.
Login failed for user 'user name'.
```

The solution may be to run `dotnet ef database update` at a command prompt.

Additional resources

- EF Core CLI.
- dotnet ef migrations CLI commands

- Package Manager Console (Visual Studio)

Next steps

The next tutorial builds out the data model, adding entity properties and new entities.

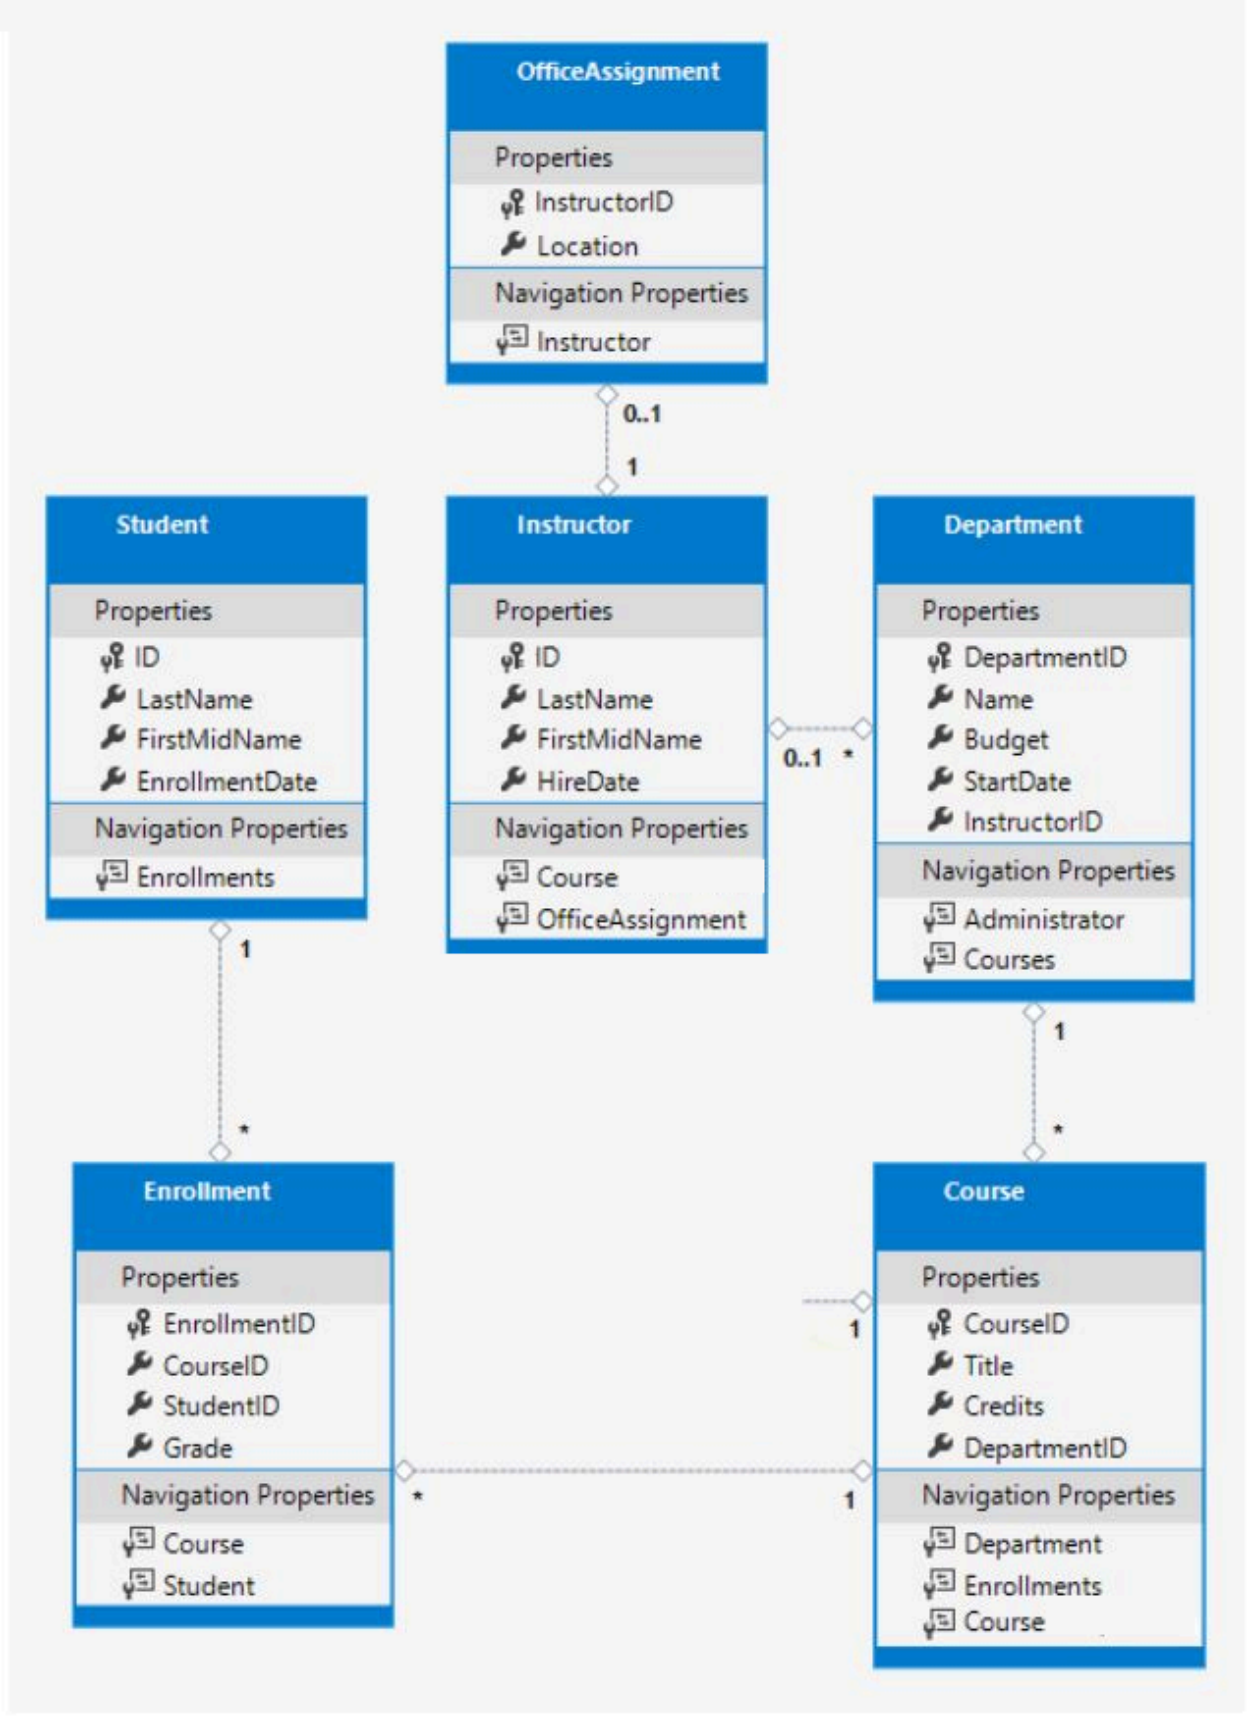
Part 5, Razor Pages with EF Core in ASP.NET Core - Data Model

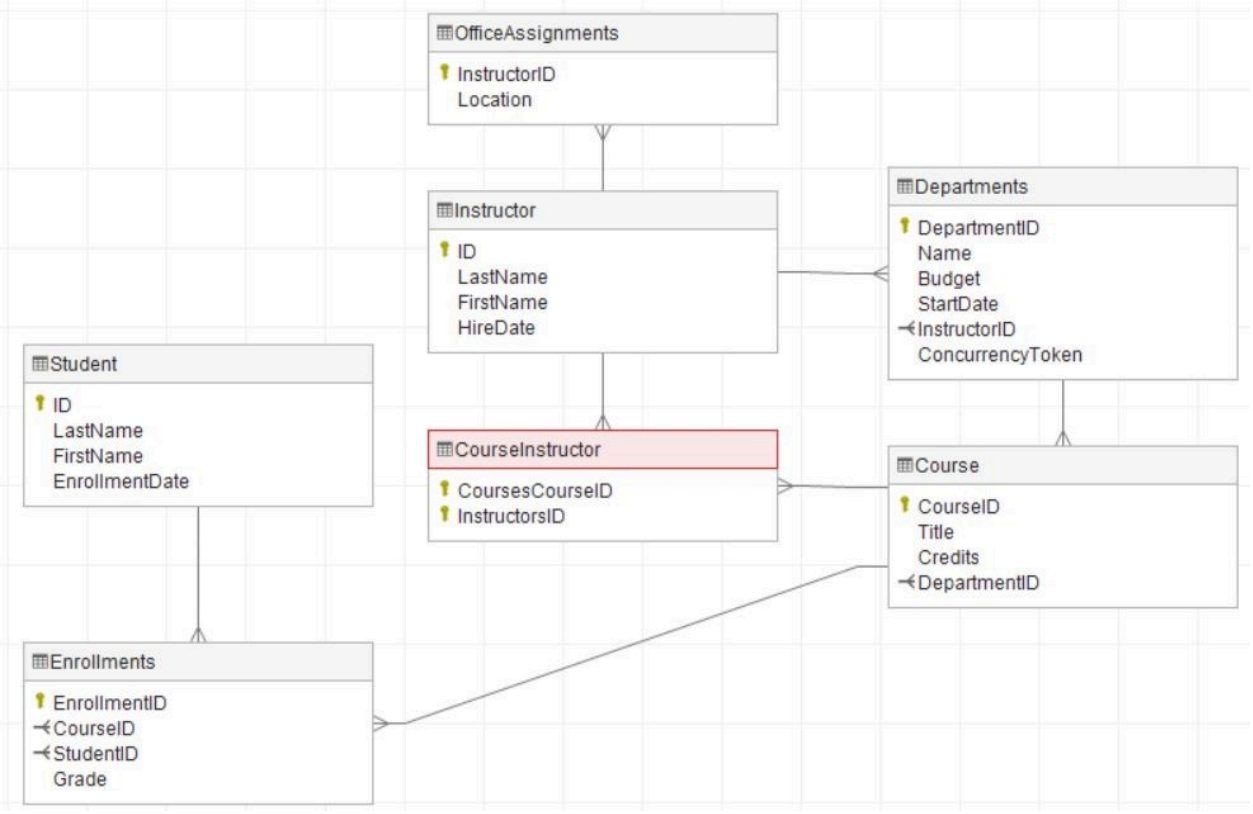
Article • 04/10/2024

By Tom Dykstra, Jeremy Likness, and Jon P Smith



The Contoso University web app demonstrates how to create Razor Pages web apps using EF Core and Visual Studio. For information about the tutorial series, see the first tutorial.

If you run into problems you can't solve, download the completed app and compare that code to what you created by following the tutorial.



The previous tutorials worked with a basic data model that was composed of three entities. In this tutorial:

- More entities and relationships are added.
- The data model is customized by specifying formatting, validation, and database mapping rules.

The completed data model is shown in the following illustration:

The following database diagram was made with Dataedo:

To create a database diagram with Dataedo:

- Deploy the app to Azure
- Download and install Dataedo on your computer.
- Follow the instructions Generate documentation for Azure SQL Database in 5 minutes

In the preceding Dataedo diagram, the `CourseInstructor` is a join table created by Entity Framework. For more information, see Many-to-many

The Student entity

Replace the code in `Models/Student.cs` with the following code:

C#

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Student
    {
        public int ID { get; set; }
        [Required]
        [StringLength(50)]
```

```
        [Display(Name = "Last Name")]
        public string LastName { get; set; }
        [Required]
        [StringLength(50, ErrorMessage = "First name cannot be longer than
50 characters.")]
        [Column("FirstName")]
        [Display(Name = "First Name")]
        public string FirstMidName { get; set; }
        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}",
ApplyFormatInEditMode = true)]
        [Display(Name = "Enrollment Date")]
        public DateTime EnrollmentDate { get; set; }
        [Display(Name = "Full Name")]
        public string FullName
        {
            get
            {
                return LastName + ", " + FirstMidName;
            }
        }

        public ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

The preceding code adds a `FullName` property and adds the following attributes to existing properties:

- [DataType]
- [DisplayFormat]
- [StringLength]
- [Column]
- [Required]
- [Display]

The FullName calculated property

`FullName` is a calculated property that returns a value that's created by concatenating two other properties. `FullName` can't be set, so it has only a get accessor. No `FullName` column is created in the database.

The DataType attribute

```
C#
```

```
[DataType(DataType.Date)]
```

For student enrollment dates, all of the pages currently display the time of day along with the date, although only the date is relevant. By using data annotation attributes, you can make one code change that will fix the display format in every page that shows the data.

The DataType attribute specifies a data type that's more specific than the database intrinsic type. In this case only the date should be displayed, not the date and time. The DataType Enumeration provides for many data types, such as Date, Time, PhoneNumber, Currency, EmailAddress, etc. The `DataType` attribute can also enable the app to automatically provide type-specific features. For example:

- The `mailto:` link is automatically created for `DataType.EmailAddress`.
- The date selector is provided for `DataType.Date` in most browsers.

The `DataType` attribute emits HTML 5 `data-` (pronounced data dash) attributes. The `DataType` attributes don't provide validation.

The DisplayFormat attribute

C#

```
[DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode =
true)]
```

`DataType.Date` doesn't specify the format of the date that's displayed. By default, the date field is displayed according to the default formats based on the server's CultureInfo.

The `DisplayFormat` attribute is used to explicitly specify the date format. The `ApplyFormatInEditMode` setting specifies that the formatting should also be applied to the edit UI. Some fields shouldn't use `ApplyFormatInEditMode`. For example, the currency symbol should generally not be displayed in an edit text box.

The `DisplayFormat` attribute can be used by itself. It's generally a good idea to use the `DataType` attribute with the `DisplayFormat` attribute. The `DataType` attribute conveys the semantics of the data as opposed to how to render it on a screen. The `DataType` attribute provides the following benefits that are not available in `DisplayFormat`:

- The browser can enable HTML5 features. For example, show a calendar control, the locale-appropriate currency symbol, email links, and client-side input validation.
- By default, the browser renders data using the correct format based on the locale.

For more information, see the <input> Tag Helper documentation.

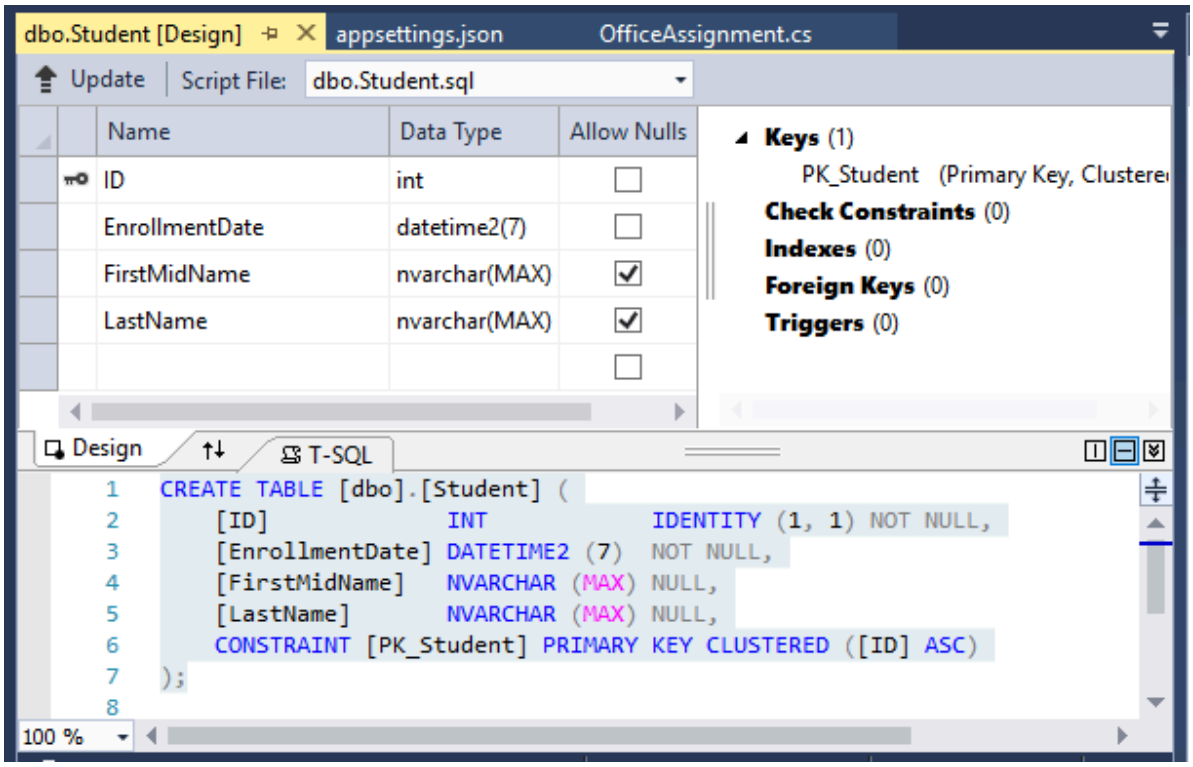
The StringLength attribute

C#

```
[StringLength(50, ErrorMessage = "First name cannot be longer than 50
characters.")]
```

Data validation rules and validation error messages can be specified with attributes. The StringLength attribute specifies the minimum and maximum length of characters that are allowed in a data field. The code shown limits names to no more than 50 characters. An example that sets the minimum string length is shown later.

The `StringLength` attribute also provides client-side and server-side validation. The minimum value has no impact on the database schema.



The `StringLength` attribute doesn't prevent a user from entering white space for a name. The RegularExpression attribute can be used to apply restrictions to the input. For example, the following code requires the first character to be upper case and the remaining characters to be alphabetical:

C#

```
[RegularExpression(@"^[A-Z]+[a-zA-Z]*$")]
```

Visual Studio

In **SQL Server Object Explorer** (SSOX), open the Student table designer by double-clicking the **Student** table.

The preceding image shows the schema for the `Student` table. The name fields have type `nvarchar(MAX)`. When a migration is created and applied later in this tutorial, the name fields become `nvarchar(50)` as a result of the string length attributes.

The Column attribute

C#

```
[Column("FirstName")]
public string FirstMidName { get; set; }
```

Attributes can control how classes and properties are mapped to the database. In the `Student` model, the `Column` attribute is used to map the name of the `FirstMidName` property to "FirstName" in the database.

When the database is created, property names on the model are used for column names (except when the `Column` attribute is used). The `Student` model uses `FirstMidName` for the first-name field because the field might also contain a middle name.

With the `[Column]` attribute, `Student.FirstMidName` in the data model maps to the `FirstName` column of the `Student` table. The addition of the `Column` attribute changes the model backing the `SchoolContext`. The model backing the `SchoolContext` no longer matches the database. That discrepancy will be resolved by adding a migration later in this tutorial.

The Required attribute

```
C#

[Required]
```

The `Required` attribute makes the name properties required fields. The `Required` attribute isn't needed for non-nullable types such as value types (for example, `DateTime`, `int`, and `double`). Types that can't be null are automatically treated as required fields.

The `Required` attribute must be used with `MinimumLength` for the `MinimumLength` to be enforced.

```
C#

[Display(Name = "Last Name")]
[Required]
[StringLength(50, MinimumLength=2)]
public string LastName { get; set; }
```

`MinimumLength` and `Required` allow whitespace to satisfy the validation. Use the `RegularExpression` attribute for full control over the string.

The Display attribute

```
C#

[Display(Name = "Last Name")]
```

The `Display` attribute specifies that the caption for the text boxes should be "First Name", "Last Name", "Full Name", and "Enrollment Date." The default captions had no space dividing the words, for example "Lastname."

Create a migration

Run the app and go to the Students page. An exception is thrown. The `[Column]` attribute causes EF to expect to find a column named `FirstName`, but the column name in the database is still `FirstMidName`.

Visual Studio

The error message is similar to the following example:

```
SqlException: Invalid column name 'FirstName'.
There are pending model changes
Pending model changes are detected in the following:

SchoolContext
```

- In the PMC, enter the following commands to create a new migration and update the database:

  ```PowerShell
  Add-Migration ColumnFirstName
  Update-Database
  ```

  The first of these commands generates the following warning message:

  ```text
  An operation was scaffolded that may result in the loss of data.
  Please review the migration for accuracy.
  ```

  The warning is generated because the name fields are now limited to 50 characters. If a name in the database had more than 50 characters, the 51 to last character would be lost.

- Open the Student table in SSOX:

Before the migration was applied, the name columns were of type nvarchar(MAX). The name columns are now `nvarchar(50)`. The column name has changed from `FirstMidName` to `FirstName`.

- Run the app and go to the Students page.
- Notice that times are not input or displayed along with dates.
- Select **Create New**, and try to enter a name longer than 50 characters.

> ⓘ Note
>
> In the following sections, building the app at some stages generates compiler errors. The instructions specify when to build the app.

The Instructor Entity

Create `Models/Instructor.cs` with the following code:

C#

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
```

```
{
    public class Instructor
    {
        public int ID { get; set; }

        [Required]
        [Display(Name = "Last Name")]
        [StringLength(50)]
        public string LastName { get; set; }

        [Required]
        [Column("FirstName")]
        [Display(Name = "First Name")]
        [StringLength(50)]
        public string FirstMidName { get; set; }

        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}",
ApplyFormatInEditMode = true)]
        [Display(Name = "Hire Date")]
        public DateTime HireDate { get; set; }

        [Display(Name = "Full Name")]
        public string FullName
        {
            get { return LastName + ", " + FirstMidName; }
        }

        public ICollection<Course> Courses { get; set; }
        public OfficeAssignment OfficeAssignment { get; set; }
    }
}
```

Multiple attributes can be on one line. The `HireDate` attributes could be written as follows:

C#

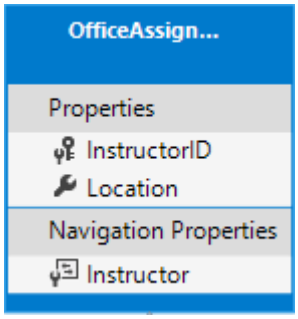
```
[DataType(DataType.Date),Display(Name = "Hire
Date"),DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}",
ApplyFormatInEditMode = true)]
```

Navigation properties

The `Courses` and `OfficeAssignment` properties are navigation properties.

An instructor can teach any number of courses, so `Courses` is defined as a collection.

C#



```
public ICollection<Course> Courses { get; set; }
```

An instructor can have at most one office, so the `OfficeAssignment` property holds a single `OfficeAssignment` entity. `OfficeAssignment` is null if no office is assigned.

C#

```
public OfficeAssignment OfficeAssignment { get; set; }
```

The OfficeAssignment entity

Create `Models/OfficeAssignment.cs` with the following code:

C#

```
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class OfficeAssignment
    {
        [Key]
        public int InstructorID { get; set; }
        [StringLength(50)]
        [Display(Name = "Office Location")]
        public string Location { get; set; }

        public Instructor Instructor { get; set; }
    }
}
```

The Key attribute

The [Key] attribute is used to identify a property as the primary key (PK) when the property name is something other than `classnameID` or `ID`.

There's a one-to-zero-or-one relationship between the `Instructor` and `OfficeAssignment` entities. An office assignment only exists in relation to the instructor it's assigned to. The `OfficeAssignment` PK is also its foreign key (FK) to the `Instructor` entity. A one-to-zero-or-one relationship occurs when a PK in one table is both a PK and a FK in another table.

EF Core can't automatically recognize `InstructorID` as the PK of `OfficeAssignment` because `InstructorID` doesn't follow the ID or classnameID naming convention. Therefore, the `Key` attribute is used to identify `InstructorID` as the PK:

C#

```
[Key]
public int InstructorID { get; set; }
```

By default, EF Core treats the key as non-database-generated because the column is for an identifying relationship. For more information, see EF Keys.

The Instructor navigation property

The `Instructor.OfficeAssignment` navigation property can be null because there might not be an `OfficeAssignment` row for a given instructor. An instructor might not have an office assignment.

The `OfficeAssignment.Instructor` navigation property will always have an instructor entity because the foreign key `InstructorID` type is `int`, a non-nullable value type. An office assignment can't exist without an instructor.

When an `Instructor` entity has a related `OfficeAssignment` entity, each entity has a reference to the other one in its navigation property.

The Course Entity

Update `Models/Course.cs` with the following code:

C#

```
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
```

```
    public class Course
    {
        [DatabaseGenerated(DatabaseGeneratedOption.None)]
        [Display(Name = "Number")]
        public int CourseID { get; set; }

        [StringLength(50, MinimumLength = 3)]
        public string Title { get; set; }

        [Range(0, 5)]
        public int Credits { get; set; }

        public int DepartmentID { get; set; }

        public Department Department { get; set; }
        public ICollection<Enrollment> Enrollments { get; set; }
        public ICollection<Instructor> Instructors { get; set; }
    }
}
```

The `Course` entity has a foreign key (FK) property `DepartmentID`. `DepartmentID` points to the related `Department` entity. The `Course` entity has a `Department` navigation property.

EF Core doesn't require a foreign key property for a data model when the model has a navigation property for a related entity. EF Core automatically creates FKs in the database wherever they're needed. EF Core creates shadow properties for automatically created FKs. However, explicitly including the FK in the data model can make updates simpler and more efficient. For example, consider a model where the FK property `DepartmentID` is ***not*** included. When a course entity is fetched to edit:

- The `Department` property is `null` if it's not explicitly loaded.
- To update the course entity, the `Department` entity must first be fetched.

When the FK property `DepartmentID` is included in the data model, there's no need to fetch the `Department` entity before an update.

The DatabaseGenerated attribute

The `[DatabaseGenerated(DatabaseGeneratedOption.None)]` attribute specifies that the PK is provided by the application rather than generated by the database.

C#

```
[DatabaseGenerated(DatabaseGeneratedOption.None)]
[Display(Name = "Number")]
public int CourseID { get; set; }
```

By default, EF Core assumes that PK values are generated by the database. Database-generated is generally the best approach. For `Course` entities, the user specifies the PK. For example, a course number such as a 1000 series for the math department, a 2000 series for the English department.

The `DatabaseGenerated` attribute can also be used to generate default values. For example, the database can automatically generate a date field to record the date a row was created or updated. For more information, see Generated Properties.

Foreign key and navigation properties

The foreign key (FK) properties and navigation properties in the `Course` entity reflect the following relationships:

A course is assigned to one department, so there's a `DepartmentID` FK and a `Department` navigation property.

C#

```
public int DepartmentID { get; set; }
public Department Department { get; set; }
```

A course can have any number of students enrolled in it, so the `Enrollments` navigation property is a collection:

C#

```
public ICollection<Enrollment> Enrollments { get; set; }
```

A course may be taught by multiple instructors, so the `Instructors` navigation property is a collection:

C#

```
public ICollection<Instructor> Instructors { get; set; }
```

The Department entity

Create `Models/Department.cs` with the following code:

C#

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Department
    {
        public int DepartmentID { get; set; }

        [StringLength(50, MinimumLength = 3)]
        public string Name { get; set; }

        [DataType(DataType.Currency)]
        [Column(TypeName = "money")]
        public decimal Budget { get; set; }

        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}",
                       ApplyFormatInEditMode = true)]
        [Display(Name = "Start Date")]
        public DateTime StartDate { get; set; }

        public int? InstructorID { get; set; }

        public Instructor Administrator { get; set; }
        public ICollection<Course> Courses { get; set; }
    }
}
```

The Column attribute

Previously the `Column` attribute was used to change column name mapping. In the code for the `Department` entity, the `Column` attribute is used to change SQL data type mapping. The `Budget` column is defined using the SQL Server money type in the database:

C#

```
[Column(TypeName="money")]
public decimal Budget { get; set; }
```

Column mapping is generally not required. EF Core chooses the appropriate SQL Server data type based on the CLR type for the property. The CLR `decimal` type maps to a SQL Server `decimal` type. `Budget` is for currency, and the money data type is more appropriate for currency.

Foreign key and navigation properties

The FK and navigation properties reflect the following relationships:

- A department may or may not have an administrator.
- An administrator is always an instructor. Therefore the `InstructorID` property is included as the FK to the `Instructor` entity.

The navigation property is named `Administrator` but holds an `Instructor` entity:

C#

```
public int? InstructorID { get; set; }
public Instructor Administrator { get; set; }
```

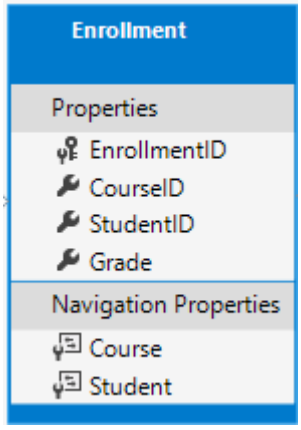
The `?` in the preceding code specifies the property is nullable.

A department may have many courses, so there's a Courses navigation property:

C#

```
public ICollection<Course> Courses { get; set; }
```

By convention, EF Core enables cascade delete for non-nullable FKs and for many-to-many relationships. This default behavior can result in circular cascade delete rules. Circular cascade delete rules cause an exception when a migration is added.



For example, if the `Department.InstructorID` property was defined as non-nullable, EF Core would configure a cascade delete rule. In that case, the department would be deleted when the instructor assigned as its administrator is deleted. In this scenario, a restrict rule would make more sense. The following fluent API would set a restrict rule and disable cascade delete.

C#

```
modelBuilder.Entity<Department>()
    .HasOne(d => d.Administrator)
    .WithMany()
    .OnDelete(DeleteBehavior.Restrict)
```

The Enrollment foreign key and navigation properties

An enrollment record is for one course taken by one student.

Update `Models/Enrollment.cs` with the following code:

C#

```
using System.ComponentModel.DataAnnotations;

namespace ContosoUniversity.Models
{
    public enum Grade
    {
        A, B, C, D, F
    }

    public class Enrollment
    {
        public int EnrollmentID { get; set; }
        public int CourseID { get; set; }
        public int StudentID { get; set; }
        [DisplayFormat(NullDisplayText = "No grade")]
        public Grade? Grade { get; set; }

        public Course Course { get; set; }
        public Student Student { get; set; }
    }
}
```

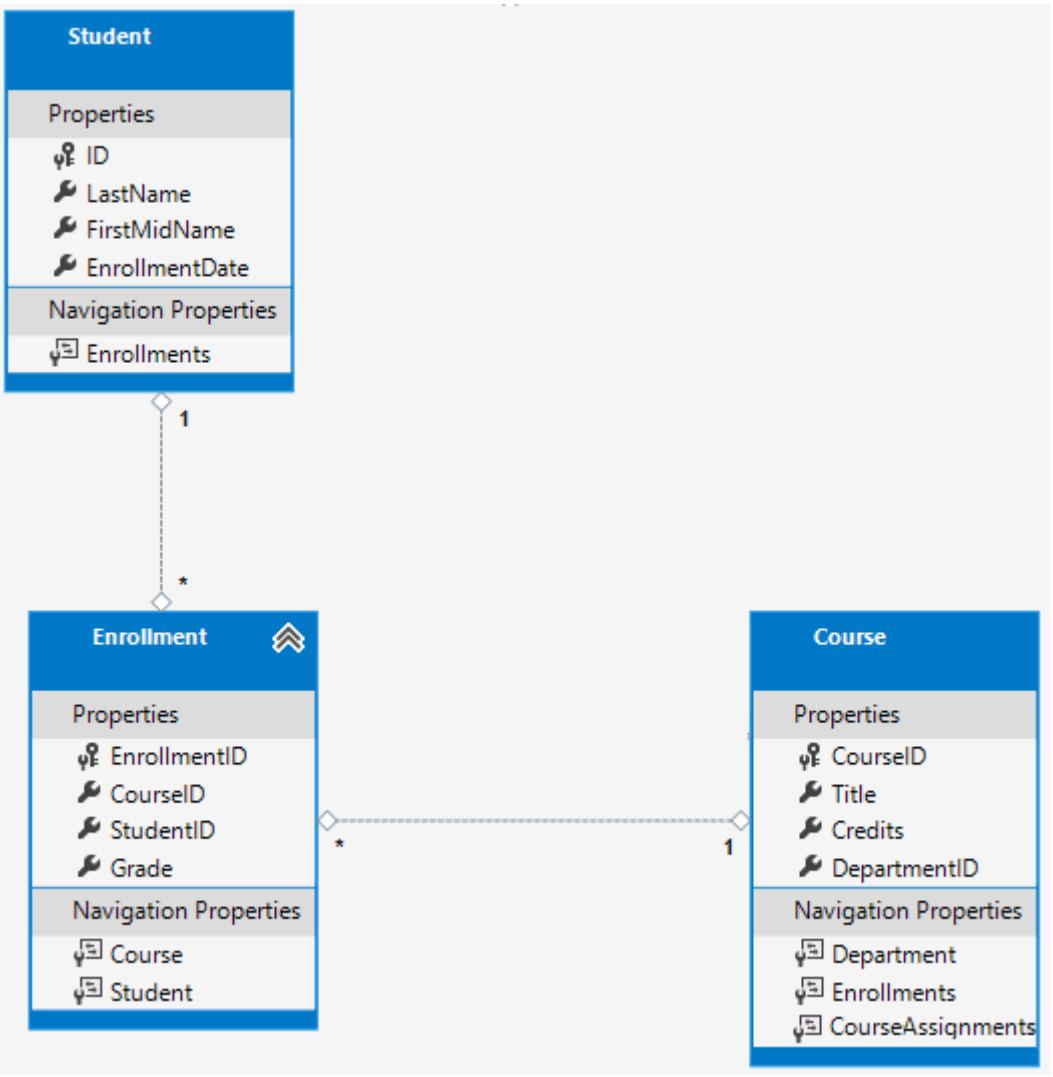
The FK properties and navigation properties reflect the following relationships:

An enrollment record is for one course, so there's a `CourseID` FK property and a `Course` navigation property:

C#

```
public int CourseID { get; set; }
public Course Course { get; set; }
```

An enrollment record is for one student, so there's a `StudentID` FK property and a `Student` navigation property:



C#

```
public int StudentID { get; set; }
public Student Student { get; set; }
```

Many-to-Many Relationships

There's a many-to-many relationship between the `Student` and `Course` entities. The `Enrollment` entity functions as a many-to-many join table ***with payload*** in the database. ***With payload*** means that the `Enrollment` table contains additional data besides FKs for the joined tables. In the `Enrollment` entity, the additional data besides FKs are the PK and `Grade`.

The following illustration shows what these relationships look like in an entity diagram. (This diagram was generated using EF Power Tools for EF 6.x. Creating the diagram isn't part of the tutorial.)

Each relationship line has a 1 at one end and an asterisk (*) at the other, indicating a one-to-many relationship.

If the `Enrollment` table didn't include grade information, it would only need to contain the two FKs, `CourseID` and `StudentID`. A many-to-many join table without payload is sometimes called a pure join table (PJT).

The `Instructor` and `Course` entities have a many-to-many relationship using a PJT.

Update the database context

Update `Data/SchoolContext.cs` with the following code:

C#

```
using ContosoUniversity.Models;
using Microsoft.EntityFrameworkCore;

namespace ContosoUniversity.Data
{
    public class SchoolContext : DbContext
    {
        public SchoolContext(DbContextOptions<SchoolContext> options) :
base(options)
        {
        }

        public DbSet<Course> Courses { get; set; }
        public DbSet<Enrollment> Enrollments { get; set; }
        public DbSet<Student> Students { get; set; }
        public DbSet<Department> Departments { get; set; }
        public DbSet<Instructor> Instructors { get; set; }
        public DbSet<OfficeAssignment> OfficeAssignments { get; set; }

        protected override void OnModelCreating(ModelBuilder modelBuilder)
        {
            modelBuilder.Entity<Course>().ToTable(nameof(Course))
                .HasMany(c => c.Instructors)
                .WithMany(i => i.Courses);
            modelBuilder.Entity<Student>().ToTable(nameof(Student));
            modelBuilder.Entity<Instructor>().ToTable(nameof(Instructor));
        }
    }
}
```

The preceding code adds the new entities and configures the many-to-many relationship between the `Instructor` and `Course` entities.

Fluent API alternative to attributes

The `OnModelCreating` method in the preceding code uses the *fluent API* to configure EF Core behavior. The API is called "fluent" because it's often used by stringing a series of method calls together into a single statement. The following code is an example of the fluent API:

```
C#
```

```
protected override void OnModelCreating(ModelBuilder modelBuilder)
{
    modelBuilder.Entity<Blog>()
        .Property(b => b.Url)
        .IsRequired();
}
```

In this tutorial, the fluent API is used only for database mapping that can't be done with attributes. However, the fluent API can specify most of the formatting, validation, and mapping rules that can be done with attributes.

Some attributes such as `MinimumLength` can't be applied with the fluent API. `MinimumLength` doesn't change the schema, it only applies a minimum length validation rule.

Some developers prefer to use the fluent API exclusively so that they can keep their entity classes *clean*. Attributes and the fluent API can be mixed. There are some configurations that can only be done with the fluent API, for example, specifying a composite PK. There are some configurations that can only be done with attributes (`MinimumLength`). The recommended practice for using fluent API or attributes:

- Choose one of these two approaches.
- Use the chosen approach consistently as much as possible.

Some of the attributes used in this tutorial are used for:

- Validation only (for example, `MinimumLength`).
- EF Core configuration only (for example, `HasKey`).
- Validation and EF Core configuration (for example, `[StringLength(50)]`).

For more information about attributes vs. fluent API, see Methods of configuration.

Seed the database

Update the code in `Data/DbInitializer.cs`:

```
C#
```

```
using ContosoUniversity.Models;
using System;
using System.Collections.Generic;
using System.Linq;

namespace ContosoUniversity.Data
{
    public static class DbInitializer
    {
        public static void Initialize(SchoolContext context)
        {
            // Look for any students.
            if (context.Students.Any())
            {
                return;   // DB has been seeded
            }

            var alexander = new Student
            {

            calculus,
            trigonometry,
            composition,
            literature
        };

        context.AddRange(courses);

        var enrollments = new Enrollment[]
        {
            new Enrollment {
                Student = alexander,
                Course = chemistry,
                Grade = Grade.A
            },
            new Enrollment {
```

```
                    Student = alexander,
                    Course = microeconomics,
                    Grade = Grade.C
                },
                new Enrollment {
                    Student = alexander,
                    Course = macroeconmics,
                    Grade = Grade.B
                },
                new Enrollment {
                    Student = alonso,
                    Course = calculus,
                    Grade = Grade.B
                },
                new Enrollment {
                    Student = alonso,
                    Course = trigonometry,
                    Grade = Grade.B
                },
                new Enrollment {
                    Student = alonso,
                    Course = composition,
                    Grade = Grade.B
                },
                new Enrollment {
                    Student = anand,
                    Course = chemistry
                },
                new Enrollment {
                    Student = anand,
                    Course = microeconomics,
                    Grade = Grade.B
                },
                new Enrollment {
                    Student = barzdukas,
                    Course = chemistry,
                    Grade = Grade.B
                },
                new Enrollment {
                    Student = li,
                    Course = composition,
                    Grade = Grade.B
                },
                new Enrollment {
                    Student = justice,
                    Course = literature,
                    Grade = Grade.B
                }
            };

            context.AddRange(enrollments);
            context.SaveChanges();
        }
    }
}
```

The preceding code provides seed data for the new entities. Most of this code creates new entity objects and loads sample data. The sample data is used for testing.

Apply the migration or drop and re-create

With the existing database, there are two approaches to changing the database:

- Drop and re-create the database. Choose this section when using SQLite.
- Apply the migration to the existing database. The instructions in this section work for SQL Server only, ***not for SQLite***.

Either choice works for SQL Server. While the apply-migration method is more complex and time-consuming, it's the preferred approach for real-world, production environments.

Drop and re-create the database

To force EF Core to create a new database, drop and update the database:

Visual Studio

- Delete the *Migrations* folder.
- In the **Package Manager Console** (PMC), run the following commands:

PowerShell

```
Drop-Database
Add-Migration InitialCreate
Update-Database
```

Run the app. Running the app runs the `DbInitializer.Initialize` method. The `DbInitializer.Initialize` populates the new database.

Visual Studio

Open the database in SSOX:

- If SSOX was opened previously, click the **Refresh** button.
- Expand the **Tables** node. The created tables are displayed.

Next steps

The next two tutorials show how to read and update related data.

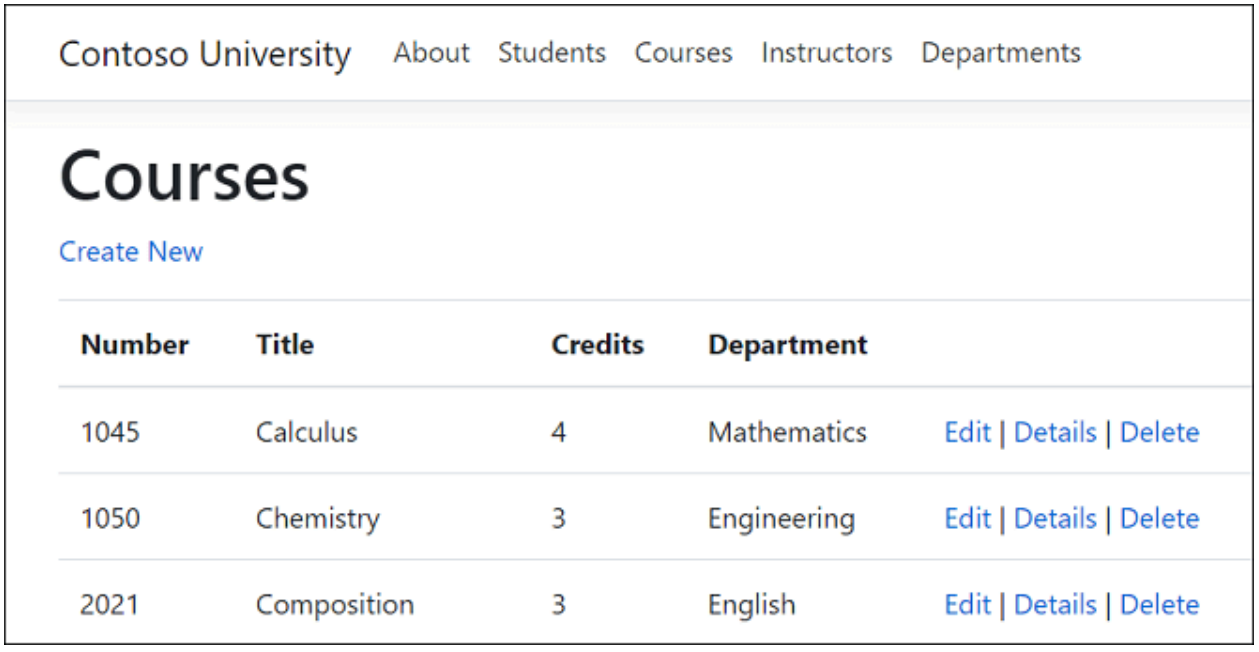
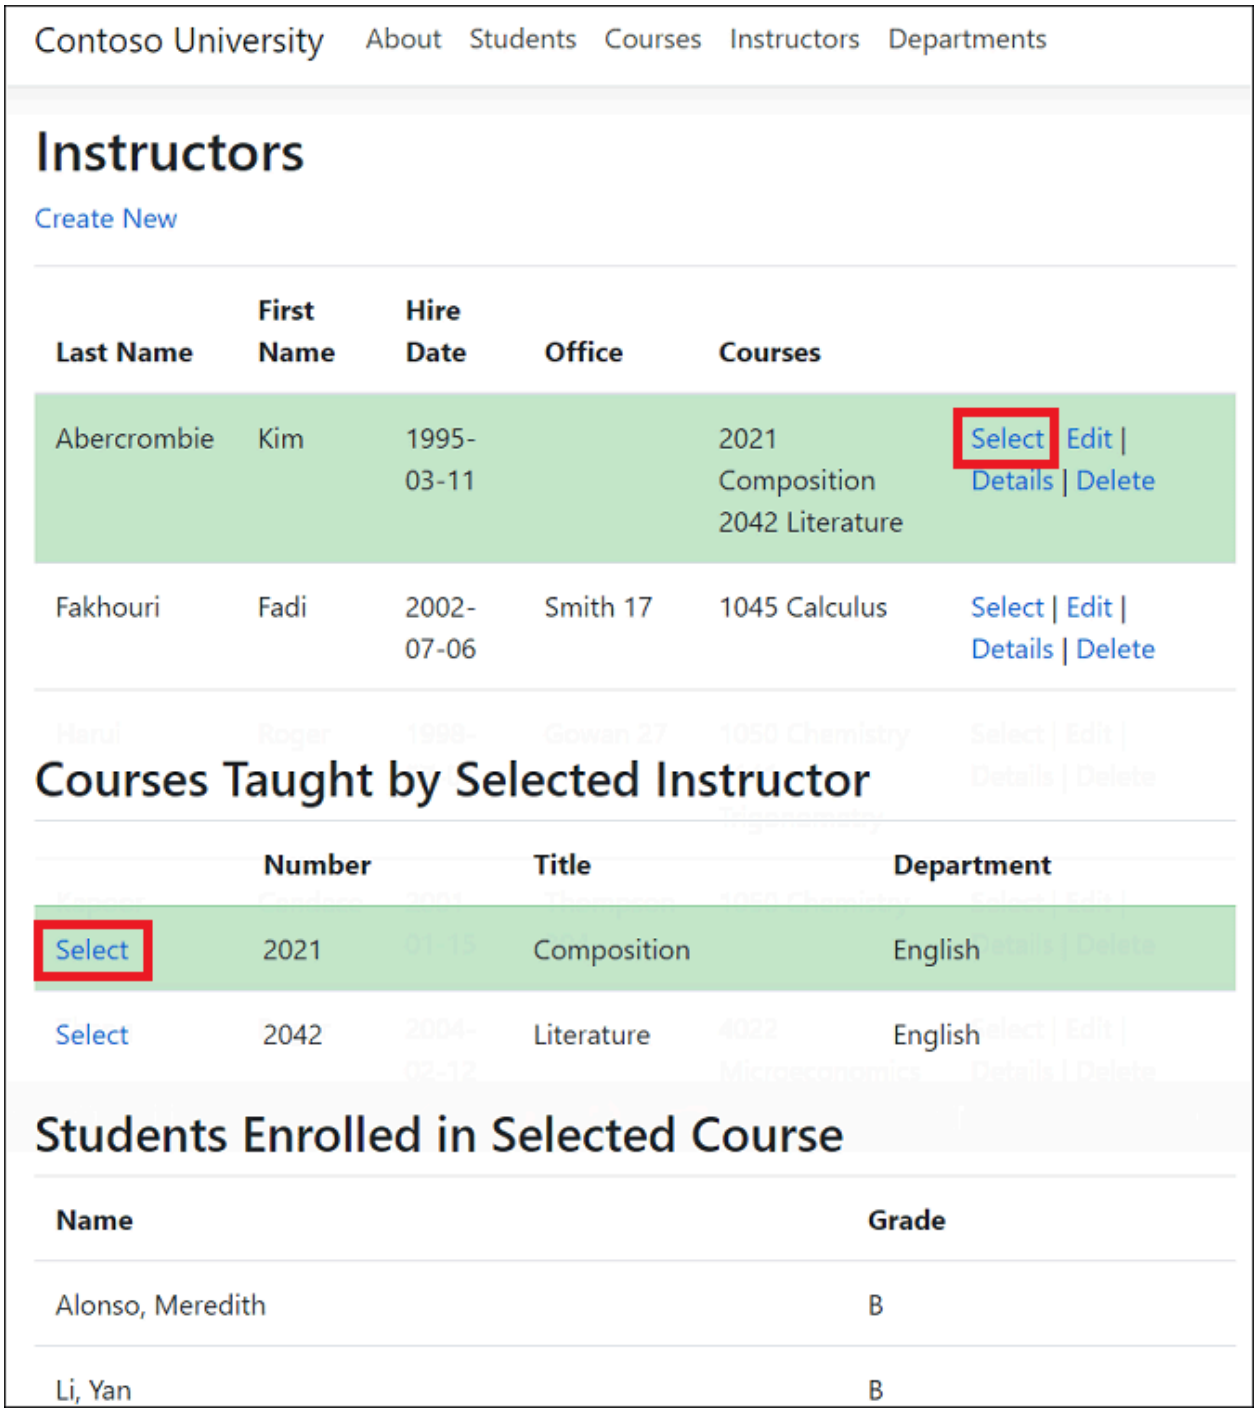
Part 6, Razor Pages with EF Core in ASP.NET Core - Read Related Data

Article • 04/10/2024



By Tom Dykstra, Jon P Smith, and Rick Anderson



The Contoso University web app demonstrates how to create Razor Pages web apps using EF Core and Visual Studio. For information about the tutorial series, see the first tutorial.

If you run into problems you can't solve, download the completed app and compare that code to what you created by following the tutorial.

This tutorial shows how to read and display related data. Related data is data that EF Core loads into navigation properties.

The following illustrations show the completed pages for this tutorial:

Eager, explicit, and lazy loading

There are several ways that EF Core can load related data into the navigation properties of an entity:

- Eager loading. Eager loading is when a query for one type of entity also loads related entities. When an entity is read, its related data is retrieved. This typically results in a single join query that retrieves all of the data that's needed. EF Core will issue multiple queries for some types of eager loading. Issuing multiple queries can be more efficient than a large single query. Eager loading is specified with the Include and ThenInclude methods.

```
var departments = _context.Departments.Include(d => d.Courses);
foreach (Department d in departments)
{
    foreach(Course c in d.Courses)
    {
        courseList.Add(d.Name + c.Title);
    }
}
```

Query: all Department entities and related Course entities

Eager loading sends multiple queries when a collection navigation is included:

- One query for the main query
- One query for each collection "edge" in the load tree.

- Separate queries with `Load`: The data can be retrieved in separate queries, and EF Core "fixes up" the navigation properties. "Fixes up" means that EF Core automatically populates the navigation properties. Separate queries with `Load` is more like explicit loading than eager loading.

```
var departments = _context.Departments;
foreach (Department d in departments)
{
    _context.Courses.Where(c => c.DepartmentID == d.DepartmentID).Load();
    foreach (Course c in d.Courses)
    {
        courseList.Add(d.Name + c.Title);
    }
}
```

Query: all Department rows

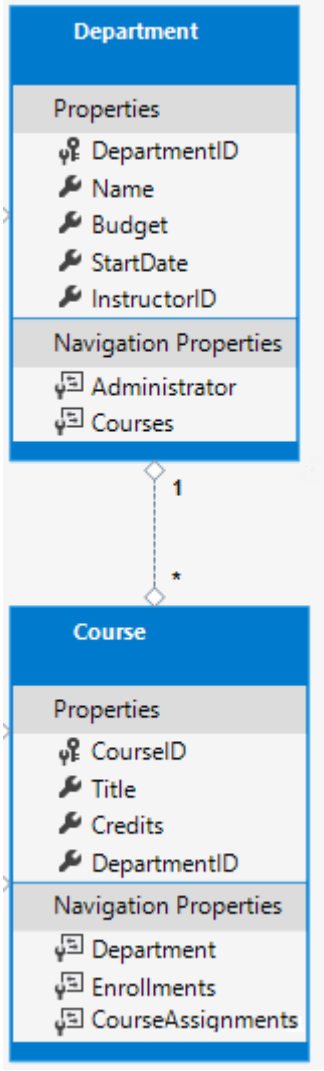
Query: Course rows related to Department d

Note: EF Core automatically fixes up navigation properties to any other entities that were previously loaded into the context instance. Even if the data for a navigation property is *not* explicitly included, the property may still be populated if some or all of the related entities were previously loaded.

- Explicit loading. When the entity is first read, related data isn't retrieved. Code must be written to retrieve the related data when it's needed. Explicit loading with separate queries results in multiple queries sent to the database. With explicit loading, the code specifies the navigation properties to be loaded. Use the `Load` method to do explicit loading. For example:

```
var departments = _context.Departments;
foreach (Department d in departments)
{
    _context.Entry(d).Collection(p => p.Courses).Load();
    foreach (Course c in d.Courses)
    {
        courseList.Add(d.Name + c.Title);
    }
}
```

Query: all Department rows



Query: Course rows related to Department d

- Lazy loading. When the entity is first read, related data isn't retrieved. The first time a navigation property is accessed, the data required for that navigation property is automatically retrieved. A query is sent to the database each time a navigation property is accessed for the first time. Lazy loading can hurt performance, for

example when developers use N+1 queries. N+1 queries load a parent and enumerate through children.

Create Course pages

The `Course` entity includes a navigation property that contains the related `Department` entity.

To display the name of the assigned department for a course:

- Load the related `Department` entity into the `Course.Department` navigation property.
- Get the name from the `Department` entity's `Name` property.

Scaffold Course pages

Visual Studio

- Follow the instructions in Scaffold Student pages with the following exceptions:
  - Create a *Pages/Courses* folder.
  - Use `Course` for the model class.
  - Use the existing context class instead of creating a new one.

- Open `Pages/Courses/Index.cshtml.cs` and examine the `OnGetAsync` method. The scaffolding engine specified eager loading for the `Department` navigation property. The `Include` method specifies eager loading.

- Run the app and select the **Courses** link. The department column displays the `DepartmentID`, which isn't useful.

Display the department name

Update Pages/Courses/Index.cshtml.cs with the following code:

C#

```
using ContosoUniversity.Models;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.EntityFrameworkCore;
using System.Collections.Generic;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Courses
{
    public class IndexModel : PageModel
    {
        private readonly ContosoUniversity.Data.SchoolContext _context;

        public IndexModel(ContosoUniversity.Data.SchoolContext context)
        {
            _context = context;
        }

        public IList<Course> Courses { get; set; }

        public async Task OnGetAsync()
        {
            Courses = await _context.Courses
                .Include(c => c.Department)
                .AsNoTracking()
                .ToListAsync();
        }
```

```
    }
}
```

The preceding code changes the `Course` property to `Courses` and adds `AsNoTracking`.

No-tracking queries are useful when the results are used in a read-only scenario. They're generally quicker to execute because there's no need to set up the change tracking information. If the entities retrieved from the database don't need to be updated, then a no-tracking query is likely to perform better than a tracking query.

In some cases a tracking query is more efficient than a no-tracking query. For more information, see Tracking vs. No-Tracking Queries. In the preceding code, `AsNoTracking` is called because the entities aren't updated in the current context.

Update `Pages/Courses/Index.cshtml` with the following code.

CSHTML

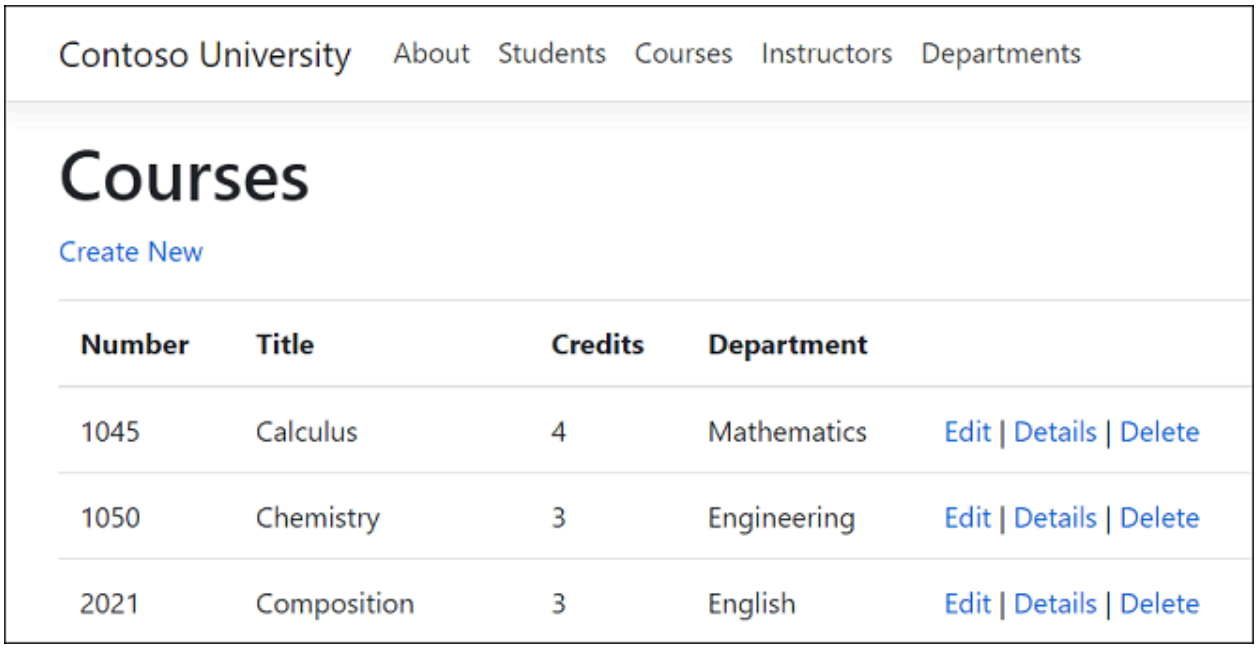
```
@page
@model ContosoUniversity.Pages.Courses.IndexModel

@{
    ViewData["Title"] = "Courses";
}

<h1>Courses</h1>

<p>
    <a asp-page="Create">Create New</a>
</p>
<table class="table">
    <thead>
        <tr>
            <th>
                @Html.DisplayNameFor(model => model.Courses[0].CourseID)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Courses[0].Title)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Courses[0].Credits)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Courses[0].Department)
            </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
@foreach (var item in Model.Courses)
{
```

```
        <tr>
            <td>
                @Html.DisplayFor(modelItem => item.CourseID)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Title)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Credits)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Department.Name)
            </td>
            <td>
                <a asp-page="./Edit" asp-route-id="@item.CourseID">Edit</a>
|
                <a asp-page="./Details" asp-route-
id="@item.CourseID">Details</a> |
                <a asp-page="./Delete" asp-route-
id="@item.CourseID">Delete</a>
            </td>
        </tr>
}
    </tbody>
</table>
```



The following changes have been made to the scaffolded code:

- Changed the `Course` property name to `Courses`.
- Added a **Number** column that shows the `CourseID` property value. By default, primary keys aren't scaffolded because normally they're meaningless to end users. However, in this case the primary key is meaningful.
- Changed the **Department** column to display the department name. The code displays the `Name` property of the `Department` entity that's loaded into the `Department` navigation property:

  HTML

  ```
  @Html.DisplayFor(modelItem => item.Department.Name)
  ```

Run the app and select the **Courses** tab to see the list with department names.

Loading related data with Select

The `OnGetAsync` method loads related data with the `Include` method. The `Select` method is an alternative that loads only the related data needed. For single items, like the `Department.Name` it uses a `SQL INNER JOIN`. For collections, it uses another database access, but so does the `Include` operator on collections.

The following code loads related data with the `Select` method:

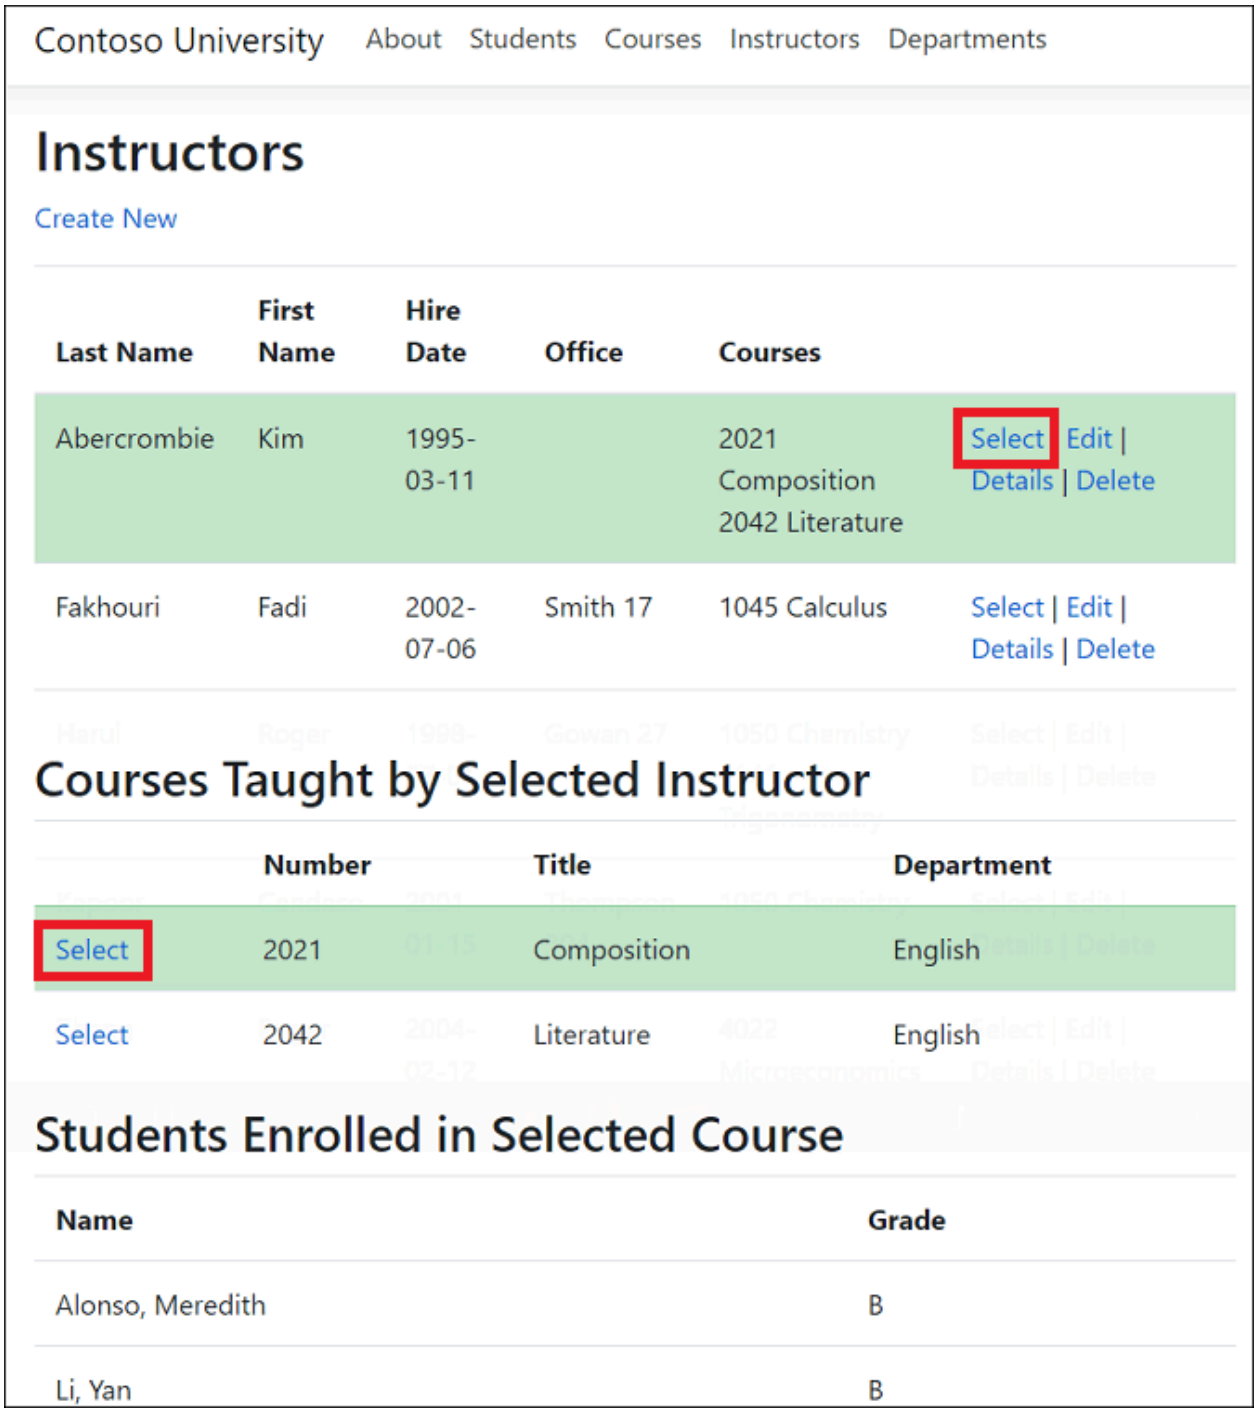
C#

```
public IList<CourseViewModel> CourseVM { get; set; }

public async Task OnGetAsync()
{
    CourseVM = await _context.Courses
    .Select(p => new CourseViewModel
    {
        CourseID = p.CourseID,
        Title = p.Title,
        Credits = p.Credits,
        DepartmentName = p.Department.Name
    }).ToListAsync();
}
```

The preceding code doesn't return any entity types, therefore no tracking is done. For more information about the EF tracking, see Tracking vs. No-Tracking Queries.

The `CourseViewModel`:



C#

```
public class CourseViewModel
{
    public int CourseID { get; set; }
    public string Title { get; set; }
    public int Credits { get; set; }
    public string DepartmentName { get; set; }
}
```

See IndexSelectModel for the complete Razor Pages.

Create Instructor pages

This section scaffolds Instructor pages and adds related Courses and Enrollments to the Instructors Index page.

This page reads and displays related data in the following ways:

- The list of instructors displays related data from the `OfficeAssignment` entity (Office in the preceding image). The `Instructor` and `OfficeAssignment` entities are in a one-to-zero-or-one relationship. Eager loading is used for the `OfficeAssignment` entities. Eager loading is typically more efficient when the related data needs to be displayed. In this case, office assignments for the instructors are displayed.
- When the user selects an instructor, related `Course` entities are displayed. The `Instructor` and `Course` entities are in a many-to-many relationship. Eager loading is used for the `Course` entities and their related `Department` entities. In this case, separate queries might be more efficient because only courses for the selected

instructor are needed. This example shows how to use eager loading for navigation properties in entities that are in navigation properties.

- When the user selects a course, related data from the `Enrollments` entity is displayed. In the preceding image, student name and grade are displayed. The `Course` and `Enrollment` entities are in a one-to-many relationship.

Create a view model

The instructors page shows data from three different tables. A view model is needed that includes three properties representing the three tables.

Create `Models/SchoolViewModels/InstructorIndexData.cs` with the following code:

C#

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;

namespace ContosoUniversity.Models.SchoolViewModels
{
    public class InstructorIndexData
    {
        public IEnumerable<Instructor> Instructors { get; set; }
        public IEnumerable<Course> Courses { get; set; }
        public IEnumerable<Enrollment> Enrollments { get; set; }
    }
}
```

Scaffold Instructor pages

Visual Studio

- Follow the instructions in Scaffold the student pages with the following exceptions:
  - Create a *Pages/Instructors* folder.
  - Use `Instructor` for the model class.
  - Use the existing context class instead of creating a new one.

Run the app and navigate to the Instructors page.

Update `Pages/Instructors/Index.cshtml.cs` with the following code:

C#

```
using ContosoUniversity.Models;
using ContosoUniversity.Models.SchoolViewModels;  // Add VM
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.EntityFrameworkCore;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Instructors
{
    public class IndexModel : PageModel
    {
        private readonly ContosoUniversity.Data.SchoolContext _context;

        public IndexModel(ContosoUniversity.Data.SchoolContext context)
        {
            _context = context;
        }

        public InstructorIndexData InstructorData { get; set; }
        public int InstructorID { get; set; }
        public int CourseID { get; set; }

        public async Task OnGetAsync(int? id, int? courseID)
        {
            InstructorData = new InstructorIndexData();
            InstructorData.Instructors = await _context.Instructors
                .Include(i => i.OfficeAssignment)
                .Include(i => i.Courses)
                    .ThenInclude(c => c.Department)
                .OrderBy(i => i.LastName)
                .ToListAsync();

            if (id != null)
            {
                InstructorID = id.Value;
                Instructor instructor = InstructorData.Instructors
                    .Where(i => i.ID == id.Value).Single();
                InstructorData.Courses = instructor.Courses;
            }

            if (courseID != null)
            {
                CourseID = courseID.Value;
                IEnumerable<Enrollment> Enrollments = await
_context.Enrollments
                    .Where(x => x.CourseID == CourseID)
                    .Include(i=>i.Student)
                    .ToListAsync();
                InstructorData.Enrollments = Enrollments;
```

```
            }
        }
    }
}
```

The `OnGetAsync` method accepts optional route data for the ID of the selected instructor.

Examine the query in the `Pages/Instructors/Index.cshtml.cs` file:

C#

```
InstructorData = new InstructorIndexData();
InstructorData.Instructors = await _context.Instructors
    .Include(i => i.OfficeAssignment)
    .Include(i => i.Courses)
        .ThenInclude(c => c.Department)
    .OrderBy(i => i.LastName)
    .ToListAsync();
```

The code specifies eager loading for the following navigation properties:

- `Instructor.OfficeAssignment`
- `Instructor.Courses`
  - `Course.Department`

The following code executes when an instructor is selected, that is, `id != null`.

C#

```
if (id != null)
{
    InstructorID = id.Value;
    Instructor instructor = InstructorData.Instructors
        .Where(i => i.ID == id.Value).Single();
    InstructorData.Courses = instructor.Courses;
}
```

The selected instructor is retrieved from the list of instructors in the view model. The view model's `Courses` property is loaded with the `Course` entities from the selected instructor's `Courses` navigation property.

The `Where` method returns a collection. In this case, the filter select a single entity, so the `Single` method is called to convert the collection into a single `Instructor` entity. The `Instructor` entity provides access to the `Course` navigation property.

The Single method is used on a collection when the collection has only one item. The `Single` method throws an exception if the collection is empty or if there's more than one item. An alternative is SingleOrDefault, which returns a default value if the collection is empty. For this query, `null` in the default returned.

The following code populates the view model's `Enrollments` property when a course is selected:

C#

```
if (courseID != null)
{
    CourseID = courseID.Value;
    IEnumerable<Enrollment> Enrollments = await _context.Enrollments
        .Where(x => x.CourseID == CourseID)
        .Include(i=>i.Student)
        .ToListAsync();
    InstructorData.Enrollments = Enrollments;
}
```

Update the instructors Index page

Update `Pages/Instructors/Index.cshtml` with the following code.

CSHTML

```
@page "{id:int?}"
@model ContosoUniversity.Pages.Instructors.IndexModel

@{
    ViewData["Title"] = "Instructors";
}

<h2>Instructors</h2>

<p>
    <a asp-page="Create">Create New</a>
</p>
<table class="table">
    <thead>
        <tr>
            <th>Last Name</th>
            <th>First Name</th>
            <th>Hire Date</th>
            <th>Office</th>
            <th>Courses</th>
            <th></th>
        </tr>
    </thead>
```

```
    <tbody>
        @foreach (var item in Model.InstructorData.Instructors)
        {
            string selectedRow = "";
            if (item.ID == Model.InstructorID)
            {
                selectedRow = "table-success";
            }
            <tr class="@selectedRow">
                <td>
                    @Html.DisplayFor(modelItem => item.LastName)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.FirstMidName)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.HireDate)
                </td>
                <td>
                    @if (item.OfficeAssignment != null)
                    {
                        @item.OfficeAssignment.Location
                    }
                </td>
                <td>
                    @{
                        foreach (var course in item.Courses)
                        {
                            @course.CourseID @:  @course.Title <br />
                        }
                    }
                </td>
                <td>
                    <a asp-page="./Index" asp-route-id="@item.ID">Select</a>
|
                    <a asp-page="./Edit" asp-route-id="@item.ID">Edit</a> |
                    <a asp-page="./Details" asp-route-
id="@item.ID">Details</a> |
                    <a asp-page="./Delete" asp-route-
id="@item.ID">Delete</a>
                </td>
            </tr>
        }
    </tbody>
</table>

@if (Model.InstructorData.Courses != null)
{
    <h3>Courses Taught by Selected Instructor</h3>
    <table class="table">
        <tr>
            <th></th>
            <th>Number</th>
            <th>Title</th>
            <th>Department</th>
```

```
        </tr>

        @foreach (var item in Model.InstructorData.Courses)
        {
            string selectedRow = "";
            if (item.CourseID == Model.CourseID)
            {
                selectedRow = "table-success";
            }
            <tr class="@selectedRow">
                <td>
                    <a asp-page="./Index" asp-route-
courseID="@item.CourseID">Select</a>
                </td>
                <td>
                    @item.CourseID
                </td>
                <td>
                    @item.Title
                </td>
                <td>
                    @item.Department.Name
                </td>
            </tr>
        }

    </table>
}

@if (Model.InstructorData.Enrollments != null)
{
    <h3>
        Students Enrolled in Selected Course
    </h3>
    <table class="table">
        <tr>
            <th>Name</th>
            <th>Grade</th>
        </tr>
        @foreach (var item in Model.InstructorData.Enrollments)
        {
            <tr>
                <td>
                    @item.Student.FullName
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Grade)
                </td>
            </tr>
        }
    </table>
}
```

The preceding code makes the following changes:

- Updates the `page` directive to `@page "{id:int?}"`. `"{id:int?}"` is a route template. The route template changes integer query strings in the URL to route data. For example, clicking on the **Select** link for an instructor with only the `@page` directive produces a URL like the following:

  `https://localhost:5001/Instructors?id=2`

  When the page directive is `@page "{id:int?}"`, the URL is: `https://localhost:5001/Instructors/2`

- Adds an **Office** column that displays `item.OfficeAssignment.Location` only if `item.OfficeAssignment` isn't null. Because this is a one-to-zero-or-one relationship, there might not be a related OfficeAssignment entity.

  HTML

  ```
  @if (item.OfficeAssignment != null)
  {
      @item.OfficeAssignment.Location
  }
  ```

- Adds a **Courses** column that displays courses taught by each instructor. See Explicit line transition for more about this razor syntax.

- Adds code that dynamically adds `class="table-success"` to the `tr` element of the selected instructor and course. This sets a background color for the selected row using a Bootstrap class.

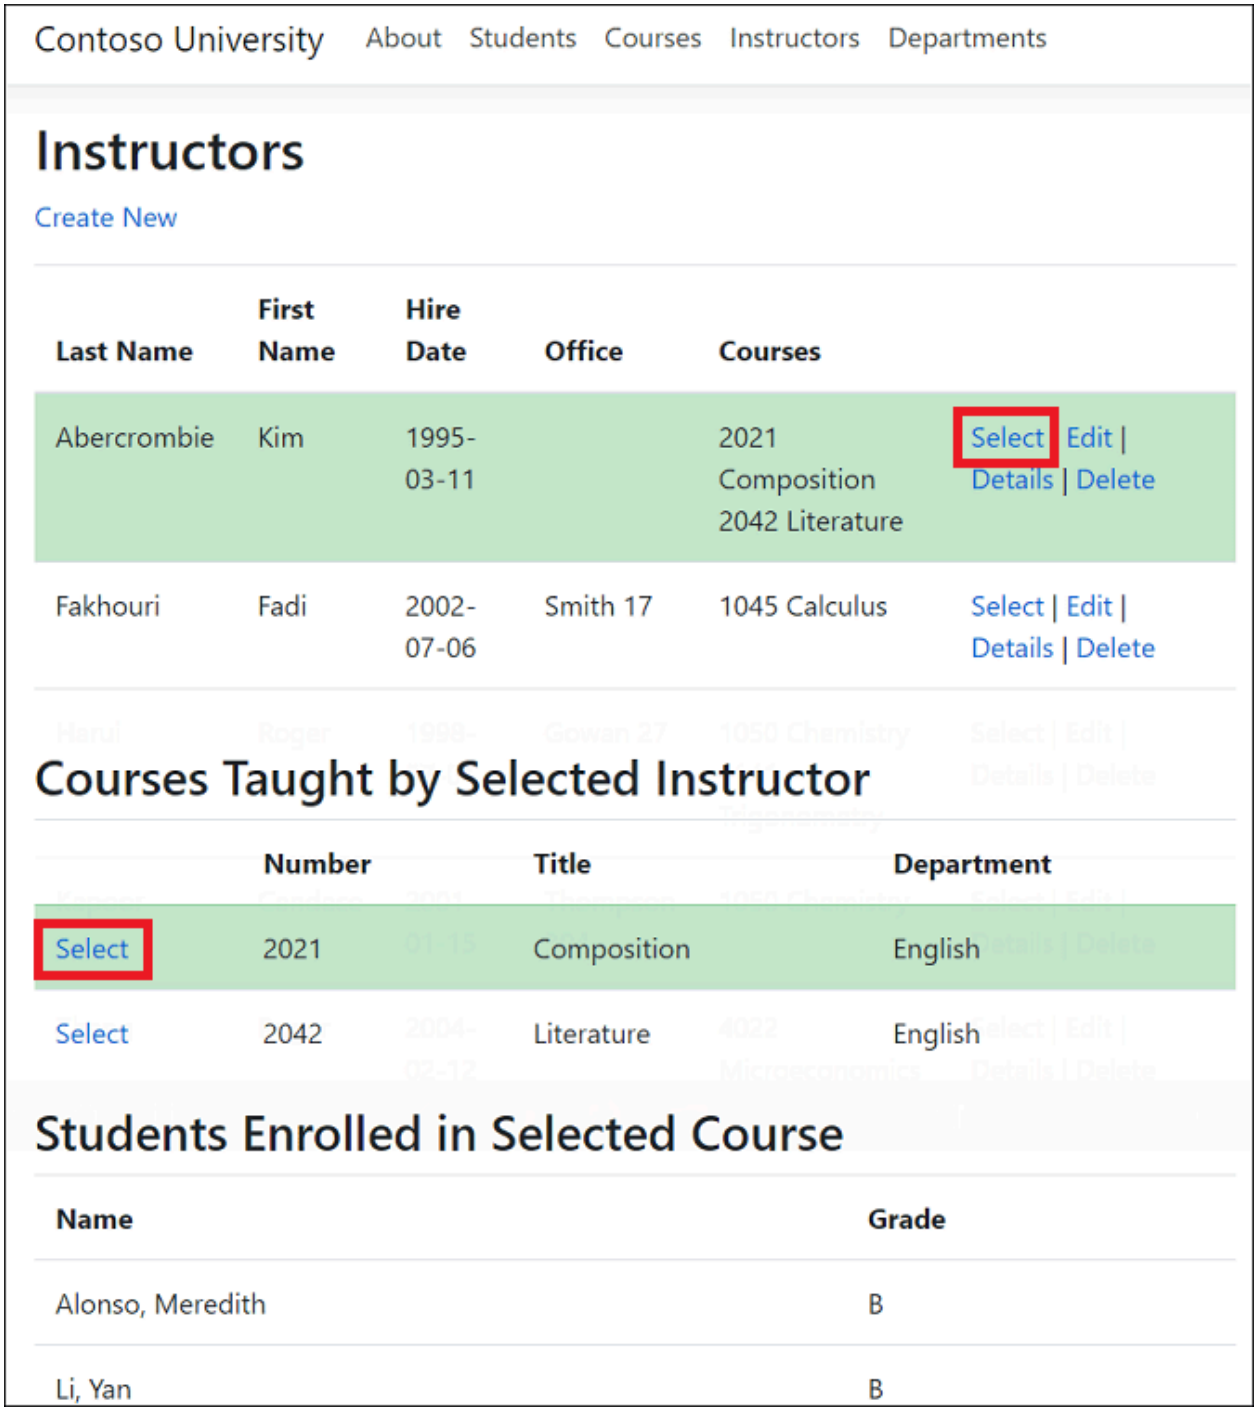
  HTML

  ```
  string selectedRow = "";
  if (item.CourseID == Model.CourseID)
  {
      selectedRow = "table-success";
  }
  <tr class="@selectedRow">
  ```

- Adds a new hyperlink labeled **Select**. This link sends the selected instructor's ID to the `Index` method and sets a background color.

  HTML

  ```
  <a asp-action="Index" asp-route-id="@item.ID">Select</a> |
  ```



- Adds a table of courses for the selected Instructor.

- Adds a table of student enrollments for the selected course.

Run the app and select the **Instructors** tab. The page displays the `Location` (office) from the related `OfficeAssignment` entity. If `OfficeAssignment` is null, an empty table cell is displayed.

Click on the **Select** link for an instructor. The row style changes and courses assigned to that instructor are displayed.

Select a course to see the list of enrolled students and their grades.

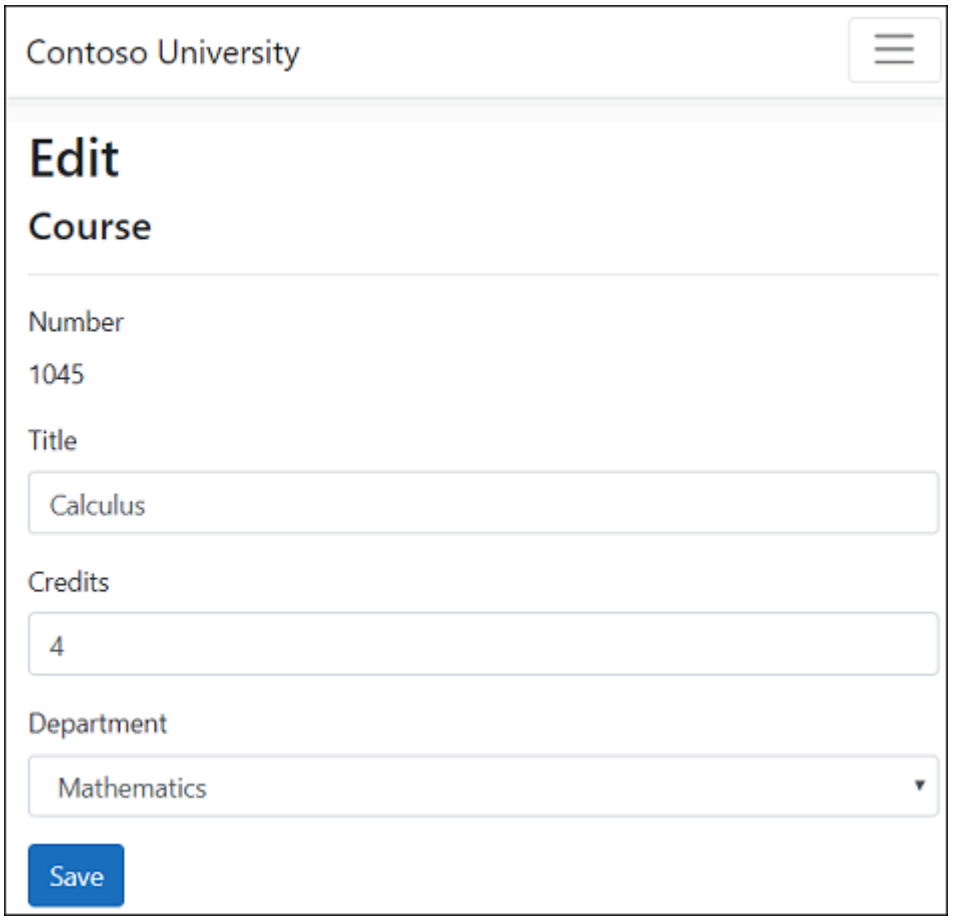
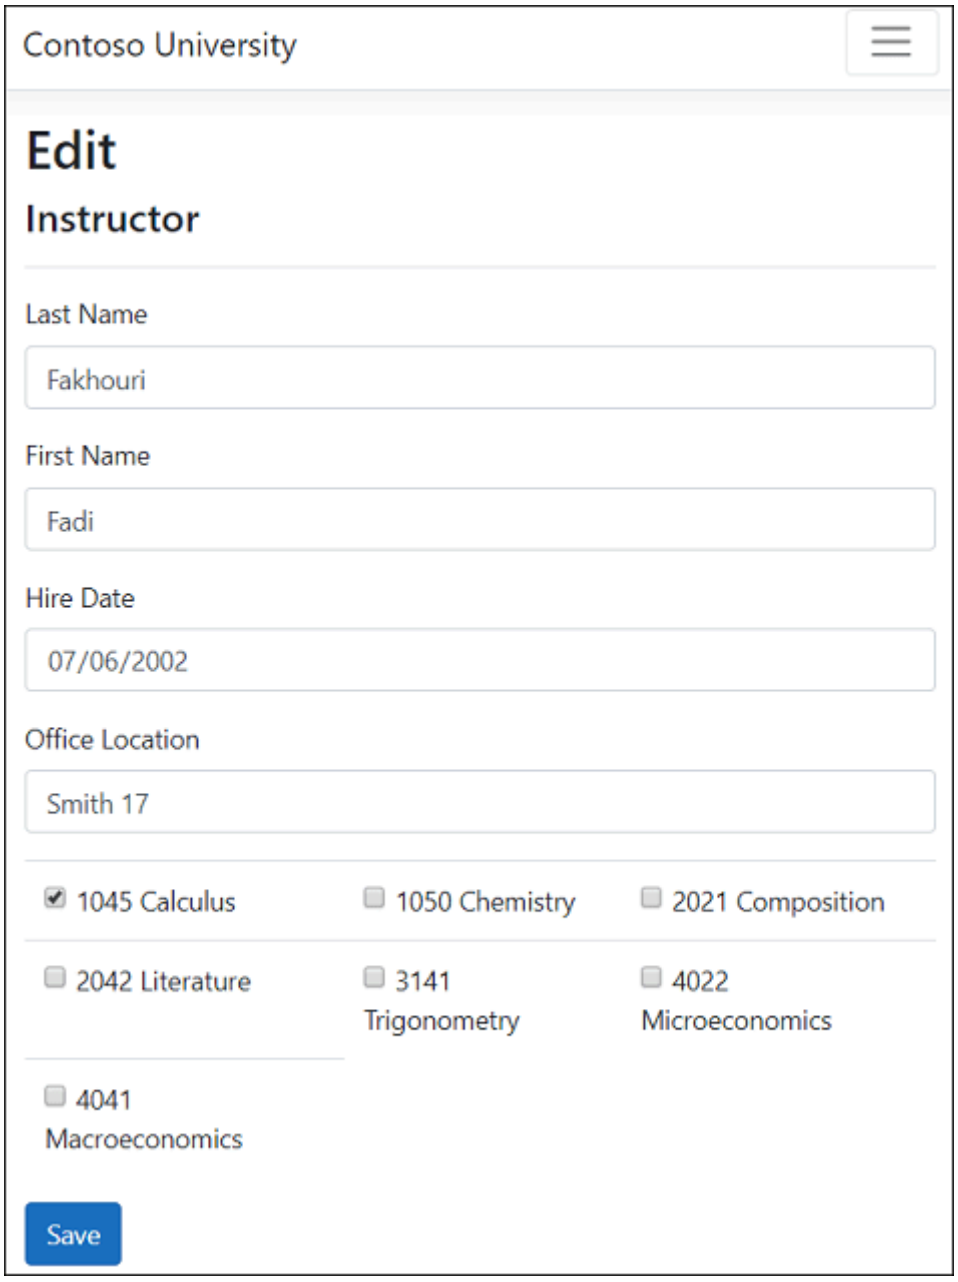
Part 7, Razor Pages with EF Core in ASP.NET Core - Update Related Data



Article • 04/10/2024



By Tom Dykstra, Jon P Smith, and Rick Anderson

The Contoso University web app demonstrates how to create Razor Pages web apps using EF Core and Visual Studio. For information about the tutorial series, see the first tutorial.

If you run into problems you can't solve, download the completed app and compare that code to what you created by following the tutorial.

This tutorial shows how to update related data. The following illustrations show some of the completed pages.

Update the Course Create and Edit pages

The scaffolded code for the Course Create and Edit pages has a Department drop-down list that shows `DepartmentID`, an `int`. The drop-down should show the Department name, so both of these pages need a list of department names. To provide that list, use a base class for the Create and Edit pages.

Create a base class for Course Create and Edit

Create a `Pages/Courses/DepartmentNamePageModel.cs` file with the following code:

```
C#

using ContosoUniversity.Data;
using ContosoUniversity.Models;
```

```
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.AspNetCore.Mvc.Rendering;
using Microsoft.EntityFrameworkCore;
using System.Linq;

namespace ContosoUniversity.Pages.Courses
{
    public class DepartmentNamePageModel : PageModel
    {
        public SelectList DepartmentNameSL { get; set; }

        public void PopulateDepartmentsDropDownList(SchoolContext _context,
            object selectedDepartment = null)
        {
            var departmentsQuery = from d in _context.Departments
                                   orderby d.Name // Sort by name.
                                   select d;

            DepartmentNameSL = new
SelectList(departmentsQuery.AsNoTracking(),
                nameof(Department.DepartmentID),
                nameof(Department.Name),
                selectedDepartment);
        }
    }
}
```

The preceding code creates a SelectList to contain the list of department names. If `selectedDepartment` is specified, that department is selected in the `SelectList`.

The Create and Edit page model classes will derive from `DepartmentNamePageModel`.

Update the Course Create page model

A Course is assigned to a Department. The base class for the Create and Edit pages provides a `SelectList` for selecting the department. The drop-down list that uses the `SelectList` sets the `Course.DepartmentID` foreign key (FK) property. EF Core uses the `Course.DepartmentID` FK to load the `Department` navigation property.

Update `Pages/Courses/Create.cshtml.cs` with the following code:

C#

```
using ContosoUniversity.Models;
using Microsoft.AspNetCore.Mvc;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Courses
{
    public class CreateModel : DepartmentNamePageModel
    {
        private readonly ContosoUniversity.Data.SchoolContext _context;

        public CreateModel(ContosoUniversity.Data.SchoolContext context)
        {
            _context = context;
        }

        public IActionResult OnGet()
```

```
        {
            PopulateDepartmentsDropDownList(_context);
            return Page();
        }

        [BindProperty]
        public Course Course { get; set; }

        public async Task<IActionResult> OnPostAsync()
        {
            var emptyCourse = new Course();

            if (await TryUpdateModelAsync<Course>(
                 emptyCourse,
                 "course",   // Prefix for form value.
                 s => s.CourseID, s => s.DepartmentID, s => s.Title, s =>
s.Credits))
            {
                _context.Courses.Add(emptyCourse);
                await _context.SaveChangesAsync();
                return RedirectToPage("./Index");
            }

            // Select DepartmentID if TryUpdateModelAsync fails.
            PopulateDepartmentsDropDownList(_context,
emptyCourse.DepartmentID);
            return Page();
        }
    }
}
```

If you would like to see code comments translated to languages other than English, let us know in this GitHub discussion issue.

The preceding code:

- Derives from `DepartmentNamePageModel`.
- Uses TryUpdateModelAsync to prevent overposting.
- Removes `ViewData["DepartmentID"]`. The `DepartmentNameSL` `SelectList` is a strongly typed model and will be used by the Razor page. Strongly typed models are preferred over weakly typed. For more information, see Weakly typed data (ViewData and ViewBag).

Update the Course Create Razor page

Update `Pages/Courses/Create.cshtml` with the following code:

CSHTML

```
@page
@model ContosoUniversity.Pages.Courses.CreateModel
@{
    ViewData["Title"] = "Create Course";
}
<h2>Create</h2>
<h4>Course</h4>
<hr />
<div class="row">
    <div class="col-md-4">
        <form method="post">
            <div asp-validation-summary="ModelOnly" class="text-danger">
</div>
            <div class="form-group">
                <label asp-for="Course.CourseID" class="control-label">
</label>
                <input asp-for="Course.CourseID" class="form-control" />
                <span asp-validation-for="Course.CourseID" class="text-
danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Course.Title" class="control-label"></label>
                <input asp-for="Course.Title" class="form-control" />
                <span asp-validation-for="Course.Title" class="text-danger">
</span>
            </div>
            <div class="form-group">
                <label asp-for="Course.Credits" class="control-label">
</label>
                <input asp-for="Course.Credits" class="form-control" />
                <span asp-validation-for="Course.Credits" class="text-
danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Course.Department" class="control-label">
</label>
                <select asp-for="Course.DepartmentID" class="form-control"
                        asp-items="@Model.DepartmentNameSL">
                    <option value="">-- Select Department --</option>
                </select>
                <span asp-validation-for="Course.DepartmentID" class="text-
danger" />
            </div>
            <div class="form-group">
                <input type="submit" value="Create" class="btn btn-primary"
/>
            </div>
        </form>
    </div>
</div>
<div>
    <a asp-page="Index">Back to List</a>
</div>
@section Scripts {
```

```
    @{await Html.RenderPartialAsync("_ValidationScriptsPartial");}
}
```

The preceding code makes the following changes:

- Changes the caption from **DepartmentID** to **Department**.
- Replaces `"ViewBag.DepartmentID"` with `DepartmentNameSL` (from the base class).
- Adds the "Select Department" option. This change renders "Select Department" in the drop-down when no department has been selected yet, rather than the first department.
- Adds a validation message when the department isn't selected.

The Razor Page uses the Select Tag Helper:

CSHTML

```
<div class="form-group">
    <label asp-for="Course.Department" class="control-label"></label>
    <select asp-for="Course.DepartmentID" class="form-control"
            asp-items="@Model.DepartmentNameSL">
        <option value="">-- Select Department --</option>
    </select>
    <span asp-validation-for="Course.DepartmentID" class="text-danger" />
</div>
```

Test the Create page. The Create page displays the department name rather than the department ID.

Update the Course Edit page model

Update `Pages/Courses/Edit.cshtml.cs` with the following code:

C#

```
using ContosoUniversity.Models;
using Microsoft.AspNetCore.Mvc;
using Microsoft.EntityFrameworkCore;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Courses
{
    public class EditModel : DepartmentNamePageModel
    {
        private readonly ContosoUniversity.Data.SchoolContext _context;

        public EditModel(ContosoUniversity.Data.SchoolContext context)
        {
```

```
            _context = context;
        }

        [BindProperty]
        public Course Course { get; set; }

        public async Task<IActionResult> OnGetAsync(int? id)
        {
            if (id == null)
            {
                return NotFound();
            }

            Course = await _context.Courses
                .Include(c => c.Department).FirstOrDefaultAsync(m =>
m.CourseID == id);

            if (Course == null)
            {
                return NotFound();
            }

            // Select current DepartmentID.
            PopulateDepartmentsDropDownList(_context, Course.DepartmentID);
            return Page();
        }

        public async Task<IActionResult> OnPostAsync(int? id)
        {
            if (id == null)
            {
                return NotFound();
            }

            var courseToUpdate = await _context.Courses.FindAsync(id);

            if (courseToUpdate == null)
            {
                return NotFound();
            }

            if (await TryUpdateModelAsync<Course>(
                 courseToUpdate,
                 "course",   // Prefix for form value.
                   c => c.Credits, c => c.DepartmentID, c => c.Title))
            {
                await _context.SaveChangesAsync();
                return RedirectToPage("./Index");
            }

            // Select DepartmentID if TryUpdateModelAsync fails.
            PopulateDepartmentsDropDownList(_context,
courseToUpdate.DepartmentID);
            return Page();
        }
```

```
    }
}
```

The changes are similar to those made in the Create page model. In the preceding code, `PopulateDepartmentsDropDownList` passes in the department ID, which selects that department in the drop-down list.

Update the Course Edit Razor page

Update `Pages/Courses/Edit.cshtml` with the following code:

CSHTML

```
@page
@model ContosoUniversity.Pages.Courses.EditModel

@{
    ViewData["Title"] = "Edit";
}

<h2>Edit</h2>

<h4>Course</h4>
<hr />
<div class="row">
    <div class="col-md-4">
        <form method="post">
            <div asp-validation-summary="ModelOnly" class="text-danger">
</div>
            <input type="hidden" asp-for="Course.CourseID" />
            <div class="form-group">
                <label asp-for="Course.CourseID" class="control-label">
</label>
                <div>@Html.DisplayFor(model => model.Course.CourseID)</div>
            </div>
            <div class="form-group">
                <label asp-for="Course.Title" class="control-label"></label>
                <input asp-for="Course.Title" class="form-control" />
                <span asp-validation-for="Course.Title" class="text-danger">
</span>
            </div>
            <div class="form-group">
                <label asp-for="Course.Credits" class="control-label">
</label>
                <input asp-for="Course.Credits" class="form-control" />
                <span asp-validation-for="Course.Credits" class="text-
danger"></span>
            </div>
            <div class="form-group">
```

```
                <label asp-for="Course.Department" class="control-label">
</label>
                <select asp-for="Course.DepartmentID" class="form-control"
                        asp-items="@Model.DepartmentNameSL"></select>
                <span asp-validation-for="Course.DepartmentID" class="text-
danger"></span>
            </div>
            <div class="form-group">
                <input type="submit" value="Save" class="btn btn-primary" />
            </div>
        </form>
    </div>
</div>

<div>
    <a asp-page="./Index">Back to List</a>
</div>

@section Scripts {
    @{await Html.RenderPartialAsync("_ValidationScriptsPartial");}
}
```

The preceding code makes the following changes:

- Displays the course ID. Generally the Primary Key (PK) of an entity isn't displayed. PKs are usually meaningless to users. In this case, the PK is the course number.
- Changes the caption for the Department drop-down from **DepartmentID** to **Department**.
- Replaces `"ViewBag.DepartmentID"` with `DepartmentNameSL`, which is in the base class.

The page contains a hidden field (`<input type="hidden">`) for the course number. Adding a `<label>` tag helper with `asp-for="Course.CourseID"` doesn't eliminate the need for the hidden field. `<input type="hidden">` is required for the course number to be included in the posted data when the user selects **Save**.

Update the Course page models

AsNoTracking can improve performance when tracking isn't required.

Update `Pages/Courses/Delete.cshtml.cs` and `Pages/Courses/Details.cshtml.cs` by adding `AsNoTracking` to the `OnGetAsync` methods:

C#

```
public async Task<IActionResult> OnGetAsync(int? id)
{
    if (id == null)
```

```
    {
        return NotFound();
    }

    Course = await _context.Courses
        .AsNoTracking()
        .Include(c => c.Department)
        .FirstOrDefaultAsync(m => m.CourseID == id);

    if (Course == null)
    {
        return NotFound();
    }
    return Page();
}
```

Update the Course Razor pages

Update `Pages/Courses/Delete.cshtml` with the following code:

CSHTML

```
@page
@model ContosoUniversity.Pages.Courses.DeleteModel

@{
    ViewData["Title"] = "Delete";
}

<h2>Delete</h2>

<h3>Are you sure you want to delete this?</h3>
<div>
    <h4>Course</h4>
    <hr />
    <dl class="row">
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Course.CourseID)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Course.CourseID)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Course.Title)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Course.Title)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Course.Credits)
        </dt>
        <dd class="col-sm-10">
```

```
            @Html.DisplayFor(model => model.Course.Credits)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Course.Department)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Course.Department.Name)
        </dd>
    </dl>

    <form method="post">
        <input type="hidden" asp-for="Course.CourseID" />
        <input type="submit" value="Delete" class="btn btn-danger" /> |
        <a asp-page="./Index">Back to List</a>
    </form>
</div>
```

Make the same changes to the Details page.

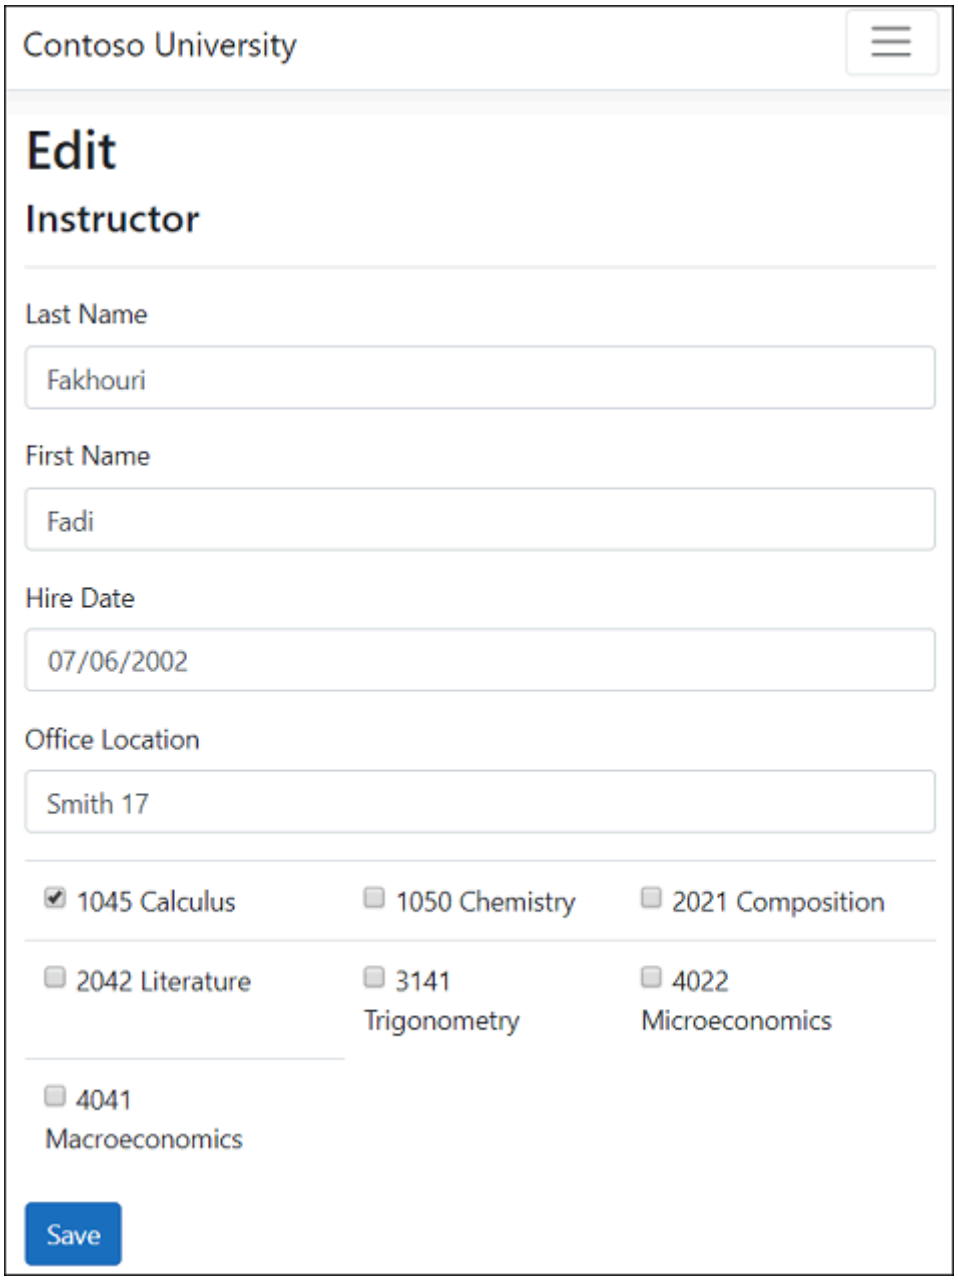
CSHTML

```
@page
@model ContosoUniversity.Pages.Courses.DetailsModel

@{
    ViewData["Title"] = "Details";
}

<h2>Details</h2>

<div>
    <h4>Course</h4>
    <hr />
    <dl class="row">
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Course.CourseID)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Course.CourseID)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Course.Title)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Course.Title)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Course.Credits)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Course.Credits)
        </dd>
        <dt class="col-sm-2">
```



```
            @Html.DisplayNameFor(model => model.Course.Department)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Course.Department.Name)
        </dd>
    </dl>
</div>
<div>
    <a asp-page="./Edit" asp-route-id="@Model.Course.CourseID">Edit</a> |
    <a asp-page="./Index">Back to List</a>
</div>
```

Test the Course pages

Test the create, edit, details, and delete pages.

Update the instructor Create and Edit pages

Instructors may teach any number of courses. The following image shows the instructor Edit page with an array of course checkboxes.

The checkboxes enable changes to courses an instructor is assigned to. A checkbox is displayed for every course in the database. Courses that the instructor is assigned to are selected. The user can select or clear checkboxes to change course assignments. If the number of courses were much greater, a different UI might work better. But the method of managing a many-to-many relationship shown here wouldn't change. To create or delete relationships, you manipulate a join entity.

Create a class for assigned courses data

Create `Models/SchoolViewModels/AssignedCourseData.cs` with the following code:

C#

```
namespace ContosoUniversity.Models.SchoolViewModels
{
    public class AssignedCourseData
```

```
    {
        public int CourseID { get; set; }
        public string Title { get; set; }
        public bool Assigned { get; set; }
    }
}
```

The `AssignedCourseData` class contains data to create the checkboxes for courses assigned to an instructor.

Create an Instructor page model base class

Create the `Pages/Instructors/InstructorCoursesPageModel.cs` base class:

C#

```
using ContosoUniversity.Data;
using ContosoUniversity.Models;
using ContosoUniversity.Models.SchoolViewModels;
using Microsoft.AspNetCore.Mvc.RazorPages;
using System.Collections.Generic;
using System.Linq;

namespace ContosoUniversity.Pages.Instructors
{
    public class InstructorCoursesPageModel : PageModel
    {
        public List<AssignedCourseData> AssignedCourseDataList;

        public void PopulateAssignedCourseData(SchoolContext context,
                                               Instructor instructor)
        {
            var allCourses = context.Courses;
            var instructorCourses = new HashSet<int>(
                instructor.Courses.Select(c => c.CourseID));
            AssignedCourseDataList = new List<AssignedCourseData>();
            foreach (var course in allCourses)
            {
                AssignedCourseDataList.Add(new AssignedCourseData
                {
                    CourseID = course.CourseID,
                    Title = course.Title,
                    Assigned = instructorCourses.Contains(course.CourseID)
                });
            }
        }
    }
}
```

The `InstructorCoursesPageModel` is the base class for the Edit and Create page models. `PopulateAssignedCourseData` reads all `Course` entities to populate `AssignedCourseDataList`. For each course, the code sets the `CourseID`, title, and whether or not the instructor is assigned to the course. A HashSet is used for efficient lookups.

Handle office location

Another relationship the edit page has to handle is the one-to-zero-or-one relationship that the Instructor entity has with the `OfficeAssignment` entity. The instructor edit code must handle the following scenarios:

- If the user clears the office assignment, delete the `OfficeAssignment` entity.
- If the user enters an office assignment and it was empty, create a new `OfficeAssignment` entity.
- If the user changes the office assignment, update the `OfficeAssignment` entity.

Update the Instructor Edit page model

Update `Pages/Instructors/Edit.cshtml.cs` with the following code:

C#

```
using ContosoUniversity.Models;
using Microsoft.AspNetCore.Mvc;
using Microsoft.EntityFrameworkCore;
using System;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Instructors
{
    public class EditModel : InstructorCoursesPageModel
    {
        private readonly ContosoUniversity.Data.SchoolContext _context;

        public EditModel(ContosoUniversity.Data.SchoolContext context)
        {
            _context = context;
        }

        [BindProperty]
        public Instructor Instructor { get; set; }

        public async Task<IActionResult> OnGetAsync(int? id)
        {
            if (id == null)
```

```
            {
                return NotFound();
            }

            Instructor = await _context.Instructors
                .Include(i => i.OfficeAssignment)
                .Include(i => i.Courses)
                .AsNoTracking()
                .FirstOrDefaultAsync(m => m.ID == id);

            if (Instructor == null)
            {
                return NotFound();
            }
            PopulateAssignedCourseData(_context, Instructor);
            return Page();
        }

        public async Task<IActionResult> OnPostAsync(int? id, string[]
selectedCourses)
        {
            if (id == null)
            {
                return NotFound();
            }

            var instructorToUpdate = await _context.Instructors
                .Include(i => i.OfficeAssignment)
                .Include(i => i.Courses)
                .FirstOrDefaultAsync(s => s.ID == id);

            if (instructorToUpdate == null)
            {
                return NotFound();
            }

            if (await TryUpdateModelAsync<Instructor>(
                instructorToUpdate,
                "Instructor",
                i => i.FirstMidName, i => i.LastName,
                i => i.HireDate, i => i.OfficeAssignment))
            {
                if (String.IsNullOrWhiteSpace(
                    instructorToUpdate.OfficeAssignment?.Location))
                {
                    instructorToUpdate.OfficeAssignment = null;
                }
                UpdateInstructorCourses(selectedCourses,
instructorToUpdate);
                await _context.SaveChangesAsync();
                return RedirectToPage("./Index");
            }
            UpdateInstructorCourses(selectedCourses, instructorToUpdate);
            PopulateAssignedCourseData(_context, instructorToUpdate);
            return Page();
```

```
        }

        public void UpdateInstructorCourses(string[] selectedCourses,
                                            Instructor instructorToUpdate)
        {
            if (selectedCourses == null)
            {
                instructorToUpdate.Courses = new List<Course>();
                return;
            }

            var selectedCoursesHS = new HashSet<string>(selectedCourses);
            var instructorCourses = new HashSet<int>
                (instructorToUpdate.Courses.Select(c => c.CourseID));
            foreach (var course in _context.Courses)
            {
                if (selectedCoursesHS.Contains(course.CourseID.ToString()))
                {
                    if (!instructorCourses.Contains(course.CourseID))
                    {
                        instructorToUpdate.Courses.Add(course);
                    }
                }
                else
                {
                    if (instructorCourses.Contains(course.CourseID))
                    {
                        var courseToRemove =
instructorToUpdate.Courses.Single(
                                                              c => c.CourseID ==
course.CourseID);
                        instructorToUpdate.Courses.Remove(courseToRemove);
                    }
                }
            }
        }
    }
}
```

The preceding code:

- Gets the current `Instructor` entity from the database using eager loading for the `OfficeAssignment` and `Courses` navigation properties.
- Updates the retrieved `Instructor` entity with values from the model binder. TryUpdateModelAsync prevents overposting.
- If the office location is blank, sets `Instructor.OfficeAssignment` to null. When `Instructor.OfficeAssignment` is null, the related row in the `OfficeAssignment` table is deleted.
- Calls `PopulateAssignedCourseData` in `OnGetAsync` to provide information for the checkboxes using the `AssignedCourseData` view model class.

- Calls `UpdateInstructorCourses` in `OnPostAsync` to apply information from the checkboxes to the Instructor entity being edited.
- Calls `PopulateAssignedCourseData` and `UpdateInstructorCourses` in `OnPostAsync` if TryUpdateModelAsync fails. These method calls restore the assigned course data entered on the page when it is redisplayed with an error message.

Since the Razor page doesn't have a collection of Course entities, the model binder can't automatically update the `Courses` navigation property. Instead of using the model binder to update the `Courses` navigation property, that's done in the new `UpdateInstructorCourses` method. Therefore you need to exclude the `Courses` property from model binding. This doesn't require any change to the code that calls TryUpdateModelAsync because you're using the overload with declared properties and `Courses` isn't in the include list.

If no checkboxes were selected, the code in `UpdateInstructorCourses` initializes the `instructorToUpdate.Courses` with an empty collection and returns:

C#

```
if (selectedCourses == null)
{
    instructorToUpdate.Courses = new List<Course>();
    return;
}
```

The code then loops through all courses in the database and checks each course against the ones currently assigned to the instructor versus the ones that were selected in the page. To facilitate efficient lookups, the latter two collections are stored in `HashSet` objects.

If the checkbox for a course is selected but the course is ***not*** in the `Instructor.Courses` navigation property, the course is added to the collection in the navigation property.

C#

```
if (selectedCoursesHS.Contains(course.CourseID.ToString()))
{
    if (!instructorCourses.Contains(course.CourseID))
    {
        instructorToUpdate.Courses.Add(course);
    }
}
```

If the checkbox for a course is ***not*** selected, but the course is in the `Instructor.Courses` navigation property, the course is removed from the navigation property.

C#

```
else
{
    if (instructorCourses.Contains(course.CourseID))
    {
        var courseToRemove = instructorToUpdate.Courses.Single(
                                        c => c.CourseID == course.CourseID);
        instructorToUpdate.Courses.Remove(courseToRemove);
    }
}
```

Update the Instructor Edit Razor page

Update `Pages/Instructors/Edit.cshtml` with the following code:

CSHTML

```
@page
@model ContosoUniversity.Pages.Instructors.EditModel
@{
    ViewData["Title"] = "Edit";
}
<h2>Edit</h2>
<h4>Instructor</h4>
<hr />
<div class="row">
    <div class="col-md-4">
        <form method="post">
            <div asp-validation-summary="ModelOnly" class="text-danger">
</div>
            <input type="hidden" asp-for="Instructor.ID" />
            <div class="form-group">
                <label asp-for="Instructor.LastName" class="control-label">
</label>
                <input asp-for="Instructor.LastName" class="form-control" />
                <span asp-validation-for="Instructor.LastName" class="text-
danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Instructor.FirstMidName" class="control-
label"></label>
                <input asp-for="Instructor.FirstMidName" class="form-
control" />
                <span asp-validation-for="Instructor.FirstMidName"
class="text-danger"></span>
            </div>
            <div class="form-group">
```

```
                <label asp-for="Instructor.HireDate" class="control-label">
</label>
                <input asp-for="Instructor.HireDate" class="form-control" />
                <span asp-validation-for="Instructor.HireDate" class="text-
danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Instructor.OfficeAssignment.Location"
class="control-label"></label>
                <input asp-for="Instructor.OfficeAssignment.Location"
class="form-control" />
                <span asp-validation-
for="Instructor.OfficeAssignment.Location" class="text-danger" />
            </div>
            <div class="form-group">
                <div class="table">
                    <table>
                        <tr>
                            @{
                                int cnt = 0;

                                foreach (var course in
Model.AssignedCourseDataList)
                                {
                                    if (cnt++ % 3 == 0)
                                    {
                                        @:</tr><tr>
                                    }
                                    @:<td>
                                        <input type="checkbox"
                                               name="selectedCourses"
                                               value="@course.CourseID"
                                               @(Html.Raw(course.Assigned ?
"checked=\"checked\"" : "")) />
                                               @course.CourseID @:
@course.Title
                                    @:</td>
                                }
                                @:</tr>
                            }
                    </table>
                </div>
            </div>
            <div class="form-group">
                <input type="submit" value="Save" class="btn btn-primary" />
            </div>
        </form>
    </div>
</div>

<div>
    <a asp-page="./Index">Back to List</a>
</div>

@section Scripts {
```

```
    @{await Html.RenderPartialAsync("_ValidationScriptsPartial");}
}
```

The preceding code creates an HTML table that has three columns. Each column has a checkbox and a caption containing the course number and title. The checkboxes all have the same name ("selectedCourses"). Using the same name informs the model binder to treat them as a group. The value attribute of each checkbox is set to `CourseID`. When the page is posted, the model binder passes an array that consists of the `CourseID` values for only the checkboxes that are selected.

When the checkboxes are initially rendered, courses assigned to the instructor are selected.

Note: The approach taken here to edit instructor course data works well when there's a limited number of courses. For collections that are much larger, a different UI and a different updating method would be more useable and efficient.

Run the app and test the updated Instructors Edit page. Change some course assignments. The changes are reflected on the Index page.

Update the Instructor Create page

Update the Instructor Create page model and with code similar to the Edit page:

C#

```
using ContosoUniversity.Data;
using ContosoUniversity.Models;
using Microsoft.AspNetCore.Mvc;
using Microsoft.EntityFrameworkCore;
using Microsoft.Extensions.Logging;
using System;
using System.Collections.Generic;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Instructors
{
    public class CreateModel : InstructorCoursesPageModel
    {
        private readonly ContosoUniversity.Data.SchoolContext _context;
        private readonly ILogger<InstructorCoursesPageModel> _logger;

        public CreateModel(SchoolContext context,
                           ILogger<InstructorCoursesPageModel> logger)
        {
            _context = context;
            _logger = logger;
        }
```

```
        public IActionResult OnGet()
        {
            var instructor = new Instructor();
            instructor.Courses = new List<Course>();

            // Provides an empty collection for the foreach loop
            // foreach (var course in Model.AssignedCourseDataList)
            // in the Create Razor page.
            PopulateAssignedCourseData(_context, instructor);
            return Page();
        }

        [BindProperty]
        public Instructor Instructor { get; set; }

        public async Task<IActionResult> OnPostAsync(string[]
selectedCourses)
        {
            var newInstructor = new Instructor();

            if (selectedCourses.Length > 0)
            {
                newInstructor.Courses = new List<Course>();
                // Load collection with one DB call.
                _context.Courses.Load();
            }

            // Add selected Courses courses to the new instructor.
            foreach (var course in selectedCourses)
            {
                var foundCourse = await
_context.Courses.FindAsync(int.Parse(course));
                if (foundCourse != null)
                {
                    newInstructor.Courses.Add(foundCourse);
                }
                else
                {
                    _logger.LogWarning("Course {course} not found", course);
                }
            }

            try
            {
                if (await TryUpdateModelAsync<Instructor>(
                                newInstructor,
                                "Instructor",
                                i => i.FirstMidName, i => i.LastName,
                                i => i.HireDate, i => i.OfficeAssignment))
                {
                    _context.Instructors.Add(newInstructor);
                    await _context.SaveChangesAsync();
                    return RedirectToPage("./Index");
                }
```

```
                return RedirectToPage("./Index");
            }
            catch (Exception ex)
            {
                _logger.LogError(ex.Message);
            }

            PopulateAssignedCourseData(_context, newInstructor);
            return Page();
        }
    }
}
```

The preceding code:

- Adds logging for warning and error messages.
- Calls Load, which fetches all the Courses in one database call. For small collections this is an optimization when using FindAsync. `FindAsync` returns the tracked entity without a request to the database.

```
C#

public async Task<IActionResult> OnPostAsync(string[] selectedCourses)
{
    var newInstructor = new Instructor();

    if (selectedCourses.Length > 0)
    {
        newInstructor.Courses = new List<Course>();
        // Load collection with one DB call.
        _context.Courses.Load();
    }

    // Add selected Courses courses to the new instructor.
    foreach (var course in selectedCourses)
    {
        var foundCourse = await
_context.Courses.FindAsync(int.Parse(course));
        if (foundCourse != null)
        {
            newInstructor.Courses.Add(foundCourse);
        }
        else
        {
            _logger.LogWarning("Course {course} not found", course);
        }
    }

    try
    {
        if (await TryUpdateModelAsync<Instructor>(
```

```
                        newInstructor,
                        "Instructor",
                        i => i.FirstMidName, i => i.LastName,
                        i => i.HireDate, i => i.OfficeAssignment))
            {
                _context.Instructors.Add(newInstructor);
                await _context.SaveChangesAsync();
                return RedirectToPage("./Index");
            }
            return RedirectToPage("./Index");
        }
        catch (Exception ex)
        {
            _logger.LogError(ex.Message);
        }

        PopulateAssignedCourseData(_context, newInstructor);
        return Page();
    }
```

- `_context.Instructors.Add(newInstructor)` creates a new `Instructor` using many-to-many relationships without explicitly mapping the join table. Many-to-many was added in EF 5.0.

Test the instructor Create page.

Update the Instructor Create Razor page with code similar to the Edit page:

CSHTML

```
@page
@model ContosoUniversity.Pages.Instructors.CreateModel

@{
    ViewData["Title"] = "Create";
}

<h2>Create</h2>

<h4>Instructor</h4>
<hr />
<div class="row">
    <div class="col-md-4">
        <form method="post">
            <div asp-validation-summary="ModelOnly" class="text-danger">
</div>
            <div class="form-group">
                <label asp-for="Instructor.LastName" class="control-label">
</label>
                <input asp-for="Instructor.LastName" class="form-control" />
                <span asp-validation-for="Instructor.LastName" class="text-
danger"></span>
```

```
            </div>
            <div class="form-group">
                <label asp-for="Instructor.FirstMidName" class="control-
label"></label>
                <input asp-for="Instructor.FirstMidName" class="form-
control" />
                <span asp-validation-for="Instructor.FirstMidName"
class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Instructor.HireDate" class="control-label">
</label>
                <input asp-for="Instructor.HireDate" class="form-control" />
                <span asp-validation-for="Instructor.HireDate" class="text-
danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Instructor.OfficeAssignment.Location"
class="control-label"></label>
                <input asp-for="Instructor.OfficeAssignment.Location"
class="form-control" />
                <span asp-validation-
for="Instructor.OfficeAssignment.Location" class="text-danger" />
            </div>
            <div class="form-group">
                <div class="table">
                    <table>
                        <tr>
                            @{
                                int cnt = 0;

                                foreach (var course in
Model.AssignedCourseDataList)
                                {
                                    if (cnt++ % 3 == 0)
                                    {
                                        @:</tr><tr>
                                    }
                                    @:<td>
                                        <input type="checkbox"
                                               name="selectedCourses"
                                               value="@course.CourseID"
                                               @(Html.Raw(course.Assigned ?
"checked=\"checked\"" : "")) />

                                               @course.CourseID @:
@course.Title
                                    @:</td>
                                }
                                @:</tr>
                            }
                    </table>
                </div>
            </div>
            <div class="form-group">
                <input type="submit" value="Create" class="btn btn-primary"
```

```
/>
            </div>
        </form>
    </div>
</div>

<div>
    <a asp-page="Index">Back to List</a>
</div>

@section Scripts {
    @{await Html.RenderPartialAsync("_ValidationScriptsPartial");}
}
```

Update the Instructor Delete page

Update `Pages/Instructors/Delete.cshtml.cs` with the following code:

C#

```
using ContosoUniversity.Models;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.EntityFrameworkCore;
using System.Linq;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Instructors
{
    public class DeleteModel : PageModel
    {
        private readonly ContosoUniversity.Data.SchoolContext _context;

        public DeleteModel(ContosoUniversity.Data.SchoolContext context)
        {
            _context = context;
        }

        [BindProperty]
        public Instructor Instructor { get; set; }

        public async Task<IActionResult> OnGetAsync(int? id)
        {
            if (id == null)
            {
                return NotFound();
            }

            Instructor = await _context.Instructors.FirstOrDefaultAsync(m =>
m.ID == id);
```

```
            if (Instructor == null)
            {
                return NotFound();
            }
            return Page();
        }

        public async Task<IActionResult> OnPostAsync(int? id)
        {
            if (id == null)
            {
                return NotFound();
            }

            Instructor instructor = await _context.Instructors
                .Include(i => i.Courses)
                .SingleAsync(i => i.ID == id);

            if (instructor == null)
            {
                return RedirectToPage("./Index");
            }

            var departments = await _context.Departments
                .Where(d => d.InstructorID == id)
                .ToListAsync();
            departments.ForEach(d => d.InstructorID = null);

            _context.Instructors.Remove(instructor);

            await _context.SaveChangesAsync();
            return RedirectToPage("./Index");
        }
    }
}
```

The preceding code makes the following changes:

- Uses eager loading for the `Courses` navigation property. `Courses` must be included or they aren't deleted when the instructor is deleted. To avoid needing to read them, configure cascade delete in the database.
- If the instructor to be deleted is assigned as administrator of any departments, removes the instructor assignment from those departments.

Run the app and test the Delete page.

Part 8, Razor Pages with EF Core in ASP.NET Core - Concurrency

Article • 04/10/2024

Tom Dykstra, and Jon P Smith

The Contoso University web app demonstrates how to create Razor Pages web apps using EF Core and Visual Studio. For information about the tutorial series, see the first tutorial.

If you run into problems you can't solve, download the completed app and compare that code to what you created by following the tutorial.

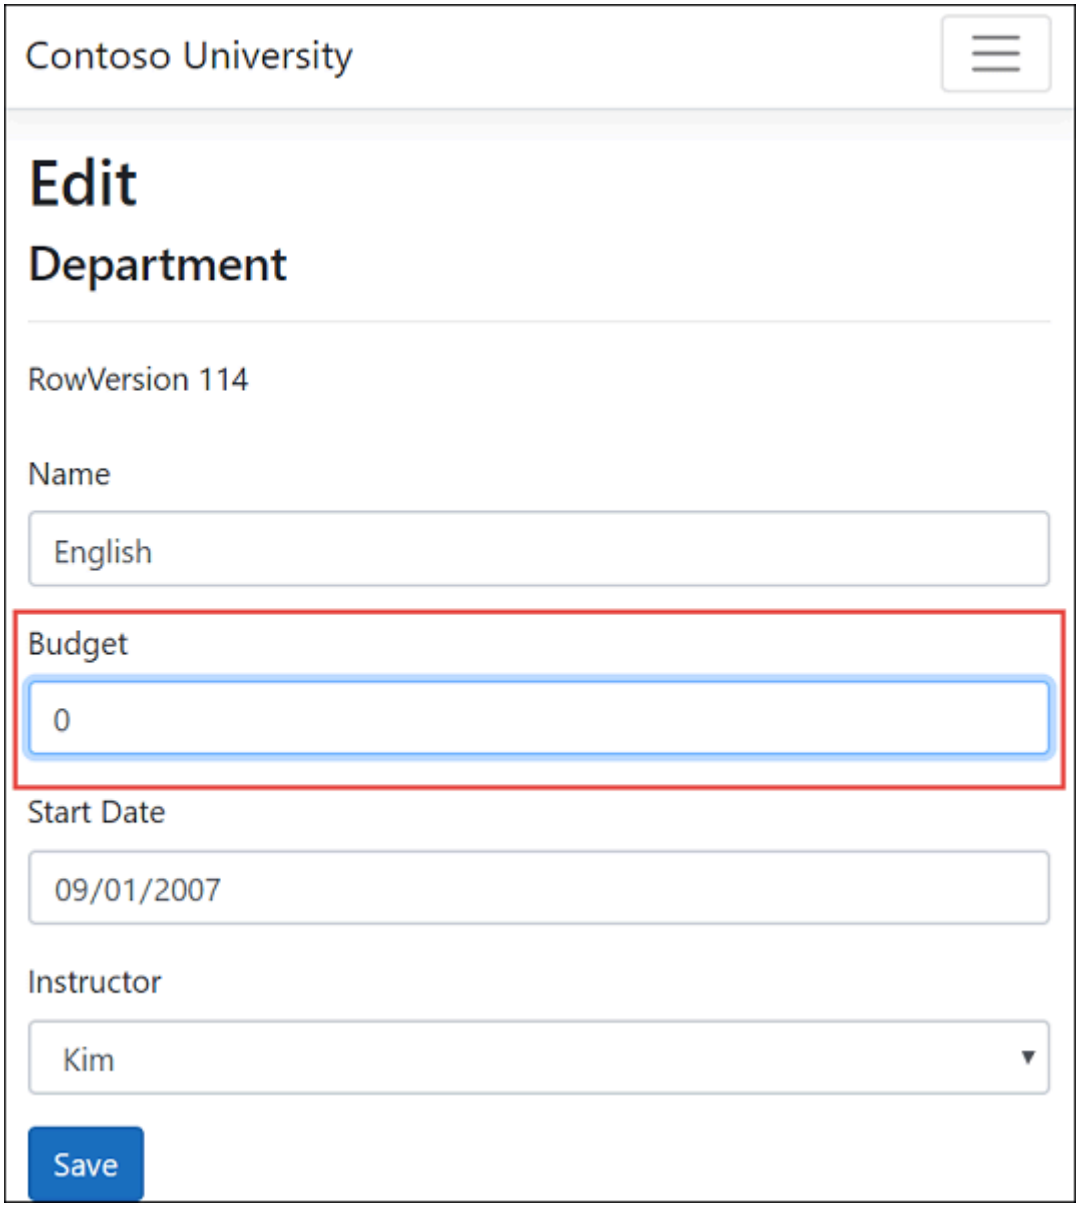
This tutorial shows how to handle conflicts when multiple users update an entity concurrently.

Concurrency conflicts

A concurrency conflict occurs when:

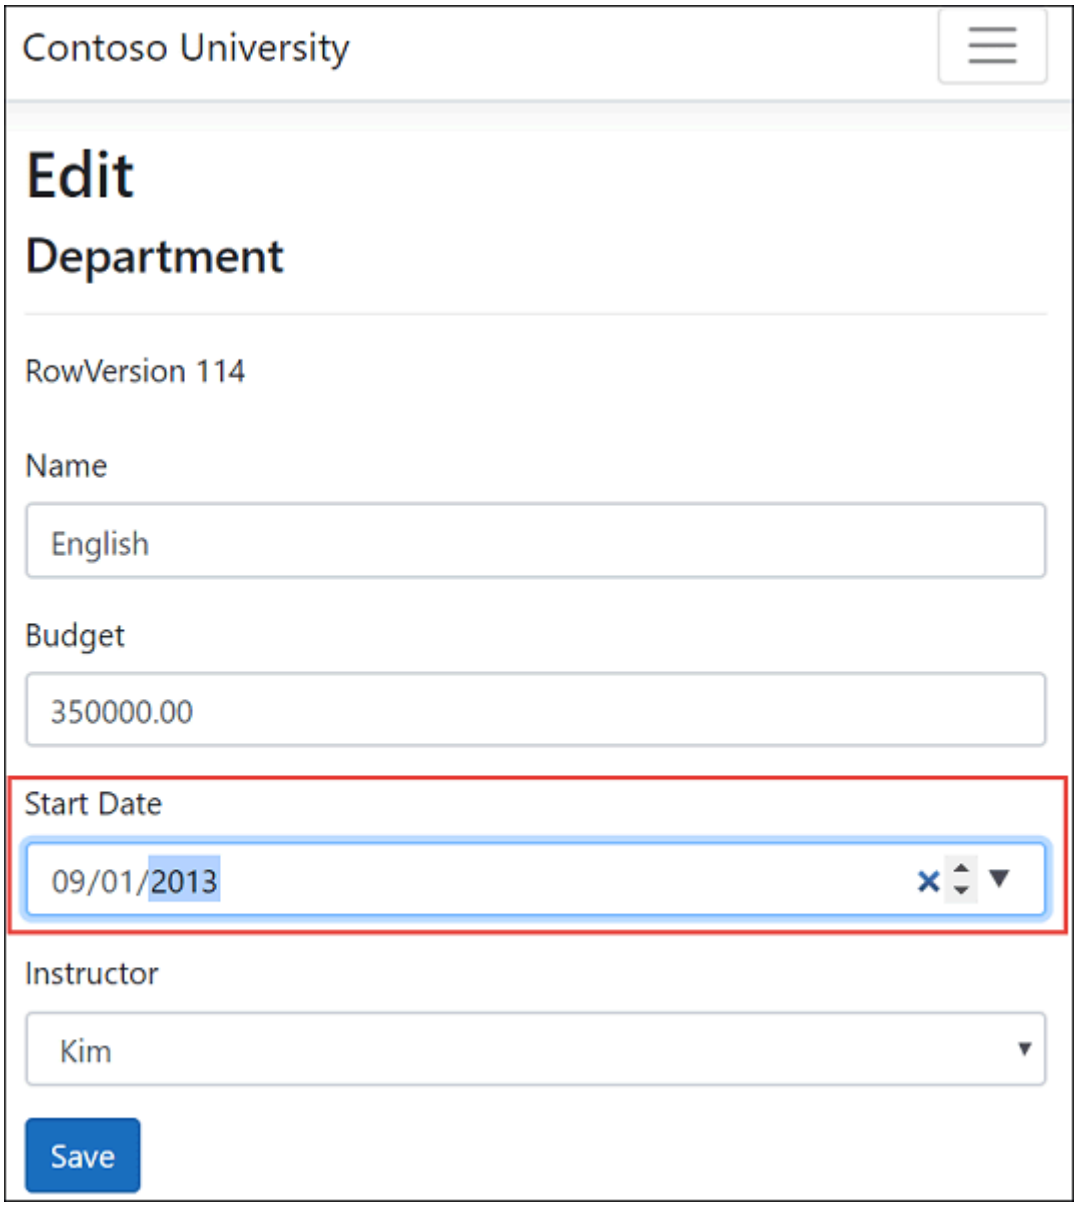
- A user navigates to the edit page for an entity.
- Another user updates the same entity before the first user's change is written to the database.

If concurrency detection isn't enabled, whoever updates the database last overwrites the other user's changes. If this risk is acceptable, the cost of programming for concurrency might outweigh the benefit.



Pessimistic concurrency

One way to prevent concurrency conflicts is to use database locks. This is called pessimistic concurrency. Before the app reads a database row that it intends to update, it requests a lock. Once a row is locked for update access, no other users are allowed to lock the row until the first lock is released.



Managing locks has disadvantages. It can be complex to program and can cause performance problems as the number of users increases. Entity Framework Core provides no built-in support for pessimistic concurrency.

Optimistic concurrency

Optimistic concurrency allows concurrency conflicts to happen, and then reacts appropriately when they do. For example, Jane visits the Department edit page and changes the budget for the English department from $350,000.00 to $0.00.

Before Jane clicks **Save**, John visits the same page and changes the Start Date field from 9/1/2007 to 9/1/2013.

Jane clicks **Save** first and sees her change take effect, since the browser displays the Index page with zero as the Budget amount.

John clicks **Save** on an Edit page that still shows a budget of $350,000.00. What happens next is determined by how you handle concurrency conflicts:

- Keep track of which property a user has modified and update only the corresponding columns in the database.

  In the scenario, no data would be lost. Different properties were updated by the two users. The next time someone browses the English department, they will see both Jane's and John's changes. This method of updating can reduce the number of conflicts that could result in data loss. This approach has some disadvantages:
  - Can't avoid data loss if competing changes are made to the same property.
  - Is generally not practical in a web app. It requires maintaining significant state in order to keep track of all fetched values and new values. Maintaining large amounts of state can affect app performance.

    - Can increase app complexity compared to concurrency detection on an entity.

- Let John's change overwrite Jane's change.

  The next time someone browses the English department, they will see 9/1/2013 and the fetched $350,000.00 value. This approach is called a *Client Wins* or *Last in Wins* scenario. All values from the client take precedence over what's in the data store. The scaffolded code does no concurrency handling, Client Wins happens automatically.

- Prevent John's change from being updated in the database. Typically, the app would:
    - Display an error message.
    - Show the current state of the data.
    - Allow the user to reapply the changes.

  This is called a *Store Wins* scenario. The data-store values take precedence over the values submitted by the client. The Store Wins scenario is used in this tutorial. This method ensures that no changes are overwritten without a user being alerted.

Conflict detection in EF Core

Properties configured as concurrency tokens are used to implement optimistic concurrency control. When an update or delete operation is triggered by SaveChanges or SaveChangesAsync, the value of the concurrency token in the database is compared against the original value read by EF Core:

- If the values match, the operation can complete.
- If the values do not match, EF Core assumes that another user has performed a conflicting operation, aborts the current transaction, and throws a DbUpdateConcurrencyException.

Another user or process performing an operation that conflicts with the current operation is known as *concurrency conflict*.

On relational databases EF Core checks for the value of the concurrency token in the `WHERE` clause of `UPDATE` and `DELETE` statements to detect a concurrency conflict.

The data model must be configured to enable conflict detection by including a tracking column that can be used to determine when a row has been changed. EF provides two approaches for concurrency tokens:

- Applying [ConcurrencyCheck] or IsConcurrencyToken to a property on the model. This approach is not recommended. For more information, see Concurrency Tokens in EF Core.
- Applying TimestampAttribute or IsRowVersion to a concurrency token in the model. This is the approach used in this tutorial.

The SQL Server approach and SQLite implementation details are slightly different. A difference file is shown later in the tutorial listing the differences. The Visual Studio tab shows the SQL Server approach. The Visual Studio Code tab shows the approach for non-SQL Server databases, such as SQLite.

Visual Studio

- In the model, include a tracking column that is used to determine when a row has been changed.
- Apply the TimestampAttribute to the concurrency property.

Update the `Models/Department.cs` file with the following highlighted code:

C#

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Department
    {
        public int DepartmentID { get; set; }

        [StringLength(50, MinimumLength = 3)]
        public string Name { get; set; }

        [DataType(DataType.Currency)]
        [Column(TypeName = "money")]
        public decimal Budget { get; set; }

        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}",
                       ApplyFormatInEditMode = true)]
        [Display(Name = "Start Date")]
        public DateTime StartDate { get; set; }

        public int? InstructorID { get; set; }

        [Timestamp]
```

```
        public byte[] ConcurrencyToken { get; set; }

        public Instructor Administrator { get; set; }
        public ICollection<Course> Courses { get; set; }
    }
}
```

The TimestampAttribute is what identifies the column as a concurrency tracking column. The fluent API is an alternative way to specify the tracking property:

C#

```
modelBuilder.Entity<Department>()
  .Property<byte[]>("ConcurrencyToken")
  .IsRowVersion();
```

The [Timestamp] attribute on an entity property generates the following code in the ModelBuilder method:

C#

```
 b.Property<byte[]>("ConcurrencyToken")
     .IsConcurrencyToken()
     .ValueGeneratedOnAddOrUpdate()
     .HasColumnType("rowversion");
```

The preceding code:

- Sets the property type `ConcurrencyToken` to byte array. `byte[]` is the required type for SQL Server.
- Calls IsConcurrencyToken. `IsConcurrencyToken` configures the property as a concurrency token. On updates, the concurrency token value in the database is compared to the original value to ensure it has not changed since the instance was retrieved from the database. If it has changed, a DbUpdateConcurrencyException is thrown and changes are not applied.
- Calls ValueGeneratedOnAddOrUpdate, which configures the `ConcurrencyToken` property to have a value automatically generated when adding or updating an entity.
- `HasColumnType("rowversion")` sets the column type in the SQL Server database to rowversion.

The following code shows a portion of the T-SQL generated by EF Core when the `Department` name is updated:

```
```

SQL

```
SET NOCOUNT ON;
UPDATE [Departments] SET [Name] = @p0
WHERE [DepartmentID] = @p1 AND [ConcurrencyToken] = @p2;
SELECT [ConcurrencyToken]
FROM [Departments]
WHERE @@ROWCOUNT = 1 AND [DepartmentID] = @p1;
```

The preceding highlighted code shows the `WHERE` clause containing `ConcurrencyToken`. If the database `ConcurrencyToken` doesn't equal the `ConcurrencyToken` parameter `@p2`, no rows are updated.

The following highlighted code shows the T-SQL that verifies exactly one row was updated:

SQL

```
SET NOCOUNT ON;
UPDATE [Departments] SET [Name] = @p0
WHERE [DepartmentID] = @p1 AND [ConcurrencyToken] = @p2;
SELECT [ConcurrencyToken]
FROM [Departments]
WHERE @@ROWCOUNT = 1 AND [DepartmentID] = @p1;
```

@@ROWCOUNT returns the number of rows affected by the last statement. If no rows are updated, EF Core throws a `DbUpdateConcurrencyException`.

Add a migration

Adding the `ConcurrencyToken` property changes the data model, which requires a migration.

Build the project.

Visual Studio

Run the following commands in the PMC:

PowerShell

```
Add-Migration RowVersion
Update-Database
```

The preceding commands:

- Creates the `Migrations/{time stamp}_RowVersion.cs` migration file.
- Updates the `Migrations/SchoolContextModelSnapshot.cs` file. The update adds the following code to the `BuildModel` method:

C#

```
b.Property<byte[]>("ConcurrencyToken")
    .IsConcurrencyToken()
    .ValueGeneratedOnAddOrUpdate()
    .HasColumnType("rowversion");
```

Scaffold Department pages

Visual Studio

Follow the instructions in Scaffold Student pages with the following exceptions:

- Create a *Pages/Departments* folder.
- Use `Department` for the model class.
- Use the existing context class instead of creating a new one.

Add a utility class

In the project folder, create the `Utility` class with the following code:

Visual Studio

C#

```
namespace ContosoUniversity
{
    public static class Utility
    {
        public static string GetLastChars(byte[] token)
        {
            return token[7].ToString();
        }
    }
}
```

The `Utility` class provides the `GetLastChars` method used to display the last few characters of the concurrency token. The following code shows the code that works with both SQLite ad SQL Server:

C#

```
#if SQLiteVersion
using System;

namespace ContosoUniversity
{
    public static class Utility
    {
        public static string GetLastChars(Guid token)
        {
            return token.ToString().Substring(
                                    token.ToString().Length - 3);
        }
    }
}
#else
namespace ContosoUniversity
{
    public static class Utility
    {
        public static string GetLastChars(byte[] token)
        {
            return token[7].ToString();
        }
    }
}
#endif
```

The `#if SQLiteVersion` preprocessor directive isolates the differences in the SQLite and SQL Server versions and helps:

- The author maintain one code base for both versions.
- SQLite developers deploy the app to Azure and use SQL Azure.

Build the project.

Update the Index page

The scaffolding tool created a `ConcurrencyToken` column for the Index page, but that field wouldn't be displayed in a production app. In this tutorial, the last portion of the `ConcurrencyToken` is displayed to help show how concurrency handling works. The last portion isn't guaranteed to be unique by itself.

Update *Pages\Departments\Index.cshtml* page:

- Replace Index with Departments.
- Change the code containing `ConcurrencyToken` to show just the last few characters.
- Replace `FirstMidName` with `FullName`.

The following code shows the updated page:

CSHTML

```
@page
@model ContosoUniversity.Pages.Departments.IndexModel

@{
    ViewData["Title"] = "Departments";
}

<h2>Departments</h2>

<p>
    <a asp-page="Create">Create New</a>
</p>
<table class="table">
    <thead>
        <tr>
            <th>
                @Html.DisplayNameFor(model => model.Department[0].Name)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Department[0].Budget)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Department[0].StartDate)
            </th>
            <th>
                @Html.DisplayNameFor(model =>
model.Department[0].Administrator)
            </th>
            <th>
                Token
            </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
        @foreach (var item in Model.Department)
        {
            <tr>
                <td>
                    @Html.DisplayFor(modelItem => item.Name)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Budget)
```

```
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.StartDate)
                </td>
                <td>
                    @Html.DisplayFor(modelItem =>
item.Administrator.FullName)
                </td>
                <td>
                    @Utility.GetLastChars(item.ConcurrencyToken)
                </td>
                <td>
                    <a asp-page="./Edit" asp-route-
id="@item.DepartmentID">Edit</a> |
                    <a asp-page="./Details" asp-route-
id="@item.DepartmentID">Details</a> |
                    <a asp-page="./Delete" asp-route-
id="@item.DepartmentID">Delete</a>
                </td>
            </tr>
        }
    </tbody>
</table>
```

Update the Edit page model

Update `Pages/Departments/Edit.cshtml.cs` with the following code:

Visual Studio

C#

```
using ContosoUniversity.Data;
using ContosoUniversity.Models;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.AspNetCore.Mvc.Rendering;
using Microsoft.EntityFrameworkCore;
using System.Linq;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Departments
{
    public class EditModel : PageModel
    {
        private readonly ContosoUniversity.Data.SchoolContext _context;

        public EditModel(ContosoUniversity.Data.SchoolContext context)
        {
            _context = context;
```

```
        }

        [BindProperty]
        public Department Department { get; set; }
        // Replace ViewData["InstructorID"]
        public SelectList InstructorNameSL { get; set; }

        public async Task<IActionResult> OnGetAsync(int id)
        {
            Department = await _context.Departments
                .Include(d => d.Administrator)  // eager loading
                .AsNoTracking()                 // tracking not required
                .FirstOrDefaultAsync(m => m.DepartmentID == id);

            if (Department == null)
            {
                return NotFound();
            }

            // Use strongly typed data rather than ViewData.
            InstructorNameSL = new SelectList(_context.Instructors,
                "ID", "FirstMidName");

            return Page();
        }

        public async Task<IActionResult> OnPostAsync(int id)
        {
            if (!ModelState.IsValid)
            {
                return Page();
            }

            // Fetch current department from DB.
            // ConcurrencyToken may have changed.
            var departmentToUpdate = await _context.Departments
                .Include(i => i.Administrator)
                .FirstOrDefaultAsync(m => m.DepartmentID == id);

            if (departmentToUpdate == null)
            {
                return HandleDeletedDepartment();
            }

            // Set ConcurrencyToken to value read in OnGetAsync
            _context.Entry(departmentToUpdate).Property(
                 d => d.ConcurrencyToken).OriginalValue =
Department.ConcurrencyToken;

            if (await TryUpdateModelAsync<Department>(
                departmentToUpdate,
                "Department",
                s => s.Name, s => s.StartDate, s => s.Budget, s =>
s.InstructorID))
            {
```

```
                try
                {
                    await _context.SaveChangesAsync();
                    return RedirectToPage("./Index");
                }
                catch (DbUpdateConcurrencyException ex)
                {
                    var exceptionEntry = ex.Entries.Single();
                    var clientValues =
(Department)exceptionEntry.Entity;
                    var databaseEntry =
exceptionEntry.GetDatabaseValues();
                    if (databaseEntry == null)
                    {
                        ModelState.AddModelError(string.Empty, "Unable
to save. " +
                            "The department was deleted by another
user.");
                        return Page();
                    }

                    var dbValues = (Department)databaseEntry.ToObject();
                    await SetDbErrorMessage(dbValues, clientValues,
_context);

                    // Save the current ConcurrencyToken so next
postback
                    // matches unless an new concurrency issue happens.
                    Department.ConcurrencyToken =
(byte[])dbValues.ConcurrencyToken;
                    // Clear the model error for the next postback.
                    ModelState.Remove($"{nameof(Department)}.
{nameof(Department.ConcurrencyToken)}");
                }
            }

            InstructorNameSL = new SelectList(_context.Instructors,
                "ID", "FullName", departmentToUpdate.InstructorID);

            return Page();
        }

        private IActionResult HandleDeletedDepartment()
        {
            // ModelState contains the posted data because of the
deletion error
            // and overides the Department instance values when
displaying Page().
            ModelState.AddModelError(string.Empty,
                "Unable to save. The department was deleted by another
user.");
            InstructorNameSL = new SelectList(_context.Instructors,
"ID", "FullName", Department.InstructorID);
            return Page();
        }
```

```
        private async Task SetDbErrorMessage(Department dbValues,
                Department clientValues, SchoolContext context)
        {

            if (dbValues.Name != clientValues.Name)
            {
                ModelState.AddModelError("Department.Name",
                    $"Current value: {dbValues.Name}");
            }
            if (dbValues.Budget != clientValues.Budget)
            {
                ModelState.AddModelError("Department.Budget",
                    $"Current value: {dbValues.Budget:c}");
            }
            if (dbValues.StartDate != clientValues.StartDate)
            {
                ModelState.AddModelError("Department.StartDate",
                    $"Current value: {dbValues.StartDate:d}");
            }
            if (dbValues.InstructorID != clientValues.InstructorID)
            {
                Instructor dbInstructor = await _context.Instructors
                   .FindAsync(dbValues.InstructorID);
                ModelState.AddModelError("Department.InstructorID",
                    $"Current value: {dbInstructor?.FullName}");
            }

            ModelState.AddModelError(string.Empty,
                "The record you attempted to edit "
              + "was modified by another user after you. The "
              + "edit operation was canceled and the current values in
the database "
              + "have been displayed. If you still want to edit this
record, click "
              + "the Save button again.");
        }
    }
}
```

The concurrency updates

OriginalValue is updated with the `ConcurrencyToken` value from the entity when it was fetched in the `OnGetAsync` method. EF Core generates a `SQL UPDATE` command with a `WHERE` clause containing the original `ConcurrencyToken` value. If no rows are affected by the `UPDATE` command, a `DbUpdateConcurrencyException` exception is thrown. No rows are affected by the `UPDATE` command when no rows have the original `ConcurrencyToken` value.

Visual Studio

C#

```
public async Task<IActionResult> OnPostAsync(int id)
{
    if (!ModelState.IsValid)
    {
        return Page();
    }

    // Fetch current department from DB.
    // ConcurrencyToken may have changed.
    var departmentToUpdate = await _context.Departments
        .Include(i => i.Administrator)
        .FirstOrDefaultAsync(m => m.DepartmentID == id);

    if (departmentToUpdate == null)
    {
        return HandleDeletedDepartment();
    }

    // Set ConcurrencyToken to value read in OnGetAsync
    _context.Entry(departmentToUpdate).Property(
         d => d.ConcurrencyToken).OriginalValue =
Department.ConcurrencyToken;
```

In the preceding highlighted code:

- The value in `Department.ConcurrencyToken` is the value when the entity was fetched in the `Get` request for the `Edit` page. The value is provided to the `OnPost` method by a hidden field in the Razor page that displays the entity to be edited. The hidden field value is copied to `Department.ConcurrencyToken` by the model binder.
- `OriginalValue` is what EF Core uses in the `WHERE` clause. Before the highlighted line of code executes:
  - `OriginalValue` has the value that was in the database when `FirstOrDefaultAsync` was called in this method.
  - This value might be different from what was displayed on the Edit page.
- The highlighted code makes sure that EF Core uses the original `ConcurrencyToken` value from the displayed `Department` entity in the SQL `UPDATE` statement's `WHERE` clause.

The following code shows the `Department` model. `Department` is initialized in the:

- `OnGetAsync` method by the EF query.

- `OnPostAsync` method by the hidden field in the Razor page using model binding:

Visual Studio

C#

```
public class EditModel : PageModel
{
    private readonly ContosoUniversity.Data.SchoolContext _context;

    public EditModel(ContosoUniversity.Data.SchoolContext context)
    {
        _context = context;
    }

    [BindProperty]
    public Department Department { get; set; }
    // Replace ViewData["InstructorID"]
    public SelectList InstructorNameSL { get; set; }

    public async Task<IActionResult> OnGetAsync(int id)
    {
        Department = await _context.Departments
            .Include(d => d.Administrator)  // eager loading
            .AsNoTracking()                 // tracking not required
            .FirstOrDefaultAsync(m => m.DepartmentID == id);

        if (Department == null)
        {
            return NotFound();
        }

        // Use strongly typed data rather than ViewData.
        InstructorNameSL = new SelectList(_context.Instructors,
            "ID", "FirstMidName");

        return Page();
    }

    public async Task<IActionResult> OnPostAsync(int id)
    {
        if (!ModelState.IsValid)
        {
            return Page();
        }

        // Fetch current department from DB.
        // ConcurrencyToken may have changed.
        var departmentToUpdate = await _context.Departments
            .Include(i => i.Administrator)
            .FirstOrDefaultAsync(m => m.DepartmentID == id);

        if (departmentToUpdate == null)
```

```
            {
                return HandleDeletedDepartment();
            }

            // Set ConcurrencyToken to value read in OnGetAsync
            _context.Entry(departmentToUpdate).Property(
                 d => d.ConcurrencyToken).OriginalValue =
    Department.ConcurrencyToken;
```

The preceding code shows the `ConcurrencyToken` value of the `Department` entity from the `HTTP POST` request is set to the `ConcurrencyToken` value from the `HTTP GET` request.

When a concurrency error happens, the following highlighted code gets the client values (the values posted to this method) and the database values.

C#

```
if (await TryUpdateModelAsync<Department>(
    departmentToUpdate,
    "Department",
    s => s.Name, s => s.StartDate, s => s.Budget, s => s.InstructorID))
{
    try
    {
        await _context.SaveChangesAsync();
        return RedirectToPage("./Index");
    }
    catch (DbUpdateConcurrencyException ex)
    {
        var exceptionEntry = ex.Entries.Single();
        var clientValues = (Department)exceptionEntry.Entity;
        var databaseEntry = exceptionEntry.GetDatabaseValues();
        if (databaseEntry == null)
        {
            ModelState.AddModelError(string.Empty, "Unable to save. " +
                "The department was deleted by another user.");
            return Page();
        }

        var dbValues = (Department)databaseEntry.ToObject();
        await SetDbErrorMessage(dbValues, clientValues, _context);

        // Save the current ConcurrencyToken so next postback
        // matches unless an new concurrency issue happens.
        Department.ConcurrencyToken = dbValues.ConcurrencyToken;
        // Clear the model error for the next postback.
        ModelState.Remove($"{nameof(Department)}.
{nameof(Department.ConcurrencyToken)}");
    }
```

The following code adds a custom error message for each column that has database values different from what was posted to `OnPostAsync`:

C#

```
private async Task SetDbErrorMessage(Department dbValues,
        Department clientValues, SchoolContext context)
{

    if (dbValues.Name != clientValues.Name)
    {
        ModelState.AddModelError("Department.Name",
            $"Current value: {dbValues.Name}");
    }
    if (dbValues.Budget != clientValues.Budget)
    {
        ModelState.AddModelError("Department.Budget",
            $"Current value: {dbValues.Budget:c}");
    }
    if (dbValues.StartDate != clientValues.StartDate)
    {
        ModelState.AddModelError("Department.StartDate",
            $"Current value: {dbValues.StartDate:d}");
    }
    if (dbValues.InstructorID != clientValues.InstructorID)
    {
        Instructor dbInstructor = await _context.Instructors
           .FindAsync(dbValues.InstructorID);
        ModelState.AddModelError("Department.InstructorID",
            $"Current value: {dbInstructor?.FullName}");
    }

    ModelState.AddModelError(string.Empty,
        "The record you attempted to edit "
      + "was modified by another user after you. The "
      + "edit operation was canceled and the current values in the database
"
      + "have been displayed. If you still want to edit this record, click "
      + "the Save button again.");
}
```

The following highlighted code sets the `ConcurrencyToken` value to the new value retrieved from the database. The next time the user clicks **Save**, only concurrency errors that happen since the last display of the Edit page will be caught.

C#

```
if (await TryUpdateModelAsync<Department>(
    departmentToUpdate,
    "Department",
    s => s.Name, s => s.StartDate, s => s.Budget, s => s.InstructorID))
```

```
{
    try
    {
        await _context.SaveChangesAsync();
        return RedirectToPage("./Index");
    }
    catch (DbUpdateConcurrencyException ex)
    {
        var exceptionEntry = ex.Entries.Single();
        var clientValues = (Department)exceptionEntry.Entity;
        var databaseEntry = exceptionEntry.GetDatabaseValues();
        if (databaseEntry == null)
        {
            ModelState.AddModelError(string.Empty, "Unable to save. " +
                "The department was deleted by another user.");
            return Page();
        }

        var dbValues = (Department)databaseEntry.ToObject();
        await SetDbErrorMessage(dbValues, clientValues, _context);

        // Save the current ConcurrencyToken so next postback
        // matches unless an new concurrency issue happens.
        Department.ConcurrencyToken = dbValues.ConcurrencyToken;
        // Clear the model error for the next postback.
        ModelState.Remove($"{nameof(Department)}.
{nameof(Department.ConcurrencyToken)}");
    }
```

The ModelState.Remove statement is required because `ModelState` has the previous `ConcurrencyToken` value. In the Razor Page, the `ModelState` value for a field takes precedence over the model property values when both are present.

SQL Server vs SQLite code differences

The following shows the differences between the SQL Server and SQLite versions:

diff

```
+ using System;    // For GUID on SQLite

+ departmentToUpdate.ConcurrencyToken = Guid.NewGuid();

 _context.Entry(departmentToUpdate)
    .Property(d => d.ConcurrencyToken).OriginalValue =
Department.ConcurrencyToken;

- Department.ConcurrencyToken = (byte[])dbValues.ConcurrencyToken;
+ Department.ConcurrencyToken = dbValues.ConcurrencyToken;
```

Update the Edit Razor page

Update `Pages/Departments/Edit.cshtml` with the following code:

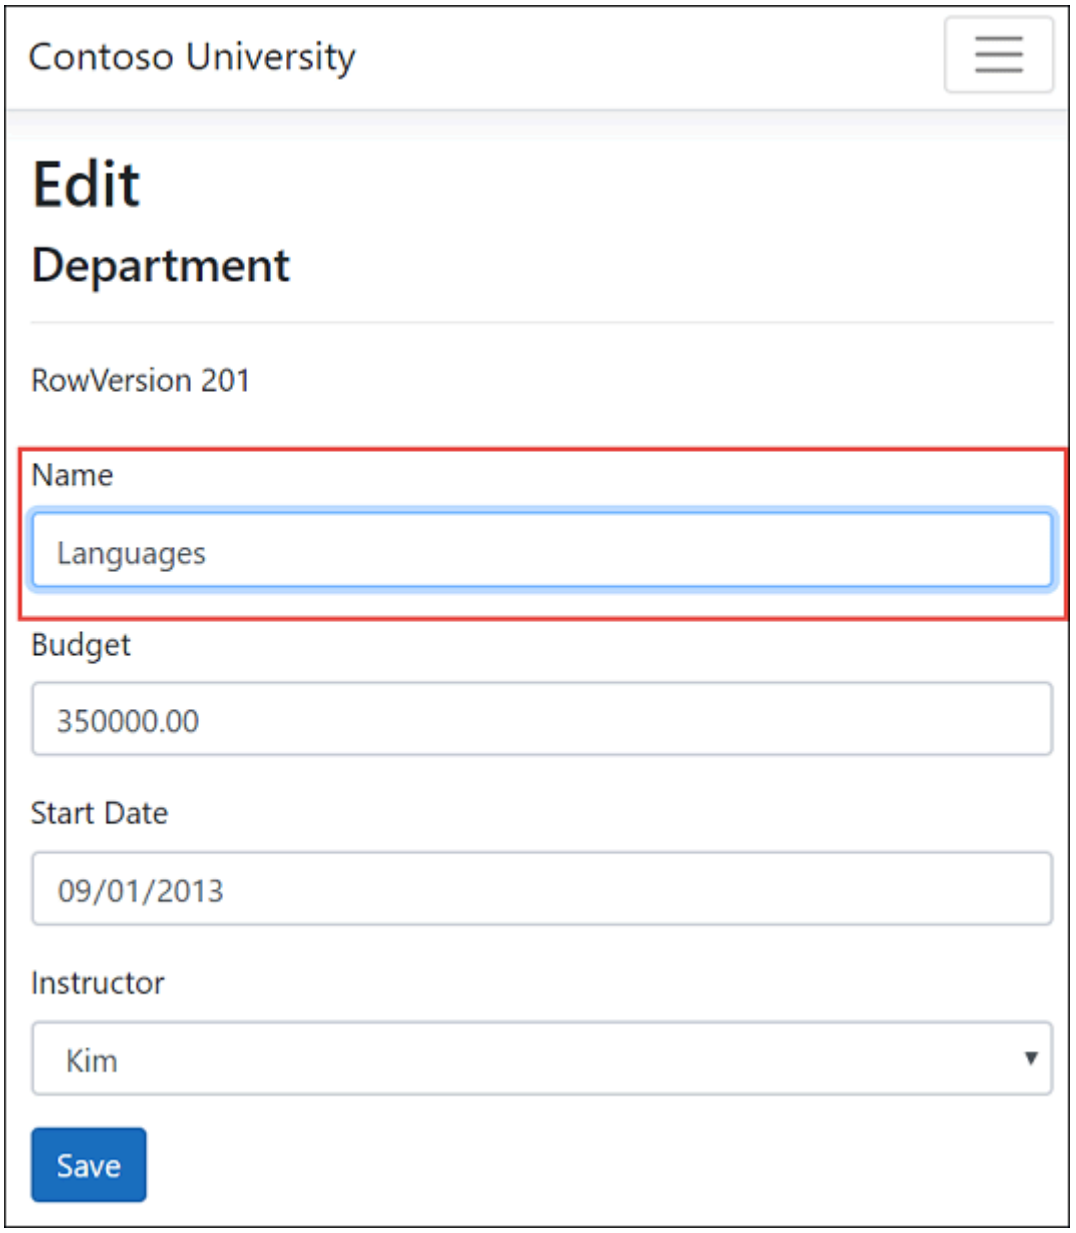
CSHTML

```
@page "{id:int}"
@model ContosoUniversity.Pages.Departments.EditModel
@{
    ViewData["Title"] = "Edit";
}
<h2>Edit</h2>
<h4>Department</h4>
<hr />
<div class="row">
    <div class="col-md-4">
        <form method="post">
            <div asp-validation-summary="ModelOnly" class="text-danger">
</div>
            <input type="hidden" asp-for="Department.DepartmentID" />
            <input type="hidden" asp-for="Department.ConcurrencyToken" />
            <div class="form-group">
                <label>Version</label>
                @Utility.GetLastChars(Model.Department.ConcurrencyToken)
            </div>
            <div class="form-group">
                <label asp-for="Department.Name" class="control-label">
</label>
                <input asp-for="Department.Name" class="form-control" />
                <span asp-validation-for="Department.Name" class="text-
danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Department.Budget" class="control-label">
</label>
                <input asp-for="Department.Budget" class="form-control" />
                <span asp-validation-for="Department.Budget" class="text-
danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Department.StartDate" class="control-label">
</label>
                <input asp-for="Department.StartDate" class="form-control"
/>
                <span asp-validation-for="Department.StartDate" class="text-
danger">
                </span>
            </div>
            <div class="form-group">
                <label class="control-label">Instructor</label>
```

```
                <select asp-for="Department.InstructorID" class="form-
control"
                        asp-items="@Model.InstructorNameSL"></select>
                <span asp-validation-for="Department.InstructorID"
class="text-danger">
                </span>
            </div>
            <div class="form-group">
                <input type="submit" value="Save" class="btn btn-primary" />
            </div>
        </form>
    </div>
</div>
<div>
    <a asp-page="./Index">Back to List</a>
</div>
@section Scripts {
    @{await Html.RenderPartialAsync("_ValidationScriptsPartial");}
}
```

The preceding code:

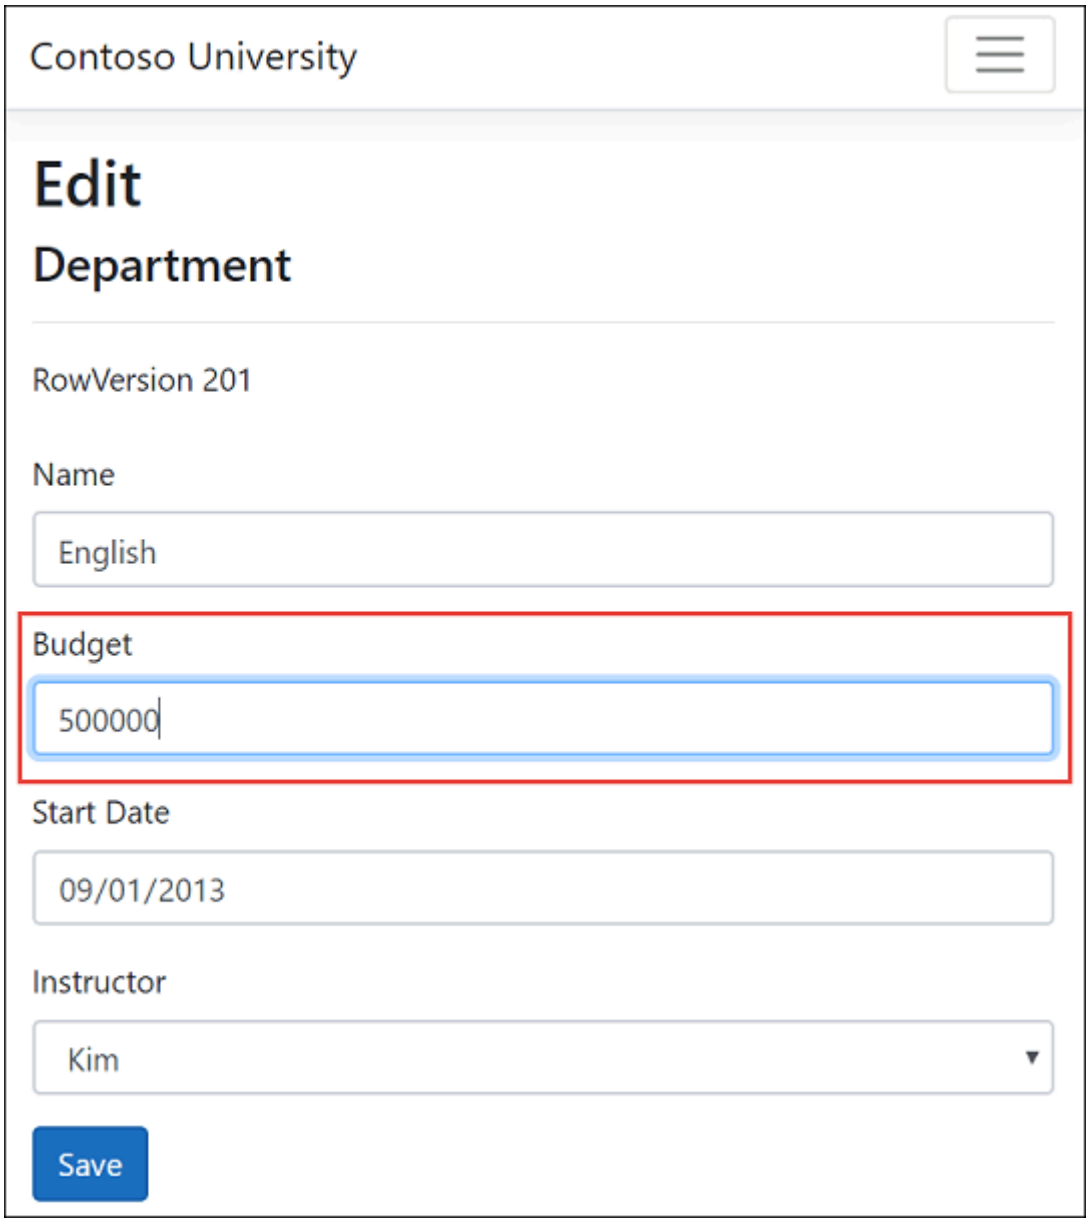
- Updates the `page` directive from `@page` to `@page "{id:int}"`.
- Adds a hidden row version. `ConcurrencyToken` must be added so postback binds the value.
- Displays the last byte of `ConcurrencyToken` for debugging purposes.
- Replaces `ViewData` with the strongly-typed `InstructorNameSL`.



Test concurrency conflicts with the Edit page

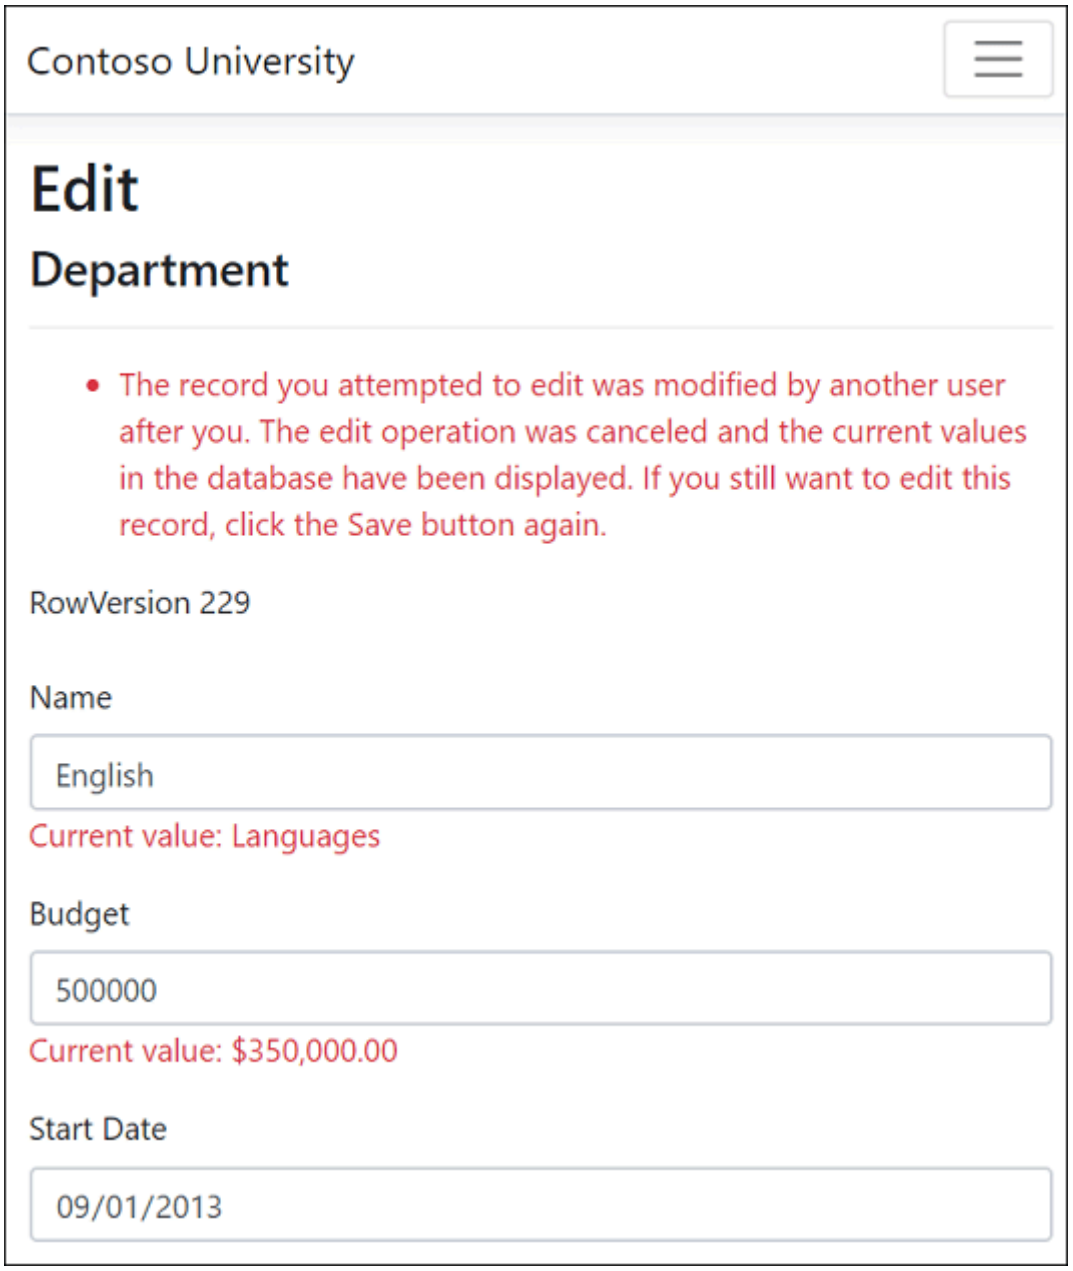
Open two browsers instances of Edit on the English department:

- Run the app and select Departments.
- Right-click the **Edit** hyperlink for the English department and select **Open in new tab**.
- In the first tab, click the **Edit** hyperlink for the English department.



The two browser tabs display the same information.

Change the name in the first browser tab and click **Save**.



The browser shows the Index page with the changed value and updated `ConcurrencyToken` indicator. Note the updated `ConcurrencyToken` indicator, it's displayed on the second postback in the other tab.

Change a different field in the second browser tab.

Click **Save**. You see error messages for all fields that don't match the database values:

This browser window didn't intend to change the Name field. Copy and paste the current value (Languages) into the Name field. Tab out. Client-side validation removes the error message.

Click **Save** again. The value you entered in the second browser tab is saved. You see the saved values in the Index page.

Update the Delete page model

Update `Pages/Departments/Delete.cshtml.cs` with the following code:

C#

```
using ContosoUniversity.Models;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;
```

```
using Microsoft.EntityFrameworkCore;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Departments
{
    public class DeleteModel : PageModel
    {
        private readonly ContosoUniversity.Data.SchoolContext _context;

        public DeleteModel(ContosoUniversity.Data.SchoolContext context)
        {
            _context = context;
        }

        [BindProperty]
        public Department Department { get; set; }
        public string ConcurrencyErrorMessage { get; set; }

        public async Task<IActionResult> OnGetAsync(int id, bool?
concurrencyError)
        {
            Department = await _context.Departments
                .Include(d => d.Administrator)
                .AsNoTracking()
                .FirstOrDefaultAsync(m => m.DepartmentID == id);

            if (Department == null)
            {
                 return NotFound();
            }

            if (concurrencyError.GetValueOrDefault())
            {
                ConcurrencyErrorMessage = "The record you attempted to
delete "
                  + "was modified by another user after you selected delete.
"
                  + "The delete operation was canceled and the current
values in the "
                  + "database have been displayed. If you still want to
delete this "
                  + "record, click the Delete button again.";
            }
            return Page();
        }

        public async Task<IActionResult> OnPostAsync(int id)
        {
            try
            {
                if (await _context.Departments.AnyAsync(
                    m => m.DepartmentID == id))
                {
                    // Department.ConcurrencyToken value is from when the
entity
```

```
                    // was fetched. If it doesn't match the DB, a
                    // DbUpdateConcurrencyException exception is thrown.
                    _context.Departments.Remove(Department);
                    await _context.SaveChangesAsync();
                }
                return RedirectToPage("./Index");
            }
            catch (DbUpdateConcurrencyException)
            {
                return RedirectToPage("./Delete",
                    new { concurrencyError = true, id = id });
            }
        }
    }
}
```

The Delete page detects concurrency conflicts when the entity has changed after it was fetched. `Department.ConcurrencyToken` is the row version when the entity was fetched. When EF Core creates the `SQL DELETE` command, it includes a WHERE clause with `ConcurrencyToken`. If the `SQL DELETE` command results in zero rows affected:

- The `ConcurrencyToken` in the `SQL DELETE` command doesn't match `ConcurrencyToken` in the database.
- A `DbUpdateConcurrencyException` exception is thrown.
- `OnGetAsync` is called with the `concurrencyError`.

Update the Delete Razor page

Update `Pages/Departments/Delete.cshtml` with the following code:

CSHTML

```
@page "{id:int}"
@model ContosoUniversity.Pages.Departments.DeleteModel

@{
    ViewData["Title"] = "Delete";
}

<h1>Delete</h1>

<p class="text-danger">@Model.ConcurrencyErrorMessage</p>

<h3>Are you sure you want to delete this?</h3>
<div>
    <h4>Department</h4>
    <hr />
    <dl class="row">
        <dt class="col-sm-2">
```

```
            @Html.DisplayNameFor(model => model.Department.Name)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Department.Name)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Department.Budget)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Department.Budget)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Department.StartDate)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Department.StartDate)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Department.ConcurrencyToken)
        </dt>
        <dd class="col-sm-10">
            @Utility.GetLastChars(Model.Department.ConcurrencyToken)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Department.Administrator)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model =>
model.Department.Administrator.FullName)
        </dd>
    </dl>

    <form method="post">
        <input type="hidden" asp-for="Department.DepartmentID" />
        <input type="hidden" asp-for="Department.ConcurrencyToken" />
        <input type="submit" value="Delete" class="btn btn-danger" /> |
        <a asp-page="./Index">Back to List</a>
    </form>
</div>
```

The preceding code makes the following changes:

- Updates the `page` directive from `@page` to `@page "{id:int}"`.
- Adds an error message.
- Replaces FirstMidName with FullName in the **Administrator** field.
- Changes `ConcurrencyToken` to display the last byte.
- Adds a hidden row version. `ConcurrencyToken` must be added so postback binds the value.

Test concurrency conflicts

Create a test department.

Open two browsers instances of Delete on the test department:

- Run the app and select Departments.
- Right-click the **Delete** hyperlink for the test department and select **Open in new tab**.
- Click the **Edit** hyperlink for the test department.

The two browser tabs display the same information.

Change the budget in the first browser tab and click **Save**.

The browser shows the Index page with the changed value and updated `ConcurrencyToken` indicator. Note the updated `ConcurrencyToken` indicator, it's displayed on the second postback in the other tab.

Delete the test department from the second tab. A concurrency error is display with the current values from the database. Clicking **Delete** deletes the entity, unless `ConcurrencyToken` has been updated.

Next steps

This is the last tutorial in the series. Additional topics are covered in the MVC version of this tutorial series.

Previous tutorial

ASP.NET Core MVC with EF Core - tutorial series

Article • 04/10/2024

This tutorial teaches ASP.NET Core MVC and Entity Framework Core with controllers and views. Razor Pages is an alternative programming model. For new development, we recommend Razor Pages over MVC with controllers and views. See the Razor Pages version of this tutorial. Each tutorial covers some material the other doesn't:

Some things this MVC tutorial has that the Razor Pages tutorial doesn't:

- Implement inheritance in the data model
- Perform raw SQL queries
- Use dynamic LINQ to simplify code

Some things the Razor Pages tutorial has that this one doesn't:

- Use Select method to load related data
- Best practices for EF.

1. Get started
2. Create, Read, Update, and Delete operations
3. Sorting, filtering, paging, and grouping
4. Migrations
5. Create a complex data model
6. Reading related data
7. Updating related data
8. Handle concurrency conflicts
9. Inheritance
10. Advanced topics

Tutorial: Get started with EF Core in an ASP.NET MVC web app

Article • 04/10/2024

By Tom Dykstra and Rick Anderson

This tutorial teaches ASP.NET Core MVC and Entity Framework Core with controllers and views. Razor Pages is an alternative programming model. For new development, we recommend Razor Pages over MVC with controllers and views. See the Razor Pages version of this tutorial. Each tutorial covers some material the other doesn't:

Some things this MVC tutorial has that the Razor Pages tutorial doesn't:

- Implement inheritance in the data model
- Perform raw SQL queries
- Use dynamic LINQ to simplify code

Some things the Razor Pages tutorial has that this one doesn't:

- Use Select method to load related data
- Best practices for EF.

The Contoso University sample web app demonstrates how to create an ASP.NET Core MVC web app using Entity Framework (EF) Core and Visual Studio.

The sample app is a web site for a fictional Contoso University. It includes functionality such as student admission, course creation, and instructor assignments. This is the first in a series of tutorials that explain how to build the Contoso University sample app.

Prerequisites

- If you're new to ASP.NET Core MVC, go through the Get started with ASP.NET Core MVC tutorial series before starting this one.

- Visual Studio 2022 with the **ASP.NET and web development** workload.
- .NET 6.0 SDK

This tutorial has not been updated for ASP.NET Core 6 or later. The tutorial's instructions will not work correctly if you create a project that targets ASP.NET Core 6 or later. For example, the ASP.NET Core 6 and later web templates use the minimal hosting model, which unifies `Startup.cs` and `Program.cs` into a single `Program.cs` file.

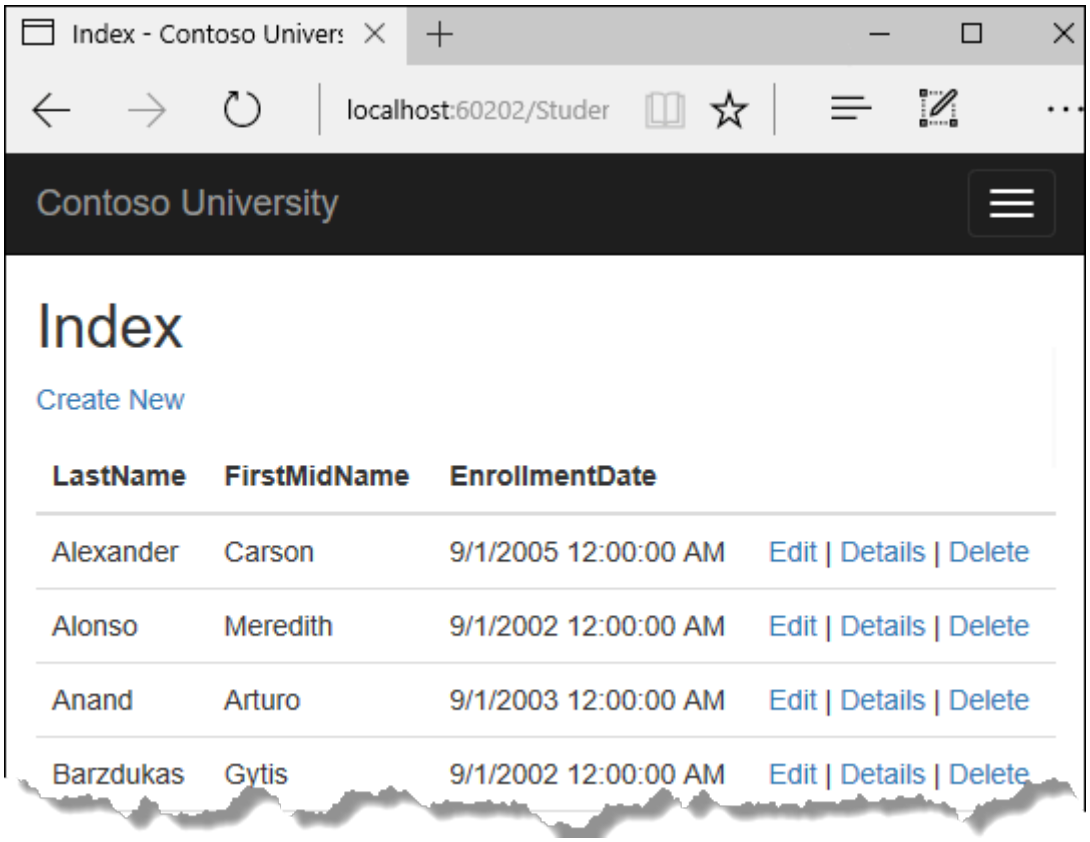
Another difference introduced in .NET 6 is the NRT (nullable reference types) feature. The project templates enable this feature by default. Problems can happen where EF considers a property to be required in .NET 6 which is nullable in .NET 5. For example, the Create Student page will fail silently unless the `Enrollments` property is made nullable or the `asp-validation-summary` helper tag is changed from `ModelOnly` to `All`.

We recommend that you install and use the .NET 5 SDK for this tutorial. Until this tutorial is updated, see Razor Pages with Entity Framework Core in ASP.NET Core - Tutorial 1 of 8 on how to use Entity Framework with ASP.NET Core 6 or later.

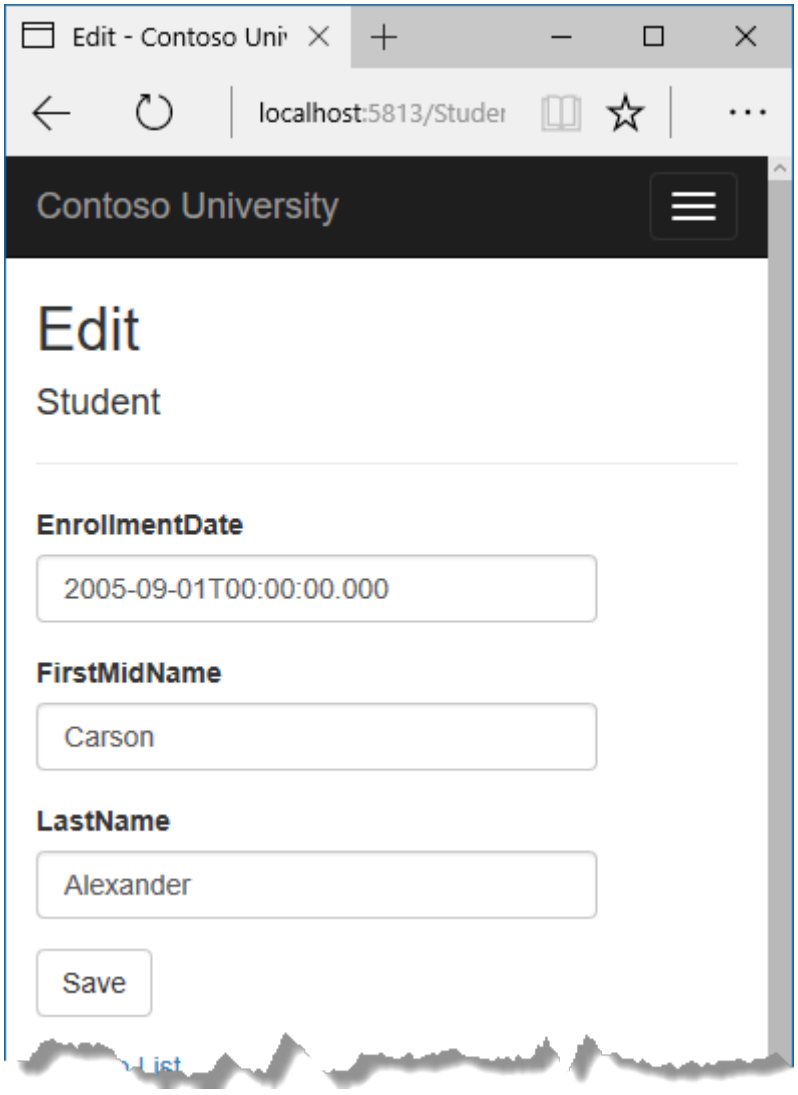
Database engines

The Visual Studio instructions use SQL Server LocalDB, a version of SQL Server Express that runs only on Windows.

Solve problems and troubleshoot



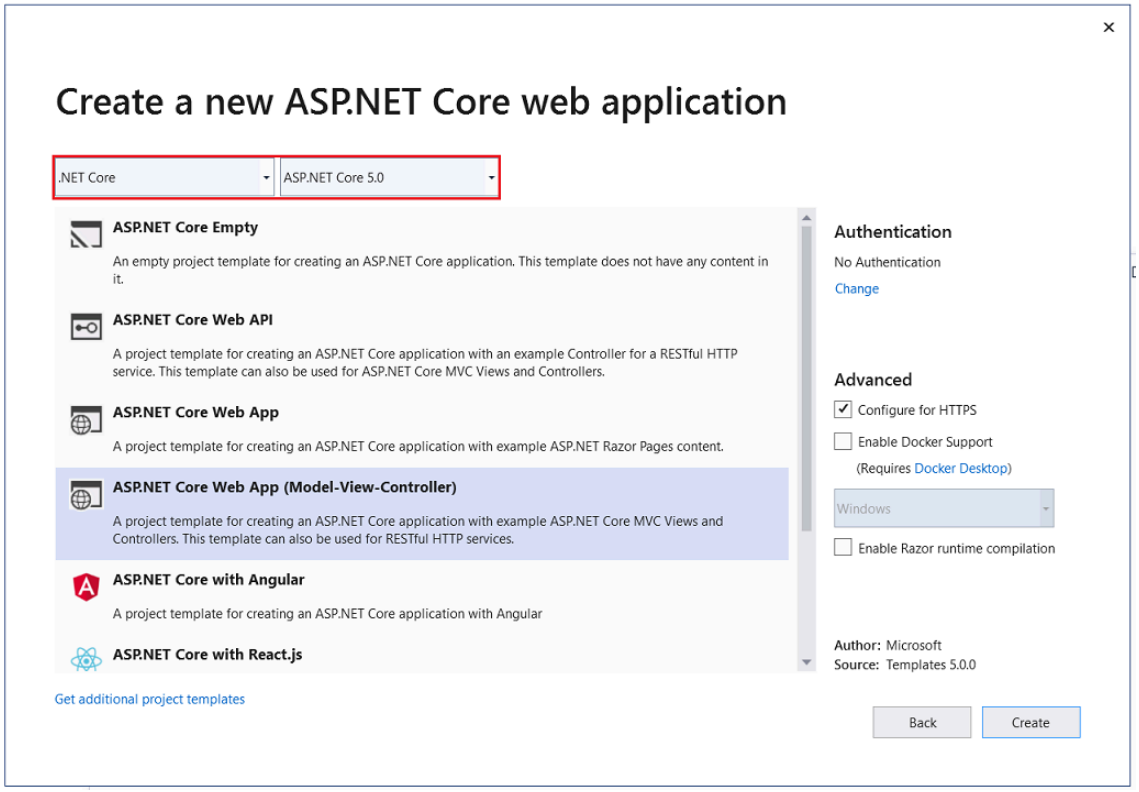
If you run into a problem you can't resolve, you can generally find the solution by comparing your code to the completed project. For a list of common errors and how to solve them, see the Troubleshooting section of the last tutorial in the series. If you don't find what you need there, you can post a question to StackOverflow.com for ASP.NET Core or EF Core.



> **Tip**
>
> This is a series of 10 tutorials, each of which builds on what is done in earlier tutorials. Consider saving a copy of the project after each successful tutorial completion. Then if you run into problems, you can start over from the previous tutorial instead of going back to the beginning of the whole series.

Contoso University web app

The app built in these tutorials is a basic university web site.



Users can view and update student, course, and instructor information. Here are a few of the screens in the app:

Index - Contoso Univers
localhost:60202/Studer
Contoso University

Save

Create web app

1. Start Visual Studio and select **Create a new project**.
2. In the **Create a new project** dialog, select **ASP.NET Core Web Application** > **Next**.
3. In the **Configure your new project** dialog, enter `ContosoUniversity` for **Project name**. It's important to use this exact name including capitalization, so each `namespace` matches when code is copied.
4. Select **Create**.
5. In the **Create a new ASP.NET Core web application** dialog, select:
   a. **.NET Core** and **ASP.NET Core 5.0** in the dropdowns.
   b. **ASP.NET Core Web App (Model-View-Controller)**.
   c. **Create**

Set up the site style

A few basic changes set up the site menu, layout, and home page.

Open `Views/Shared/_Layout.cshtml` and make the following changes:

- Change each occurrence of `ContosoUniversity` to `Contoso University`. There are three occurrences.
- Add menu entries for **About**, **Students**, **Courses**, **Instructors**, and **Departments**, and delete the **Privacy** menu entry.

The preceding changes are highlighted in the following code:

CSHTML

```
<!DOCTYPE html>
<html lang="en">
<head>
    <meta charset="utf-8" />
    <meta name="viewport" content="width=device-width, initial-scale=1.0" />
    <title>@ViewData["Title"] - Contoso University</title>
    <link rel="stylesheet" href="~/lib/bootstrap/dist/css/bootstrap.css" />
    <link rel="stylesheet" href="~/css/site.css" />
</head>
<body>
    <header>
        <nav class="navbar navbar-expand-sm navbar-toggleable-sm navbar-
light bg-white border-bottom box-shadow mb-3">
            <div class="container">
                <a class="navbar-brand" asp-area="" asp-controller="Home"
asp-action="Index">Contoso University</a>
                <button class="navbar-toggler" type="button" data-
toggle="collapse" data-target=".navbar-collapse" aria-
controls="navbarSupportedContent"
                        aria-expanded="false" aria-label="Toggle
navigation">
                    <span class="navbar-toggler-icon"></span>
                </button>
                <div class="navbar-collapse collapse d-sm-inline-flex
justify-content-between">
                    <ul class="navbar-nav flex-grow-1">
                        <li class="nav-item">
                            <a class="nav-link text-dark" asp-area="" asp-
controller="Home" asp-action="Index">Home</a>
                        </li>
                        <li class="nav-item">
                            <a class="nav-link text-dark" asp-area="" asp-
controller="Home" asp-action="About">About</a>
                        </li>
                        <li class="nav-item">
                            <a class="nav-link text-dark" asp-area="" asp-
controller="Students" asp-action="Index">Students</a>
                        </li>
                        <li class="nav-item">
                            <a class="nav-link text-dark" asp-area="" asp-

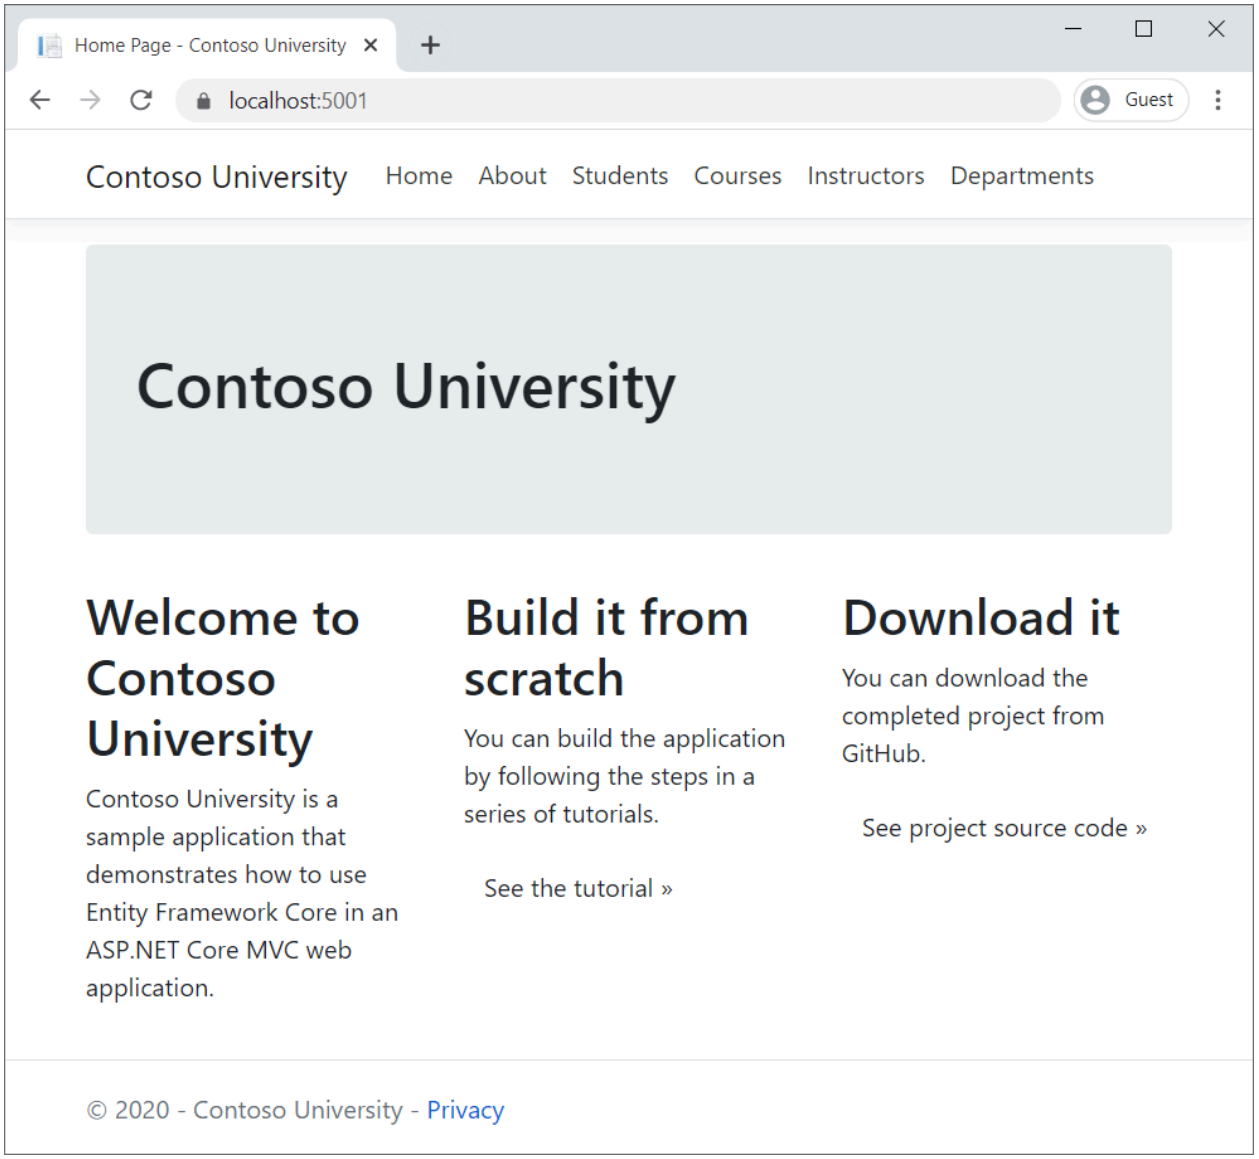
                        <li class="nav-item">
                            <a class="nav-link text-dark" asp-area="" asp-
controller="Instructors" asp-action="Index">Instructors</a>
                        </li>
                        <li class="nav-item">
                            <a class="nav-link text-dark" asp-area="" asp-
controller="Departments" asp-action="Index">Departments</a>
                        </li>
                    </ul>
                </div>
```

```
            </div>
        </nav>
    </header>
    <div class="container">
        <main role="main" class="pb-3">
            @RenderBody()
        </main>
    </div>

    <footer class="border-top footer text-muted">
        <div class="container">
            &copy; 2020 - Contoso University - <a asp-area="" asp-
controller="Home" asp-action="Privacy">Privacy</a>
        </div>
    </footer>
    <script src="~/lib/jquery/dist/jquery.js"></script>
    <script src="~/lib/bootstrap/dist/js/bootstrap.bundle.js"></script>
    <script src="~/js/site.js" asp-append-version="true"></script>
    @await RenderSectionAsync("Scripts", required: false)
</body>
</html>
```

In `Views/Home/Index.cshtml`, replace the contents of the file with the following markup:



CSHTML

```
@{
    ViewData["Title"] = "Home Page";
}

<div class="jumbotron">
    <h1>Contoso University</h1>
</div>
<div class="row">
    <div class="col-md-4">
        <h2>Welcome to Contoso University</h2>
        <p>
            Contoso University is a sample application that
            demonstrates how to use Entity Framework Core in an
            ASP.NET Core MVC web application.
        </p>
    </div>
    <div class="col-md-4">
        <h2>Build it from scratch</h2>
        <p>You can build the application by following the steps in a series
of tutorials.</p>
        <p><a class="btn btn-default"
href="https://docs.asp.net/en/latest/data/ef-mvc/intro.html">See the
tutorial &raquo;</a></p>
    </div>
    <div class="col-md-4">
        <h2>Download it</h2>
        <p>You can download the completed project from GitHub.</p>
```

```
        <p><a class="btn btn-default"
href="https://github.com/dotnet/AspNetCore.Docs/tree/main/aspnetcore/data/ef
-mvc/intro/samples/5cu-final">See project source code &raquo;</a></p>
    </div>
</div>
```

Press CTRL+F5 to run the project or choose **Debug** > **Start Without Debugging** from the menu. The home page is displayed with tabs for the pages created in this tutorial.

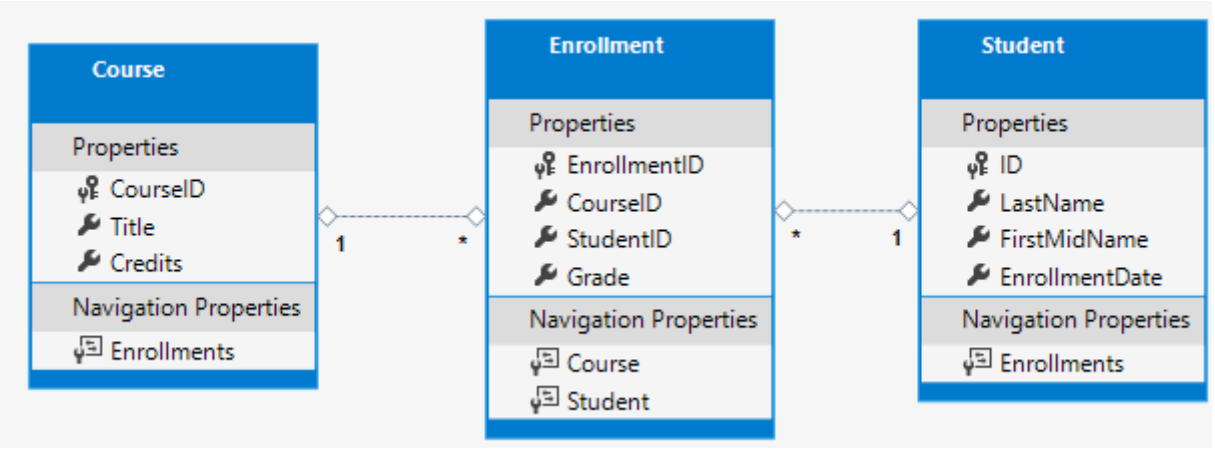
EF Core NuGet packages

This tutorial uses SQL Server, and the provider package is Microsoft.EntityFrameworkCore.SqlServer.

The EF SQL Server package and its dependencies, `Microsoft.EntityFrameworkCore` and `Microsoft.EntityFrameworkCore.Relational`, provide runtime support for EF.

Add the Microsoft.AspNetCore.Diagnostics.EntityFrameworkCore NuGet package. In the Package Manager Console (PMC), enter the following commands to add the NuGet packages:

```
PowerShell



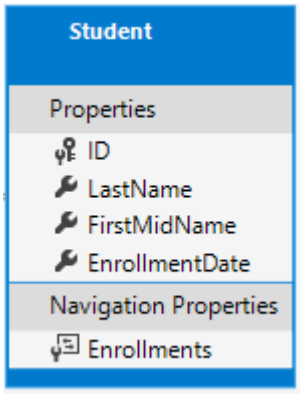
Install-Package Microsoft.AspNetCore.Diagnostics.EntityFrameworkCore
Install-Package Microsoft.EntityFrameworkCore.SqlServer
```

The `Microsoft.AspNetCore.Diagnostics.EntityFrameworkCore` NuGet package provides ASP.NET Core middleware for EF Core error pages. This middleware helps to detect and diagnose errors with EF Core migrations.

For information about other database providers that are available for EF Core, see Database providers.

Create the data model

The following entity classes are created for this app:



The preceding entities have the following relationships:

- A one-to-many relationship between `Student` and `Enrollment` entities. A student can be enrolled in any number of courses.
- A one-to-many relationship between `Course` and `Enrollment` entities. A course can have any number of students enrolled in it.

In the following sections, a class is created for each of these entities.

The Student entity

In the *Models* folder, create the `Student` class with the following code:

C#

```
using System;
using System.Collections.Generic;

namespace ContosoUniversity.Models
{
    public class Student
    {
        public int ID { get; set; }
        public string LastName { get; set; }
        public string FirstMidName { get; set; }
        public DateTime EnrollmentDate { get; set; }

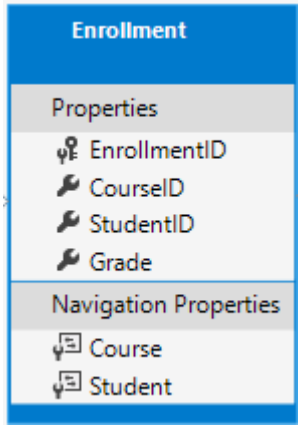
        public ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

The `ID` property is the primary key (**PK**) column of the database table that corresponds to this class. By default, EF interprets a property that's named `ID` or `classnameID` as the primary key. For example, the PK could be named `StudentID` rather than `ID`.

The `Enrollments` property is a navigation property. Navigation properties hold other entities that are related to this entity. The `Enrollments` property of a `Student` entity:

- Contains all of the `Enrollment` entities that are related to that `Student` entity.
- If a specific `Student` row in the database has two related `Enrollment` rows:
  - That `Student` entity's `Enrollments` navigation property contains those two `Enrollment` entities.

`Enrollment` rows contain a student's PK value in the `StudentID` foreign key (**FK**) column.



If a navigation property can hold multiple entities:

- The type must be a list, such as `ICollection<T>`, `List<T>`, or `HashSet<T>`.

- Entities can be added, deleted, and updated.

Many-to-many and one-to-many navigation relationships can contain multiple entities. When `ICollection<T>` is used, EF creates a `HashSet<T>` collection by default.

The Enrollment entity

In the *Models* folder, create the `Enrollment` class with the following code:

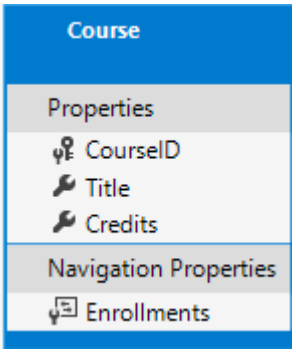
C#

```
namespace ContosoUniversity.Models
{
    public enum Grade
    {
        A, B, C, D, F
    }

    public class Enrollment
    {
        public int EnrollmentID { get; set; }
        public int CourseID { get; set; }
        public int StudentID { get; set; }
        public Grade? Grade { get; set; }

        public Course Course { get; set; }
        public Student Student { get; set; }
    }
}
```

The `EnrollmentID` property is the PK. This entity uses the `classnameID` pattern instead of `ID` by itself. The `Student` entity used the `ID` pattern. Some developers prefer to use one pattern throughout the data model. In this tutorial, the variation illustrates that either pattern can be used. A later tutorial shows how using `ID` without classname makes it easier to implement inheritance in the data model.



The `Grade` property is an `enum`. The `?` after the `Grade` type declaration indicates that the `Grade` property is nullable. A grade that's `null` is different from a zero grade. `null` means a grade isn't known or hasn't been assigned yet.

The `StudentID` property is a foreign key (FK), and the corresponding navigation property is `Student`. An `Enrollment` entity is associated with one `Student` entity, so the property can only hold a single `Student` entity. This differs from the `Student.Enrollments` navigation property, which can hold multiple `Enrollment` entities.

The `CourseID` property is a FK, and the corresponding navigation property is `Course`. An `Enrollment` entity is associated with one `Course` entity.

Entity Framework interprets a property as a FK property if it's named `<`navigation property name`><`primary key property name`>`. For example, `StudentID` for the `Student` navigation property since the `Student` entity's PK is `ID`. FK properties can also be named `<`primary key property name`>`. For example, `CourseID` because the `Course` entity's PK is `CourseID`.

The Course entity

In the *Models* folder, create the `Course` class with the following code:

C#

```
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Course
    {
        [DatabaseGenerated(DatabaseGeneratedOption.None)]
        public int CourseID { get; set; }
        public string Title { get; set; }
        public int Credits { get; set; }

        public ICollection<Enrollment> Enrollments { get; set; }
```

```
    }
}
```

The `Enrollments` property is a navigation property. A `Course` entity can be related to any number of `Enrollment` entities.

The DatabaseGenerated attribute is explained in a later tutorial. This attribute allows entering the PK for the course rather than having the database generate it.

Create the database context

The main class that coordinates EF functionality for a given data model is the DbContext database context class. This class is created by deriving from the `Microsoft.EntityFrameworkCore.DbContext` class. The `DbContext` derived class specifies which entities are included in the data model. Some EF behaviors can be customized. In this project, the class is named `SchoolContext`.

In the project folder, create a folder named `Data`.

In the *Data* folder create a `SchoolContext` class with the following code:

C#

```
using ContosoUniversity.Models;
using Microsoft.EntityFrameworkCore;

namespace ContosoUniversity.Data
{
    public class SchoolContext : DbContext
    {
        public SchoolContext(DbContextOptions<SchoolContext> options) :
base(options)
        {
        }

        public DbSet<Course> Courses { get; set; }
        public DbSet<Enrollment> Enrollments { get; set; }
        public DbSet<Student> Students { get; set; }
    }
}
```

The preceding code creates a `DbSet` property for each entity set. In EF terminology:

- An entity set typically corresponds to a database table.
- An entity corresponds to a row in the table.

The `DbSet<Enrollment>` and `DbSet<Course>` statements could be omitted and it would work the same. EF would include them implicitly because:

- The `Student` entity references the `Enrollment` entity.
- The `Enrollment` entity references the `Course` entity.

When the database is created, EF creates tables that have names the same as the `DbSet` property names. Property names for collections are typically plural. For example, `Students` rather than `Student`. Developers disagree about whether table names should be pluralized or not. For these tutorials, the default behavior is overridden by specifying singular table names in the `DbContext`. To do that, add the following highlighted code after the last DbSet property.

C#

```
using ContosoUniversity.Models;
using Microsoft.EntityFrameworkCore;

namespace ContosoUniversity.Data
{
    public class SchoolContext : DbContext
    {
        public SchoolContext(DbContextOptions<SchoolContext> options) :
base(options)
        {
        }

        public DbSet<Course> Courses { get; set; }
        public DbSet<Enrollment> Enrollments { get; set; }
        public DbSet<Student> Students { get; set; }

        protected override void OnModelCreating(ModelBuilder modelBuilder)
        {
            modelBuilder.Entity<Course>().ToTable("Course");
            modelBuilder.Entity<Enrollment>().ToTable("Enrollment");
            modelBuilder.Entity<Student>().ToTable("Student");
        }
    }
}
```

Register the `SchoolContext`

ASP.NET Core includes dependency injection. Services, such as the EF database context, are registered with dependency injection during app startup. Components that require these services, such as MVC controllers, are provided these services via constructor

parameters. The controller constructor code that gets a context instance is shown later in this tutorial.

To register `SchoolContext` as a service, open `Startup.cs`, and add the highlighted lines to the `ConfigureServices` method.

C#

```
using ContosoUniversity.Data;
using Microsoft.EntityFrameworkCore;
using Microsoft.AspNetCore.Builder;
using Microsoft.AspNetCore.Hosting;
using Microsoft.Extensions.Configuration;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.Extensions.Hosting;

namespace ContosoUniversity
{
    public class Startup
    {
        public Startup(IConfiguration configuration)
        {
            Configuration = configuration;
        }

        public IConfiguration Configuration { get; }

        public void ConfigureServices(IServiceCollection services)
        {
            services.AddDbContext<SchoolContext>(options =>

options.UseSqlServer(Configuration.GetConnectionString("DefaultConnection"))
);

            services.AddControllersWithViews();
        }
```

The name of the connection string is passed in to the context by calling a method on a `DbContextOptionsBuilder` object. For local development, the ASP.NET Core configuration system reads the connection string from the `appsettings.json` file.

Open the `appsettings.json` file and add a connection string as shown in the following markup:

JSON

```
{
  "ConnectionStrings": {
    "DefaultConnection": "Server=
(localdb)\\mssqllocaldb;Database=ContosoUniversity1;Trusted_Connection=True;
MultipleActiveResultSets=true"
  },
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "Microsoft": "Warning",
      "Microsoft.Hosting.Lifetime": "Information"
    }
  },
  "AllowedHosts": "*"
}
```

Add the database exception filter

Add AddDatabaseDeveloperPageExceptionFilter to `ConfigureServices` as shown in the following code:

C#

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddDbContext<SchoolContext>(options =>

options.UseSqlServer(Configuration.GetConnectionString("DefaultConnection"))
);

    services.AddDatabaseDeveloperPageExceptionFilter();

    services.AddControllersWithViews();
}
```

The `AddDatabaseDeveloperPageExceptionFilter` provides helpful error information in the development environment.

SQL Server Express LocalDB

The connection string specifies SQL Server LocalDB. LocalDB is a lightweight version of the SQL Server Express Database Engine and is intended for app development, not production use. LocalDB starts on demand and runs in user mode, so there's no complex configuration. By default, LocalDB creates *.mdf* DB files in the `C:/Users/<user>` directory.

Initialize DB with test data

EF creates an empty database. In this section, a method is added that's called after the database is created in order to populate it with test data.

The `EnsureCreated` method is used to automatically create the database. In a later tutorial, you see how to handle model changes by using Code First Migrations to change the database schema instead of dropping and re-creating the database.

In the *Data* folder, create a new class named `DbInitializer` with the following code:

C#

```
using ContosoUniversity.Models;
using System;
using System.Linq;

namespace ContosoUniversity.Data
{
    public static class DbInitializer
    {
        public static void Initialize(SchoolContext context)
        {
            context.Database.EnsureCreated();

            // Look for any students.
            if (context.Students.Any())
            {
                return;   // DB has been seeded
            }

            var students = new Student[]
            {
            new
Student{FirstMidName="Carson",LastName="Alexander",EnrollmentDate=DateTime.P
arse("2005-09-01")},
            new
Student{FirstMidName="Meredith",LastName="Alonso",EnrollmentDate=DateTime.Pa
rse("2002-09-01")},
            new
Student{FirstMidName="Arturo",LastName="Anand",EnrollmentDate=DateTime.Parse
("2003-09-01")},
            new
Student{FirstMidName="Gytis",LastName="Barzdukas",EnrollmentDate=DateTime.Pa
rse("2002-09-01")},
            new
Student{FirstMidName="Yan",LastName="Li",EnrollmentDate=DateTime.Parse("2002
-09-01")},
            new
Student{FirstMidName="Peggy",LastName="Justice",EnrollmentDate=DateTime.Pars
e("2001-09-01")},
            new
```

```
Student{FirstMidName="Laura",LastName="Norman",EnrollmentDate=DateTime.Parse
("2003-09-01")},
            new
Student{FirstMidName="Nino",LastName="Olivetto",EnrollmentDate=DateTime.Pars
e("2005-09-01")}
            };
            foreach (Student s in students)
            {
                context.Students.Add(s);
            }
            context.SaveChanges();

            var courses = new Course[]
            {
            new Course{CourseID=1050,Title="Chemistry",Credits=3},
            new Course{CourseID=4022,Title="Microeconomics",Credits=3},
            new Course{CourseID=4041,Title="Macroeconomics",Credits=3},
            new Course{CourseID=1045,Title="Calculus",Credits=4},
            new Course{CourseID=3141,Title="Trigonometry",Credits=4},
            new Course{CourseID=2021,Title="Composition",Credits=3},
            new Course{CourseID=2042,Title="Literature",Credits=4}
            };
            foreach (Course c in courses)
            {
                context.Courses.Add(c);
            }
            context.SaveChanges();

            var enrollments = new Enrollment[]
            {
            new Enrollment{StudentID=1,CourseID=1050,Grade=Grade.A},
            new Enrollment{StudentID=1,CourseID=4022,Grade=Grade.C},
            new Enrollment{StudentID=1,CourseID=4041,Grade=Grade.B},
            new Enrollment{StudentID=2,CourseID=1045,Grade=Grade.B},
            new Enrollment{StudentID=2,CourseID=3141,Grade=Grade.F},
            new Enrollment{StudentID=2,CourseID=2021,Grade=Grade.F},
            new Enrollment{StudentID=3,CourseID=1050},
            new Enrollment{StudentID=4,CourseID=1050},
            new Enrollment{StudentID=4,CourseID=4022,Grade=Grade.F},
            new Enrollment{StudentID=5,CourseID=4041,Grade=Grade.C},
            new Enrollment{StudentID=6,CourseID=1045},
            new Enrollment{StudentID=7,CourseID=3141,Grade=Grade.A},
            };
            foreach (Enrollment e in enrollments)
            {
                context.Enrollments.Add(e);
            }
            context.SaveChanges();
        }
    }
}
```

The preceding code checks if the database exists:

- If the database is not found;
  - It is created and loaded with test data. It loads test data into arrays rather than `List<T>` collections to optimize performance.
- If the database is found, it takes no action.

Update `Program.cs` with the following code:

C#

```
using ContosoUniversity.Data;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.AspNetCore.Hosting;
using Microsoft.Extensions.Hosting;
using Microsoft.Extensions.Logging;
using System;

namespace ContosoUniversity
{
    public class Program
    {
        public static void Main(string[] args)
        {
            var host = CreateHostBuilder(args).Build();

            CreateDbIfNotExists(host);

            host.Run();
        }

        private static void CreateDbIfNotExists(IHost host)
        {
            using (var scope = host.Services.CreateScope())
            {
                var services = scope.ServiceProvider;
                try
                {
                    var context = services.GetRequiredService<SchoolContext>
();
                    DbInitializer.Initialize(context);
                }
                catch (Exception ex)
                {
                    var logger =
services.GetRequiredService<ILogger<Program>>();
                    logger.LogError(ex, "An error occurred creating the
DB.");
                }
            }
        }

        public static IHostBuilder CreateHostBuilder(string[] args) =>
            Host.CreateDefaultBuilder(args)
                .ConfigureWebHostDefaults(webBuilder =>
```

```
                {
                    webBuilder.UseStartup<Startup>();
                });
    }
}
```

`Program.cs` does the following on app startup:

- Get a database context instance from the dependency injection container.
- Call the `DbInitializer.Initialize` method.
- Dispose the context when the `Initialize` method completes as shown in the following code:

C#

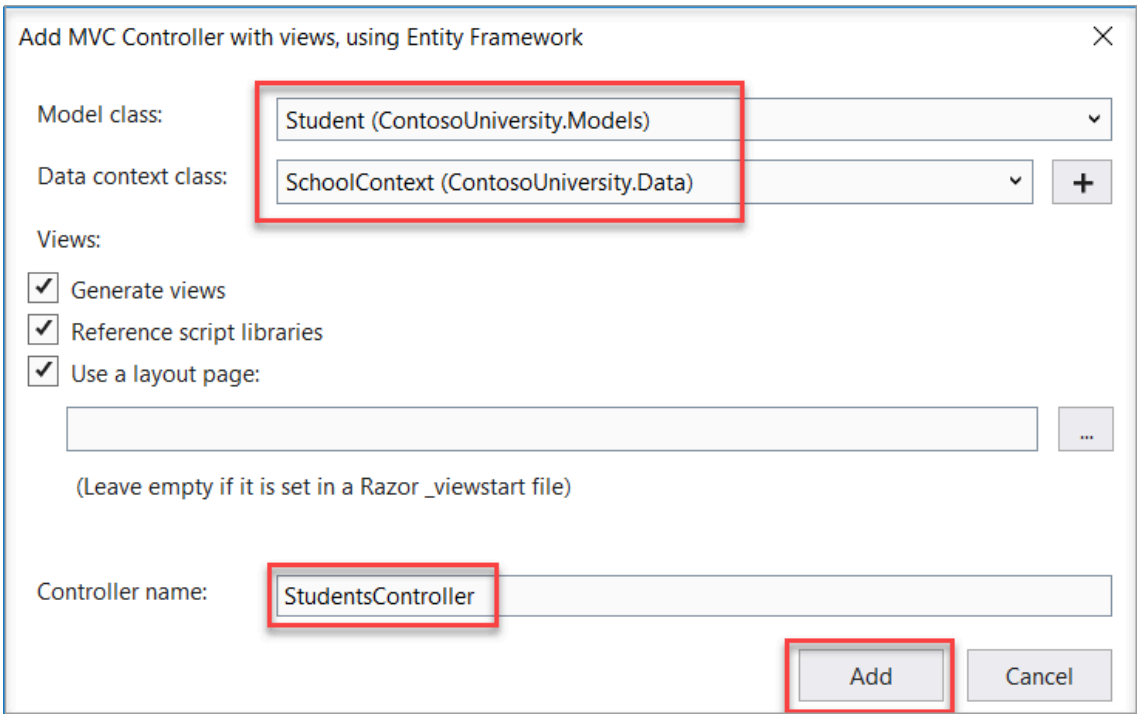
```
public static void Main(string[] args)
{
     var host = CreateWebHostBuilder(args).Build();

    using (var scope = host.Services.CreateScope())
    {
        var services = scope.ServiceProvider;
        try
        {
            var context = services.GetRequiredService<SchoolContext>();
            DbInitializer.Initialize(context);
        }
        catch (Exception ex)
        {
            var logger = services.GetRequiredService<ILogger<Program>>();
            logger.LogError(ex, "An error occurred while seeding the
database.");
        }
    }

    host.Run();
}
```

The first time the app is run, the database is created and loaded with test data. Whenever the data model changes:

- Delete the database.
- Update the seed method, and start afresh with a new database.



In later tutorials, the database is modified when the data model changes, without deleting and re-creating it. No data is lost when the data model changes.

Create controller and views

Use the scaffolding engine in Visual Studio to add an MVC controller and views that will use EF to query and save data.

The automatic creation of CRUD action methods and views is known as scaffolding.

- In **Solution Explorer**, right-click the `Controllers` folder and select **Add** > **New Scaffolded Item**.
- In the **Add Scaffold** dialog box:
  - Select **MVC controller with views, using Entity Framework**.
  - Click **Add**. The **Add MVC Controller with views, using Entity Framework** dialog box appears:

  - In **Model class**, select **Student**.
  - In **Data context class**, select **SchoolContext**.
  - Accept the default **StudentsController** as the name.
  - Click **Add**.

The Visual Studio scaffolding engine creates a `StudentsController.cs` file and a set of views (`*.cshtml` files) that work with the controller.

Notice the controller takes a `SchoolContext` as a constructor parameter.

C#

```
namespace ContosoUniversity.Controllers
{
    public class StudentsController : Controller
    {
```

```
        private readonly SchoolContext _context;

        public StudentsController(SchoolContext context)
        {
            _context = context;
        }
```

ASP.NET Core dependency injection takes care of passing an instance of `SchoolContext` into the controller. You configured that in the `Startup` class.

The controller contains an `Index` action method, which displays all students in the database. The method gets a list of students from the Students entity set by reading the `Students` property of the database context instance:

C#

```
public async Task<IActionResult> Index()
{
    return View(await _context.Students.ToListAsync());
}
```

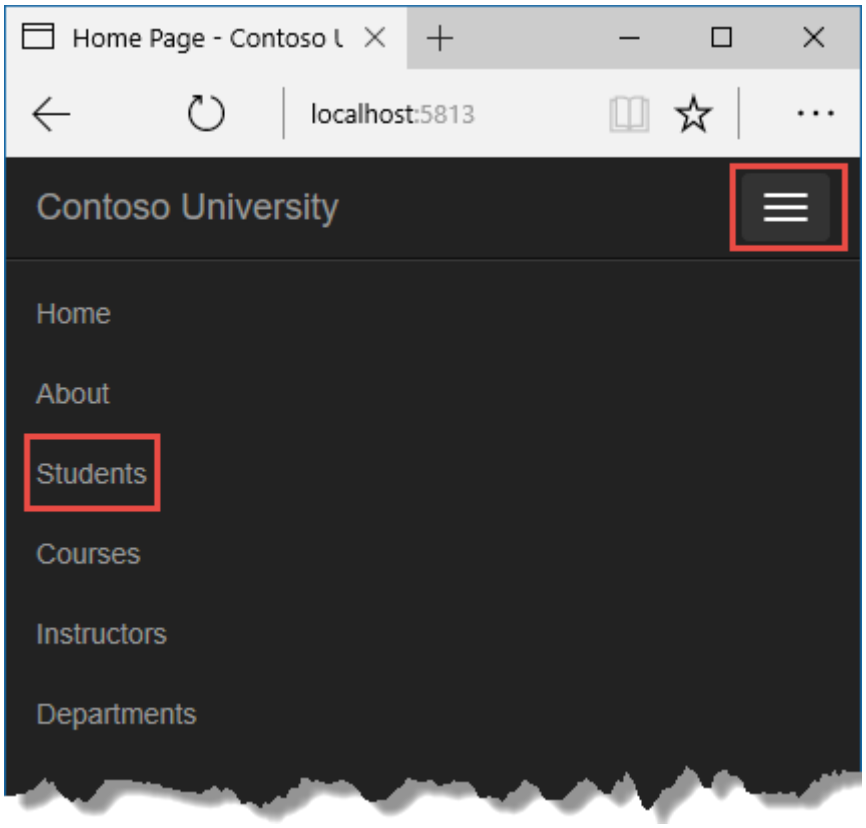
The asynchronous programming elements in this code are explained later in the tutorial.

The `Views/Students/Index.cshtml` view displays this list in a table:

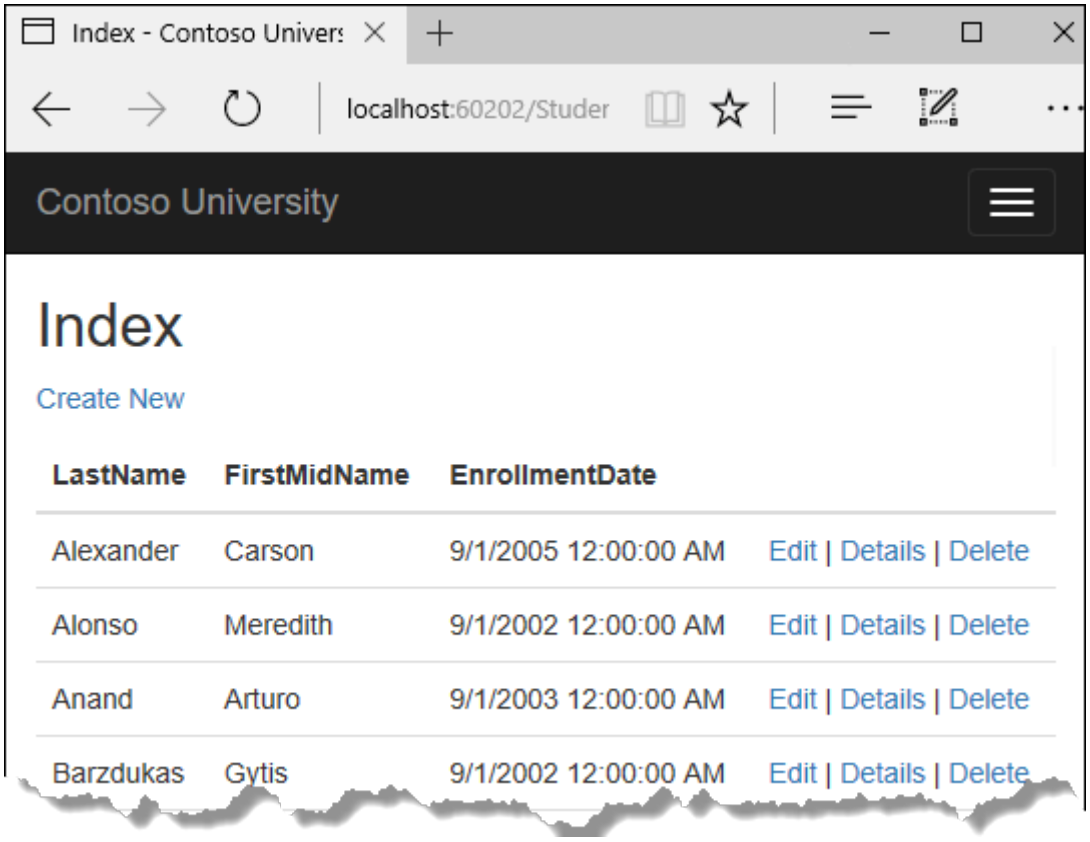
CSHTML

```
@model IEnumerable<ContosoUniversity.Models.Student>

@{
    ViewData["Title"] = "Index";
}



<h2>Index</h2>



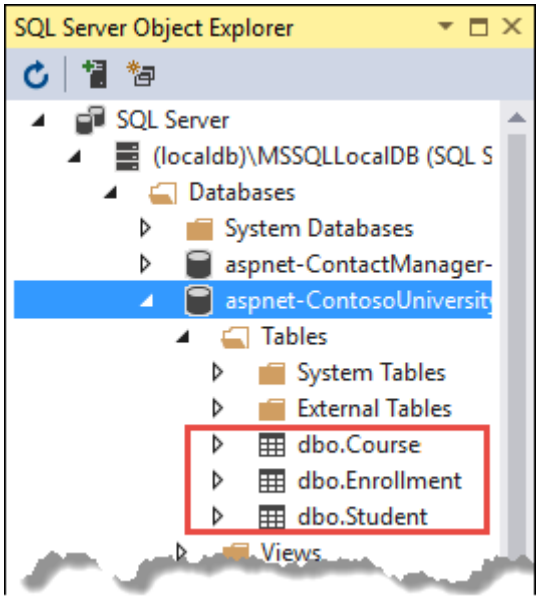
<p>
    <a asp-action="Create">Create New</a>
</p>
<table class="table">
    <thead>
        <tr>
                <th>
                    @Html.DisplayNameFor(model => model.LastName)
                </th>
                <th>
                    @Html.DisplayNameFor(model => model.FirstMidName)
                </th>
                <th>
                    @Html.DisplayNameFor(model => model.EnrollmentDate)
                </th>
```

```
            <th></th>
        </tr>
    </thead>
    <tbody>
@foreach (var item in Model) {
        <tr>
            <td>
                @Html.DisplayFor(modelItem => item.LastName)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.FirstMidName)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.EnrollmentDate)
            </td>
            <td>
                <a asp-action="Edit" asp-route-id="@item.ID">Edit</a> |
                <a asp-action="Details" asp-route-id="@item.ID">Details</a>
|
                <a asp-action="Delete" asp-route-id="@item.ID">Delete</a>
            </td>
        </tr>
}
    </tbody>
</table>
```

Press CTRL+F5 to run the project or choose **Debug** > **Start Without Debugging** from the menu.

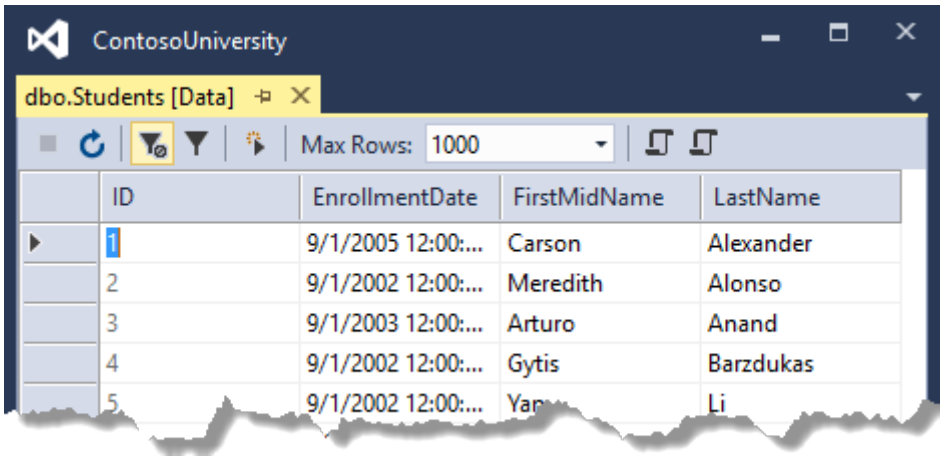
Click the Students tab to see the test data that the `DbInitializer.Initialize` method inserted. Depending on how narrow your browser window is, you'll see the `Students` tab link at the top of the page or you'll have to click the navigation icon in the upper right corner to see the link.

View the database



When the app is started, the `DbInitializer.Initialize` method calls `EnsureCreated`. EF saw that there was no database:

- So it created a database.



- The `Initialize` method code populated the database with data.

Use **SQL Server Object Explorer** (SSOX) to view the database in Visual Studio:

- Select **SQL Server Object Explorer** from the **View** menu in Visual Studio.
- In SSOX, select **(localdb)\MSSQLLocalDB** > **Databases**.
- Select `ContosoUniversity1`, the entry for the database name that's in the connection string in the `appsettings.json` file.
- Expand the **Tables** node to see the tables in the database.

Right-click the **Student** table and click **View Data** to see the data in the table.

The `*.mdf` and `*.ldf` database files are in the *C:\Users\<username>* folder.

Because `EnsureCreated` is called in the initializer method that runs on app start, you could:

- Make a change to the `Student` class.
- Delete the database.

- Stop, then start the app. The database is automatically re-created to match the change.

For example, if an `EmailAddress` property is added to the `Student` class, a new `EmailAddress` column in the re-created table. The view won't display the new `EmailAddress` property.

Conventions

The amount of code written in order for the EF to create a complete database is minimal because of the use of the conventions EF uses:

- The names of `DbSet` properties are used as table names. For entities not referenced by a `DbSet` property, entity class names are used as table names.
- Entity property names are used for column names.
- Entity properties that are named `ID` or `classnameID` are recognized as PK properties.
- A property is interpreted as a FK property if it's named `<`navigation property name`><`PK property name`>`. For example, `StudentID` for the `Student` navigation property since the `Student` entity's PK is `ID`. FK properties can also be named `<`primary key property name`>`. For example, `EnrollmentID` since the `Enrollment` entity's PK is `EnrollmentID`.

Conventional behavior can be overridden. For example, table names can be explicitly specified, as shown earlier in this tutorial. Column names and any property can be set as a PK or FK.

Asynchronous code

Asynchronous programming is the default mode for ASP.NET Core and EF Core.

A web server has a limited number of threads available, and in high load situations all of the available threads might be in use. When that happens, the server can't process new requests until the threads are freed up. With synchronous code, many threads may be tied up while they aren't actually doing any work because they're waiting for I/O to complete. With asynchronous code, when a process is waiting for I/O to complete, its thread is freed up for the server to use for processing other requests. As a result, asynchronous code enables server resources to be used more efficiently, and the server is enabled to handle more traffic without delays.

Asynchronous code does introduce a small amount of overhead at run time, but for low traffic situations the performance hit is negligible, while for high traffic situations, the potential performance improvement is substantial.

In the following code, `async`, `Task<T>`, `await`, and `ToListAsync` make the code execute asynchronously.

```
C#

public async Task<IActionResult> Index()
{
    return View(await _context.Students.ToListAsync());
}
```

- The `async` keyword tells the compiler to generate callbacks for parts of the method body and to automatically create the `Task<IActionResult>` object that's returned.
- The return type `Task<IActionResult>` represents ongoing work with a result of type `IActionResult`.
- The `await` keyword causes the compiler to split the method into two parts. The first part ends with the operation that's started asynchronously. The second part is put into a callback method that's called when the operation completes.
- `ToListAsync` is the asynchronous version of the `ToList` extension method.

Some things to be aware of when writing asynchronous code that uses EF:

- Only statements that cause queries or commands to be sent to the database are executed asynchronously. That includes, for example, `ToListAsync`, `SingleOrDefaultAsync`, and `SaveChangesAsync`. It doesn't include, for example, statements that just change an `IQueryable`, such as `var students = context.Students.Where(s => s.LastName == "Davolio")`.
- An EF context isn't thread safe: don't try to do multiple operations in parallel. When you call any async EF method, always use the `await` keyword.
- To take advantage of the performance benefits of async code, make sure that any library packages used also use async if they call any EF methods that cause queries to be sent to the database.

For more information about asynchronous programming in .NET, see Async Overview.

Limit entities fetched

See Performance considerations for information on limiting the number of entities returned from a query.

SQL Logging of Entity Framework Core

Logging configuration is commonly provided by the `Logging` section of `appsettings.{Environment}.json` files. To log SQL statements, add `"Microsoft.EntityFrameworkCore.Database.Command": "Information"` to the `appsettings.Development.json` file:

JSON

```
{
  "ConnectionStrings": {
    "DefaultConnection": "Server=(localdb)\\mssqllocaldb;Database=MyDB-
2;Trusted_Connection=True;MultipleActiveResultSets=true"
  },
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "Microsoft": "Warning",
      "Microsoft.Hosting.Lifetime": "Information"
     ,"Microsoft.EntityFrameworkCore.Database.Command": "Information"
    }
  },
  "AllowedHosts": "*"
}
```

With the preceding JSON, SQL statements are displayed on the command line and in the Visual Studio output window.

For more information, see Logging in .NET Core and ASP.NET Core and this GitHub issue.

Advance to the next tutorial to learn how to perform basic CRUD (create, read, update, delete) operations.

Implement basic CRUD functionality

Tutorial: Implement CRUD Functionality - ASP.NET MVC with EF Core

Article • 04/10/2024

In the previous tutorial, you created an MVC application that stores and displays data using the Entity Framework and SQL Server LocalDB. In this tutorial, you'll review and customize the CRUD (create, read, update, delete) code that the MVC scaffolding automatically creates for you in controllers and views.

> **Note**
>
> It's a common practice to implement the repository pattern in order to create an abstraction layer between your controller and the data access layer. To keep these tutorials simple and focused on teaching how to use the Entity Framework itself, they don't use repositories. For information about repositories with EF, see the last tutorial in this series.

In this tutorial, you:

- ✓ Customize the Details page
- ✓ Update the Create page
- ✓ Update the Edit page
- ✓ Update the Delete page
- ✓ Close database connections

Prerequisites

- Get started with EF Core and ASP.NET Core MVC

Customize the Details page

The scaffolded code for the Students Index page left out the `Enrollments` property, because that property holds a collection. In the **Details** page, you'll display the contents of the collection in an HTML table.

In `Controllers/StudentsController.cs`, the action method for the Details view uses the `FirstOrDefaultAsync` method to retrieve a single `Student` entity. Add code that calls

`Include`. `ThenInclude`, and `AsNoTracking` methods, as shown in the following highlighted code.

C#

```
public async Task<IActionResult> Details(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    var student = await _context.Students
        .Include(s => s.Enrollments)
            .ThenInclude(e => e.Course)
        .AsNoTracking()
        .FirstOrDefaultAsync(m => m.ID == id);

    if (student == null)
    {
        return NotFound();
    }

    return View(student);
}
```

The `Include` and `ThenInclude` methods cause the context to load the `Student.Enrollments` navigation property, and within each enrollment the `Enrollment.Course` navigation property. You'll learn more about these methods in the read related data tutorial.

The `AsNoTracking` method improves performance in scenarios where the entities returned won't be updated in the current context's lifetime. You'll learn more about `AsNoTracking` at the end of this tutorial.

Route data

The key value that's passed to the `Details` method comes from *route data*. Route data is data that the model binder found in a segment of the URL. For example, the default route specifies controller, action, and id segments:

C#

```
app.UseEndpoints(endpoints =>
{
    endpoints.MapControllerRoute(
        name: "default",
```

```
        pattern: "{controller=Home}/{action=Index}/{id?}");
});
```

In the following URL, the default route maps Instructor as the controller, Index as the action, and 1 as the id; these are route data values.

```
http://localhost:1230/Instructor/Index/1?courseID=2021
```

The last part of the URL ("?courseID=2021") is a query string value. The model binder will also pass the ID value to the `Index` method `id` parameter if you pass it as a query string value:

```
http://localhost:1230/Instructor/Index?id=1&CourseID=2021
```

In the Index page, hyperlink URLs are created by tag helper statements in the Razor view. In the following Razor code, the `id` parameter matches the default route, so `id` is added to the route data.

HTML

```
<a asp-action="Edit" asp-route-id="@item.ID">Edit</a>
```

This generates the following HTML when `item.ID` is 6:

HTML

```
<a href="/Students/Edit/6">Edit</a>
```

In the following Razor code, `studentID` doesn't match a parameter in the default route, so it's added as a query string.

HTML

```
<a asp-action="Edit" asp-route-studentID="@item.ID">Edit</a>
```

This generates the following HTML when `item.ID` is 6:

HTML

```
<a href="/Students/Edit?studentID=6">Edit</a>
```

For more information about tag helpers, see Tag Helpers in ASP.NET Core.

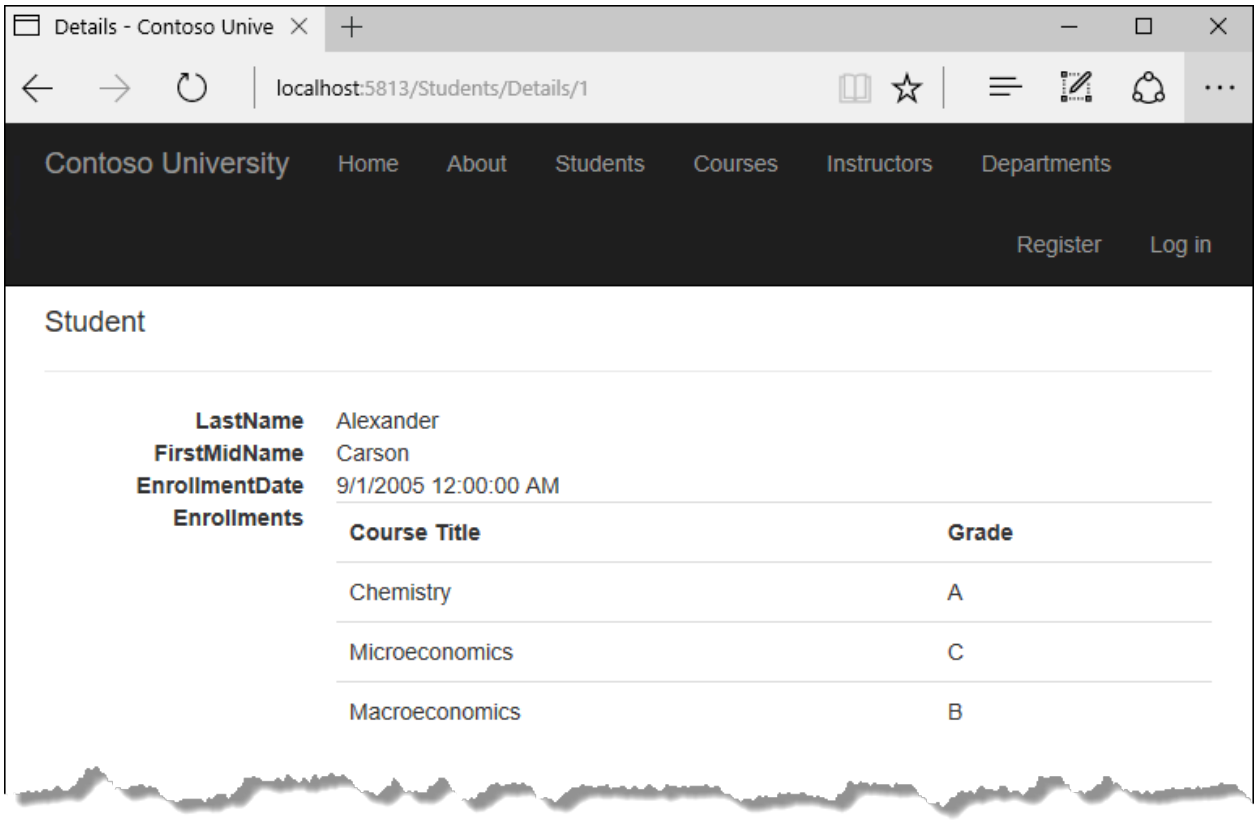
Add enrollments to the Details view

Open `Views/Students/Details.cshtml`. Each field is displayed using `DisplayNameFor` and `DisplayFor` helpers, as shown in the following example:

CSHTML

```
<dt class="col-sm-2">
    @Html.DisplayNameFor(model => model.LastName)
</dt>
<dd class="col-sm-10">
    @Html.DisplayFor(model => model.LastName)
</dd>
```

After the last field and immediately before the closing `</dl>` tag, add the following code to display a list of enrollments:



CSHTML

```
<dt class="col-sm-2">
    @Html.DisplayNameFor(model => model.Enrollments)
</dt>
<dd class="col-sm-10">
    <table class="table">
        <tr>
            <th>Course Title</th>
            <th>Grade</th>
        </tr>
        @foreach (var item in Model.Enrollments)
        {
            <tr>
                <td>
                    @Html.DisplayFor(modelItem => item.Course.Title)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Grade)
                </td>
            </tr>
        }
    </table>
</dd>
```

If code indentation is wrong after you paste the code, press CTRL-K-D to correct it.

This code loops through the entities in the `Enrollments` navigation property. For each enrollment, it displays the course title and the grade. The course title is retrieved from the Course entity that's stored in the `Course` navigation property of the Enrollments entity.

Run the app, select the **Students** tab, and click the **Details** link for a student. You see the list of courses and grades for the selected student:

Update the Create page

In `StudentsController.cs`, modify the HttpPost `Create` method by adding a try-catch block and removing ID from the `Bind` attribute.

C#

```
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<IActionResult> Create(
    [Bind("EnrollmentDate,FirstMidName,LastName")] Student student)
{
    try
    {
        if (ModelState.IsValid)
        {
            _context.Add(student);
            await _context.SaveChangesAsync();
            return RedirectToAction(nameof(Index));
```

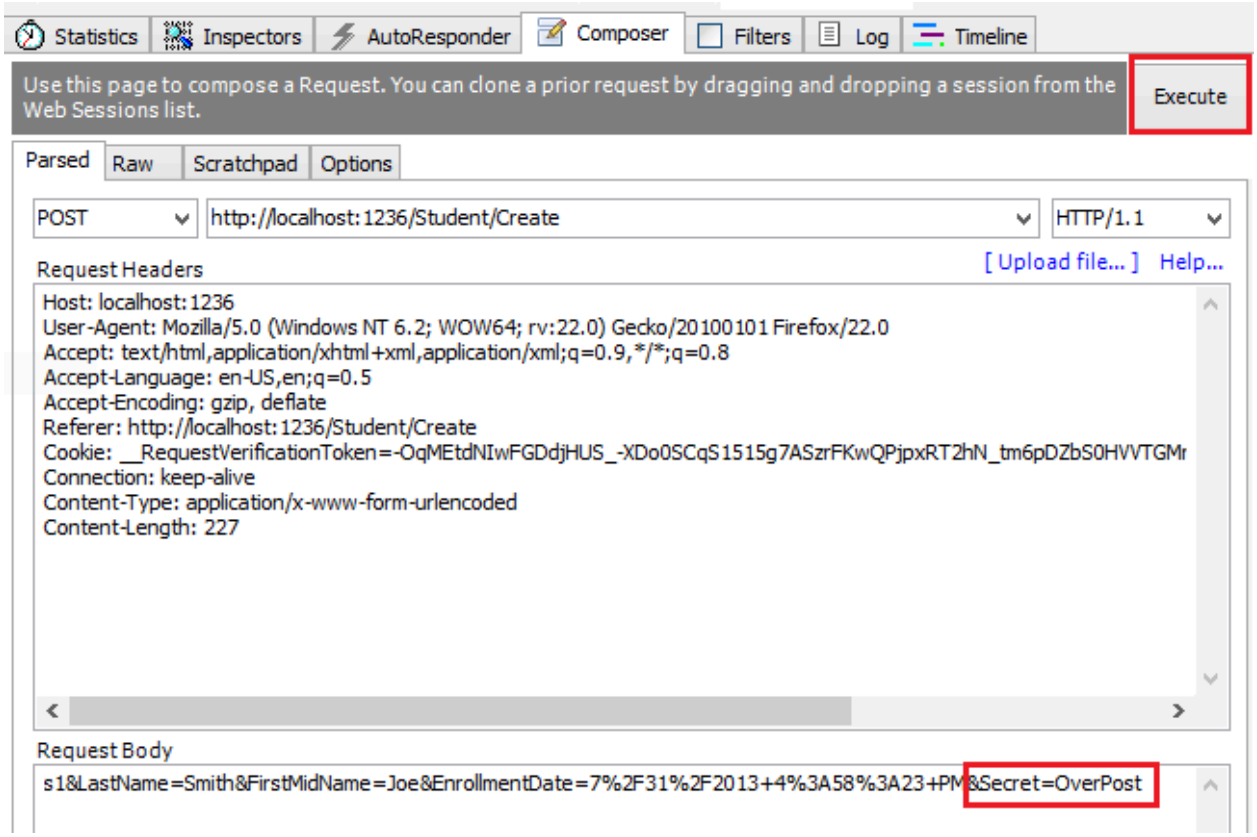
```
            }
        }
        catch (DbUpdateException /* ex */)
        {
            //Log the error (uncomment ex variable name and write a log.
            ModelState.AddModelError("", "Unable to save changes. " +
                "Try again, and if the problem persists " +
                "see your system administrator.");
        }
        return View(student);
    }
```

This code adds the Student entity created by the ASP.NET Core MVC model binder to the Students entity set and then saves the changes to the database. (Model binder refers to the ASP.NET Core MVC functionality that makes it easier for you to work with data submitted by a form; a model binder converts posted form values to CLR types and passes them to the action method in parameters. In this case, the model binder instantiates a Student entity for you using property values from the Form collection.)

You removed `ID` from the `Bind` attribute because ID is the primary key value which SQL Server will set automatically when the row is inserted. Input from the user doesn't set the ID value.

Other than the `Bind` attribute, the try-catch block is the only change you've made to the scaffolded code. If an exception that derives from `DbUpdateException` is caught while the changes are being saved, a generic error message is displayed. `DbUpdateException` exceptions are sometimes caused by something external to the application rather than a programming error, so the user is advised to try again. Although not implemented in this sample, a production quality application would log the exception. For more information, see the **Log for insight** section in Monitoring and Telemetry (Building Real-World Cloud Apps with Azure).

The `ValidateAntiForgeryToken` attribute helps prevent cross-site request forgery (CSRF) attacks. The token is automatically injected into the view by the FormTagHelper and is included when the form is submitted by the user. The token is validated by the `ValidateAntiForgeryToken` attribute. For more information, see Prevent Cross-Site Request Forgery (XSRF/CSRF) attacks in ASP.NET Core.



Security note about overposting

The `Bind` attribute that the scaffolded code includes on the `Create` method is one way to protect against overposting in create scenarios. For example, suppose the Student entity includes a `Secret` property that you don't want this web page to set.

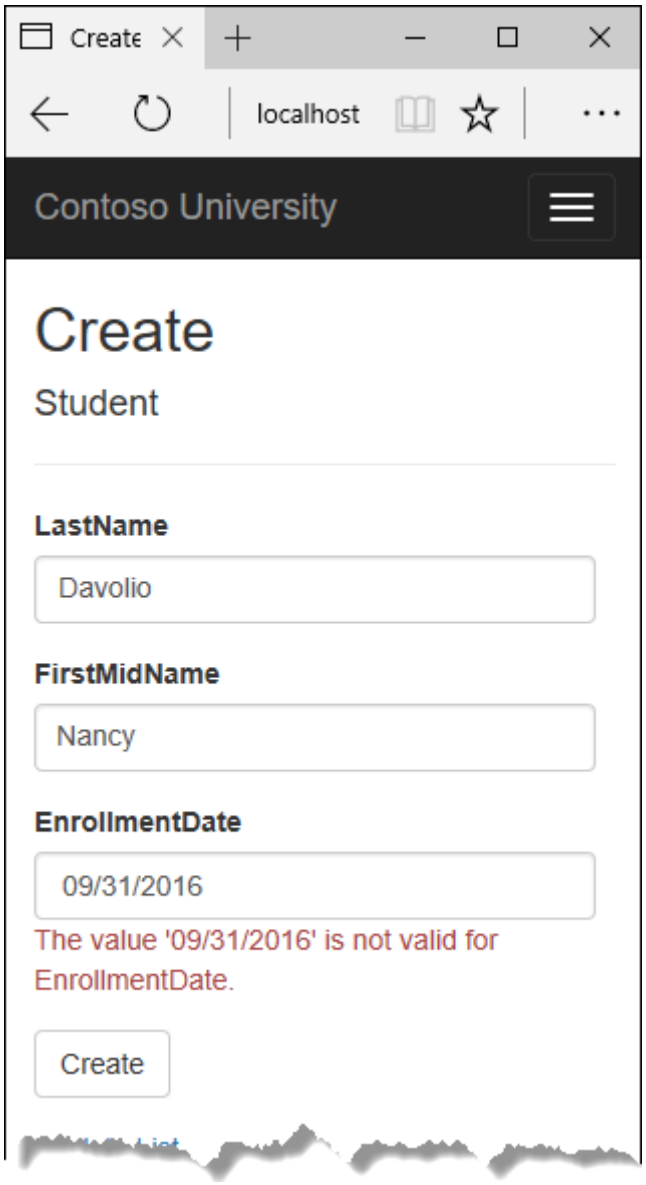
C#

```
public class Student
{
    public int ID { get; set; }
    public string LastName { get; set; }
    public string FirstMidName { get; set; }
    public DateTime EnrollmentDate { get; set; }
    public string Secret { get; set; }
}
```

Even if you don't have a `Secret` field on the web page, a hacker could use a tool such as Fiddler, or write some JavaScript, to post a `Secret` form value. Without the `Bind` attribute limiting the fields that the model binder uses when it creates a Student instance, the model binder would pick up that `Secret` form value and use it to create the Student entity instance. Then whatever value the hacker specified for the `Secret` form field would be updated in your database. The following image shows the Fiddler tool adding the `Secret` field (with the value "OverPost") to the posted form values.

The value "OverPost" would then be successfully added to the `Secret` property of the inserted row, although you never intended that the web page be able to set that property.

You can prevent overposting in edit scenarios by reading the entity from the database first and then calling `TryUpdateModel`, passing in an explicit allowed properties list. That's the method used in these tutorials.



An alternative way to prevent overposting that's preferred by many developers is to use view models rather than entity classes with model binding. Include only the properties you want to update in the view model. Once the MVC model binder has finished, copy the view model properties to the entity instance, optionally using a tool such as AutoMapper. Use `_context.Entry` on the entity instance to set its state to `Unchanged`, and then set `Property("PropertyName").IsModified` to true on each entity property that's included in the view model. This method works in both edit and create scenarios.

Test the Create page

The code in `Views/Students/Create.cshtml` uses `label`, `input`, and `span` (for validation messages) tag helpers for each field.

Run the app, select the **Students** tab, and click **Create New**.

Enter names and a date. Try entering an invalid date if your browser lets you do that. (Some browsers force you to use a date picker.) Then click **Create** to see the error message.

This is server-side validation that you get by default; in a later tutorial you'll see how to add attributes that will generate code for client-side validation also. The following highlighted code shows the model validation check in the `Create` method.

C#

```
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<IActionResult> Create(
    [Bind("EnrollmentDate,FirstMidName,LastName")] Student student)
{
    try
    {
        if (ModelState.IsValid)
        {
            _context.Add(student);
            await _context.SaveChangesAsync();
            return RedirectToAction(nameof(Index));
        }
    }
    catch (DbUpdateException /* ex */)
```

```
    {
        //Log the error (uncomment ex variable name and write a log.
        ModelState.AddModelError("", "Unable to save changes. " +
            "Try again, and if the problem persists " +
            "see your system administrator.");
    }
    return View(student);
}
```

Change the date to a valid value and click **Create** to see the new student appear in the **Index** page.

Update the Edit page

In `StudentController.cs`, the HttpGet `Edit` method (the one without the `HttpPost` attribute) uses the `FirstOrDefaultAsync` method to retrieve the selected Student entity, as you saw in the `Details` method. You don't need to change this method.

Recommended HttpPost Edit code: Read and update

Replace the HttpPost Edit action method with the following code.

C#

```
[HttpPost, ActionName("Edit")]
[ValidateAntiForgeryToken]
public async Task<IActionResult> EditPost(int? id)
{
    if (id == null)
    {
        return NotFound();
    }
    var studentToUpdate = await _context.Students.FirstOrDefaultAsync(s =>
s.ID == id);
    if (await TryUpdateModelAsync<Student>(
        studentToUpdate,
        "",
        s => s.FirstMidName, s => s.LastName, s => s.EnrollmentDate))
    {
        try
        {
            await _context.SaveChangesAsync();
            return RedirectToAction(nameof(Index));
        }
        catch (DbUpdateException /* ex */)
        {
            //Log the error (uncomment ex variable name and write a log.)
            ModelState.AddModelError("", "Unable to save changes. " +
                "Try again, and if the problem persists, " +
```

```
                "see your system administrator.");
        }
    }
    return View(studentToUpdate);
}
```

These changes implement a security best practice to prevent overposting. The scaffolder generated a `Bind` attribute and added the entity created by the model binder to the entity set with a `Modified` flag. That code isn't recommended for many scenarios because the `Bind` attribute clears out any pre-existing data in fields not listed in the `Include` parameter.

The new code reads the existing entity and calls `TryUpdateModel` to update fields in the retrieved entity based on user input in the posted form data. The Entity Framework's automatic change tracking sets the `Modified` flag on the fields that are changed by form input. When the `SaveChanges` method is called, the Entity Framework creates SQL statements to update the database row. Concurrency conflicts are ignored, and only the table columns that were updated by the user are updated in the database. (A later tutorial shows how to handle concurrency conflicts.)

As a best practice to prevent overposting, the fields that you want to be updateable by the **Edit** page are declared in the `TryUpdateModel` parameters. (The empty string preceding the list of fields in the parameter list is for a prefix to use with the form fields names.) Currently there are no extra fields that you're protecting, but listing the fields that you want the model binder to bind ensures that if you add fields to the data model in the future, they're automatically protected until you explicitly add them here.

As a result of these changes, the method signature of the HttpPost `Edit` method is the same as the HttpGet `Edit` method; therefore you've renamed the method `EditPost`.

Alternative HttpPost Edit code: Create and attach

The recommended HttpPost edit code ensures that only changed columns get updated and preserves data in properties that you don't want included for model binding. However, the read-first approach requires an extra database read, and can result in more complex code for handling concurrency conflicts. An alternative is to attach an entity created by the model binder to the EF context and mark it as modified. (Don't update your project with this code, it's only shown to illustrate an optional approach.)

C#

```
public async Task<IActionResult> Edit(int id,
[Bind("ID,EnrollmentDate,FirstMidName,LastName")] Student student)
```

```
{
    if (id != student.ID)
    {
        return NotFound();
    }
    if (ModelState.IsValid)
    {
        try
        {
            _context.Update(student);
            await _context.SaveChangesAsync();
            return RedirectToAction(nameof(Index));
        }
        catch (DbUpdateException /* ex */)
        {
            //Log the error (uncomment ex variable name and write a log.)
            ModelState.AddModelError("", "Unable to save changes. " +
                "Try again, and if the problem persists, " +
                "see your system administrator.");
        }
    }
    return View(student);
}
```

You can use this approach when the web page UI includes all of the fields in the entity and can update any of them.

The scaffolded code uses the create-and-attach approach but only catches `DbUpdateConcurrencyException` exceptions and returns 404 error codes. The example shown catches any database update exception and displays an error message.

Entity States

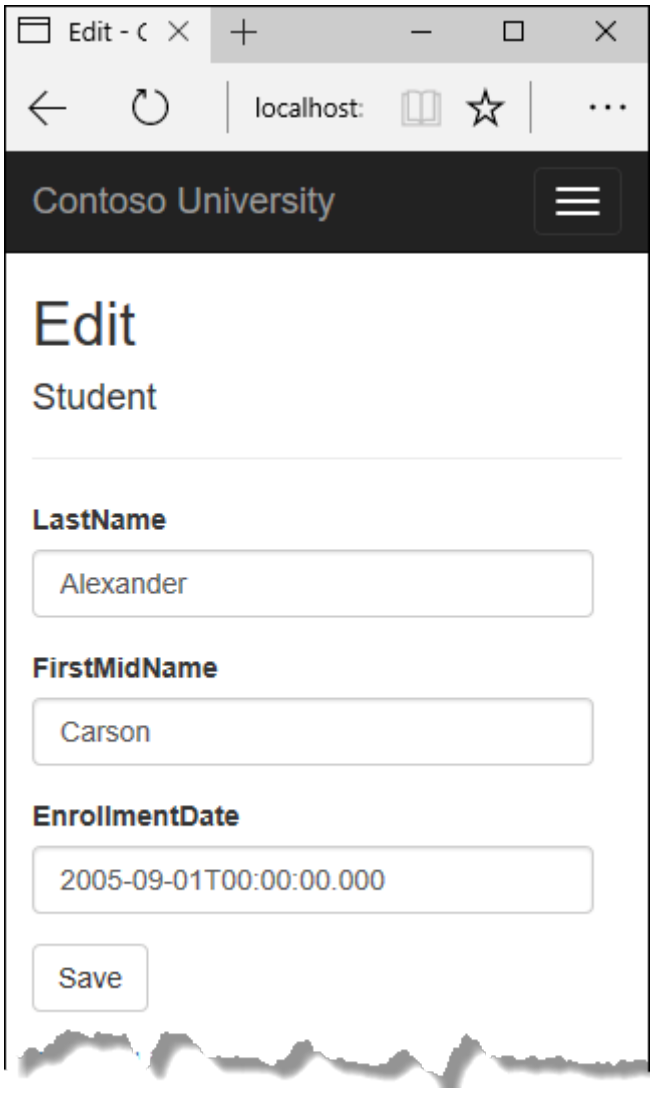
The database context keeps track of whether entities in memory are in sync with their corresponding rows in the database, and this information determines what happens when you call the `SaveChanges` method. For example, when you pass a new entity to the `Add` method, that entity's state is set to `Added`. Then when you call the `SaveChanges` method, the database context issues a SQL INSERT command.

An entity may be in one of the following states:

- `Added`. The entity doesn't yet exist in the database. The `SaveChanges` method issues an INSERT statement.
- `Unchanged`. Nothing needs to be done with this entity by the `SaveChanges` method. When you read an entity from the database, the entity starts out with this status.

- `Modified`. Some or all of the entity's property values have been modified. The `SaveChanges` method issues an UPDATE statement.
- `Deleted`. The entity has been marked for deletion. The `SaveChanges` method issues a DELETE statement.
- `Detached`. The entity isn't being tracked by the database context.

In a desktop application, state changes are typically set automatically. You read an entity and make changes to some of its property values. This causes its entity state to automatically be changed to `Modified`. Then when you call `SaveChanges`, the Entity Framework generates a SQL UPDATE statement that updates only the actual properties that you changed.



In a web app, the `DbContext` that initially reads an entity and displays its data to be edited is disposed after a page is rendered. When the HttpPost `Edit` action method is called, a new web request is made and you have a new instance of the `DbContext`. If you re-read the entity in that new context, you simulate desktop processing.

But if you don't want to do the extra read operation, you have to use the entity object created by the model binder. The simplest way to do this is to set the entity state to Modified as is done in the alternative HttpPost Edit code shown earlier. Then when you call `SaveChanges`, the Entity Framework updates all columns of the database row, because the context has no way to know which properties you changed.

If you want to avoid the read-first approach, but you also want the SQL UPDATE statement to update only the fields that the user actually changed, the code is more complex. You have to save the original values in some way (such as by using hidden fields) so that they're available when the HttpPost `Edit` method is called. Then you can create a Student entity using the original values, call the `Attach` method with that original version of the entity, update the entity's values to the new values, and then call `SaveChanges`.

Test the Edit page

Run the app, select the **Students** tab, then click an **Edit** hyperlink.

Change some of the data and click **Save**. The **Index** page opens and you see the changed data.

Update the Delete page

In `StudentController.cs`, the template code for the HttpGet `Delete` method uses the `FirstOrDefaultAsync` method to retrieve the selected Student entity, as you saw in the Details and Edit methods. However, to implement a custom error message when the call to `SaveChanges` fails, you'll add some functionality to this method and its corresponding view.

As you saw for update and create operations, delete operations require two action methods. The method that's called in response to a GET request displays a view that gives the user a chance to approve or cancel the delete operation. If the user approves it, a POST request is created. When that happens, the HttpPost `Delete` method is called and then that method actually performs the delete operation.

You'll add a try-catch block to the HttpPost `Delete` method to handle any errors that might occur when the database is updated. If an error occurs, the HttpPost Delete

method calls the HttpGet Delete method, passing it a parameter that indicates that an error has occurred. The HttpGet Delete method then redisplays the confirmation page along with the error message, giving the user an opportunity to cancel or try again.

Replace the HttpGet `Delete` action method with the following code, which manages error reporting.

C#

```
public async Task<IActionResult> Delete(int? id, bool? saveChangesError =
false)
{
    if (id == null)
    {
        return NotFound();
    }

    var student = await _context.Students
        .AsNoTracking()
        .FirstOrDefaultAsync(m => m.ID == id);
    if (student == null)
    {
        return NotFound();
    }

    if (saveChangesError.GetValueOrDefault())
    {
        ViewData["ErrorMessage"] =
            "Delete failed. Try again, and if the problem persists " +
            "see your system administrator.";
    }

    return View(student);
}
```

This code accepts an optional parameter that indicates whether the method was called after a failure to save changes. This parameter is false when the HttpGet `Delete` method is called without a previous failure. When it's called by the HttpPost `Delete` method in response to a database update error, the parameter is true and an error message is passed to the view.

The read-first approach to HttpPost Delete

Replace the HttpPost `Delete` action method (named `DeleteConfirmed`) with the following code, which performs the actual delete operation and catches any database update errors.

C#

```
[HttpPost, ActionName("Delete")]
[ValidateAntiForgeryToken]
public async Task<IActionResult> DeleteConfirmed(int id)
{
    var student = await _context.Students.FindAsync(id);
    if (student == null)
    {
        return RedirectToAction(nameof(Index));
    }

    try
    {
        _context.Students.Remove(student);
        await _context.SaveChangesAsync();
        return RedirectToAction(nameof(Index));
    }
    catch (DbUpdateException /* ex */)
    {
        //Log the error (uncomment ex variable name and write a log.)
        return RedirectToAction(nameof(Delete), new { id = id,
saveChangesError = true });
    }
}
```

This code retrieves the selected entity, then calls the `Remove` method to set the entity's status to `Deleted`. When `SaveChanges` is called, a SQL DELETE command is generated.

The create-and-attach approach to HttpPost Delete

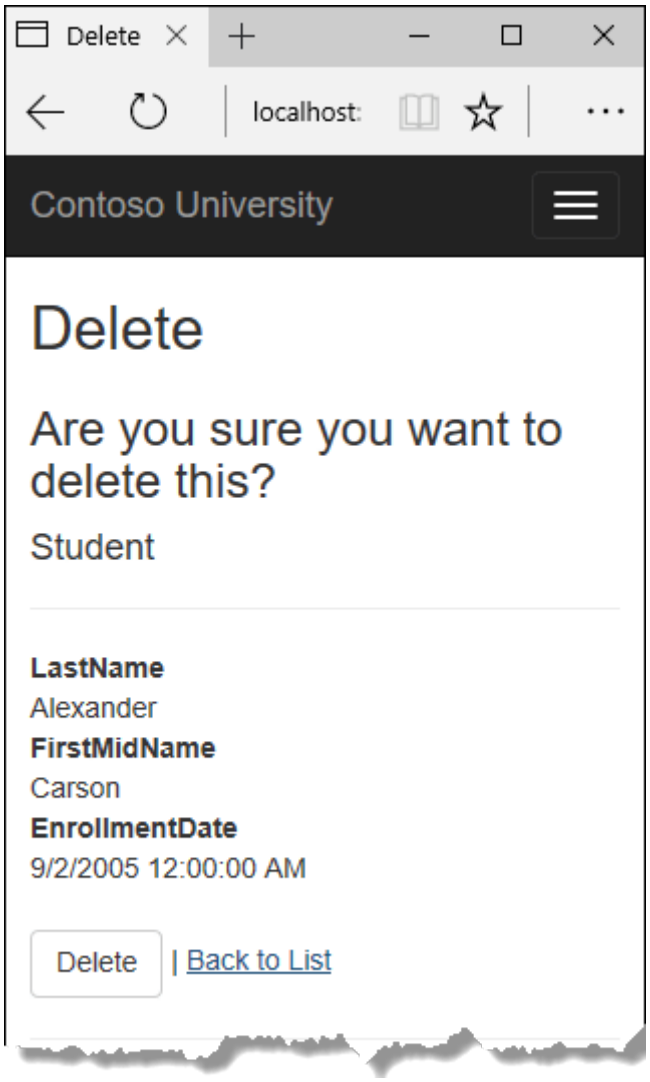
If improving performance in a high-volume application is a priority, you could avoid an unnecessary SQL query by instantiating a Student entity using only the primary key value and then setting the entity state to `Deleted`. That's all that the Entity Framework needs in order to delete the entity. (Don't put this code in your project; it's here just to illustrate an alternative.)

C#

```
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<IActionResult> DeleteConfirmed(int id)
{
    try
    {
        Student studentToDelete = new Student() { ID = id };
        _context.Entry(studentToDelete).State = EntityState.Deleted;
        await _context.SaveChangesAsync();
        return RedirectToAction(nameof(Index));
```

```
    }
    catch (DbUpdateException /* ex */)
    {
        //Log the error (uncomment ex variable name and write a log.)
        return RedirectToAction(nameof(Delete), new { id = id,
saveChangesError = true });
    }
}
```

If the entity has related data that should also be deleted, make sure that cascade delete is configured in the database. With this approach to entity deletion, EF might not realize there are related entities to be deleted.



Update the Delete view

In `Views/Student/Delete.cshtml`, add an error message between the h2 heading and the h3 heading, as shown in the following example:

CSHTML

```
<h2>Delete</h2>
<p class="text-danger">@ViewData["ErrorMessage"]</p>
<h3>Are you sure you want to delete this?</h3>
```

Run the app, select the **Students** tab, and click a **Delete** hyperlink:

Click **Delete**. The Index page is displayed without the deleted student. (You'll see an example of the error handling code in action in the concurrency tutorial.)

Close database connections

To free up the resources that a database connection holds, the context instance must be disposed as soon as possible when you are done with it. The ASP.NET Core built-in dependency injection takes care of that task for you.

In `Startup.cs`, you call the AddDbContext extension method to provision the `DbContext` class in the ASP.NET Core DI container. That method sets the service lifetime to `Scoped` by default. `Scoped` means the context object lifetime coincides with the web request life time, and the `Dispose` method will be called automatically at the end of the web request.

Handle transactions

By default the Entity Framework implicitly implements transactions. In scenarios where you make changes to multiple rows or tables and then call `SaveChanges`, the Entity Framework automatically makes sure that either all of your changes succeed or they all fail. If some changes are done first and then an error happens, those changes are automatically rolled back. For scenarios where you need more control -- for example, if you want to include operations done outside of Entity Framework in a transaction -- see Transactions.

No-tracking queries

When a database context retrieves table rows and creates entity objects that represent them, by default it keeps track of whether the entities in memory are in sync with what's in the database. The data in memory acts as a cache and is used when you update an entity. This caching is often unnecessary in a web application because context instances are typically short-lived (a new one is created and disposed for each request) and the context that reads an entity is typically disposed before that entity is used again.

You can disable tracking of entity objects in memory by calling the `AsNoTracking` method. Typical scenarios in which you might want to do that include the following:

- During the context lifetime you don't need to update any entities, and you don't need EF to automatically load navigation properties with entities retrieved by separate queries. Frequently these conditions are met in a controller's HttpGet action methods.
- You are running a query that retrieves a large volume of data, and only a small portion of the returned data will be updated. It may be more efficient to turn off tracking for the large query, and run a query later for the few entities that need to be updated.
- You want to attach an entity in order to update it, but earlier you retrieved the same entity for a different purpose. Because the entity is already being tracked by the database context, you can't attach the entity that you want to change. One way to handle this situation is to call `AsNoTracking` on the earlier query.

For more information, see Tracking vs. No-Tracking.

Get the code

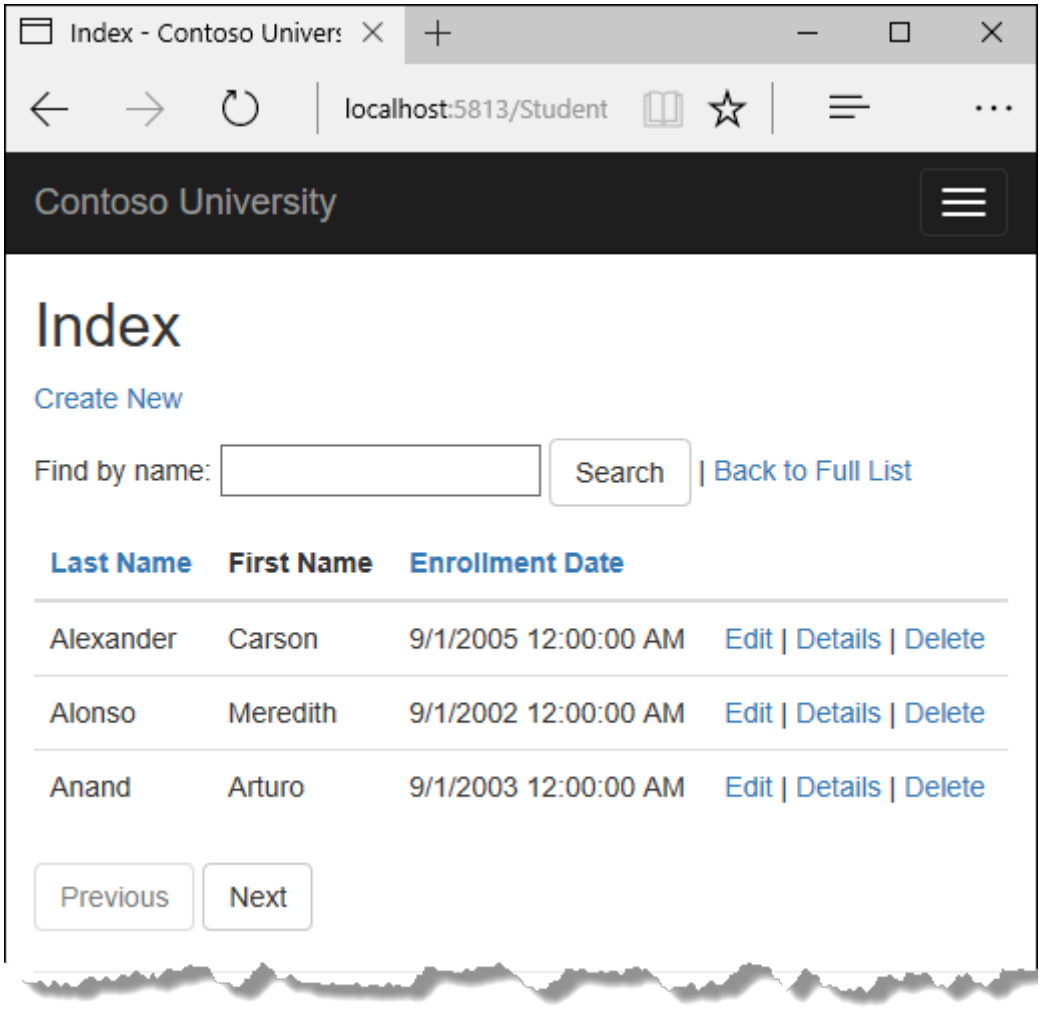
Download or view the completed application.

Next steps

In this tutorial, you:

- ✓ Customized the Details page
- ✓ Updated the Create page
- ✓ Updated the Edit page
- ✓ Updated the Delete page
- ✓ Closed database connections

Advance to the next tutorial to learn how to expand the functionality of the **Index** page by adding sorting, filtering, and paging.



Next: Sorting, filtering, and paging

Tutorial: Add sorting, filtering, and paging - ASP.NET MVC with EF Core

Article • 04/10/2024

In the previous tutorial, you implemented a set of web pages for basic CRUD operations for Student entities. In this tutorial you'll add sorting, filtering, and paging functionality to the Students Index page. You'll also create a page that does simple grouping.

The following illustration shows what the page will look like when you're done. The column headings are links that the user can click to sort by that column. Clicking a column heading repeatedly toggles between ascending and descending sort order.

In this tutorial, you:

- ✓ Add column sort links
- ✓ Add a Search box
- ✓ Add paging to Students Index
- ✓ Add paging to Index method
- ✓ Add paging links

✔ Create an About page

Prerequisites

- Implement CRUD Functionality

Add column sort links

To add sorting to the Student Index page, you'll change the `Index` method of the Students controller and add code to the Student Index view.

Add sorting Functionality to the Index method

In `StudentsController.cs`, replace the `Index` method with the following code:

C#

```
public async Task<IActionResult> Index(string sortOrder)
{
    ViewData["NameSortParm"] = String.IsNullOrEmpty(sortOrder) ? "name_desc"
: "";
    ViewData["DateSortParm"] = sortOrder == "Date" ? "date_desc" : "Date";
    var students = from s in _context.Students
                   select s;
    switch (sortOrder)
    {
        case "name_desc":
            students = students.OrderByDescending(s => s.LastName);
            break;
        case "Date":
            students = students.OrderBy(s => s.EnrollmentDate);
            break;
        case "date_desc":
            students = students.OrderByDescending(s => s.EnrollmentDate);
            break;
        default:
            students = students.OrderBy(s => s.LastName);
            break;
    }
    return View(await students.AsNoTracking().ToListAsync());
}
```

This code receives a `sortOrder` parameter from the query string in the URL. The query string value is provided by ASP.NET Core MVC as a parameter to the action method. The parameter will be a string that's either "Name" or "Date", optionally followed by an

underscore and the string "desc" to specify descending order. The default sort order is ascending.

The first time the Index page is requested, there's no query string. The students are displayed in ascending order by last name, which is the default as established by the fall-through case in the `switch` statement. When the user clicks a column heading hyperlink, the appropriate `sortOrder` value is provided in the query string.

The two `ViewData` elements (NameSortParm and DateSortParm) are used by the view to configure the column heading hyperlinks with the appropriate query string values.

C#

```
public async Task<IActionResult> Index(string sortOrder)
{
    ViewData["NameSortParm"] = String.IsNullOrEmpty(sortOrder) ? "name_desc"
: "";
    ViewData["DateSortParm"] = sortOrder == "Date" ? "date_desc" : "Date";
    var students = from s in _context.Students
                   select s;
    switch (sortOrder)
    {
        case "name_desc":
            students = students.OrderByDescending(s => s.LastName);
            break;
        case "Date":
            students = students.OrderBy(s => s.EnrollmentDate);
            break;
        case "date_desc":
            students = students.OrderByDescending(s => s.EnrollmentDate);
            break;
        default:
            students = students.OrderBy(s => s.LastName);
            break;
    }
    return View(await students.AsNoTracking().ToListAsync());
}
```

These are ternary statements. The first one specifies that if the `sortOrder` parameter is null or empty, NameSortParm should be set to "name_desc"; otherwise, it should be set to an empty string. These two statements enable the view to set the column heading hyperlinks as follows:

Expand table

Current sort order	Last Name Hyperlink	Date Hyperlink
Last Name ascending	descending	ascending

Current sort order	Last Name Hyperlink	Date Hyperlink
Last Name descending	ascending	ascending
Date ascending	ascending	descending
Date descending	ascending	ascending

The method uses LINQ to Entities to specify the column to sort by. The code creates an `IQueryable` variable before the switch statement, modifies it in the switch statement, and calls the `ToListAsync` method after the `switch` statement. When you create and modify `IQueryable` variables, no query is sent to the database. The query isn't executed until you convert the `IQueryable` object into a collection by calling a method such as `ToListAsync`. Therefore, this code results in a single query that's not executed until the `return View` statement.

This code could get verbose with a large number of columns. The last tutorial in this series shows how to write code that lets you pass the name of the `OrderBy` column in a string variable.

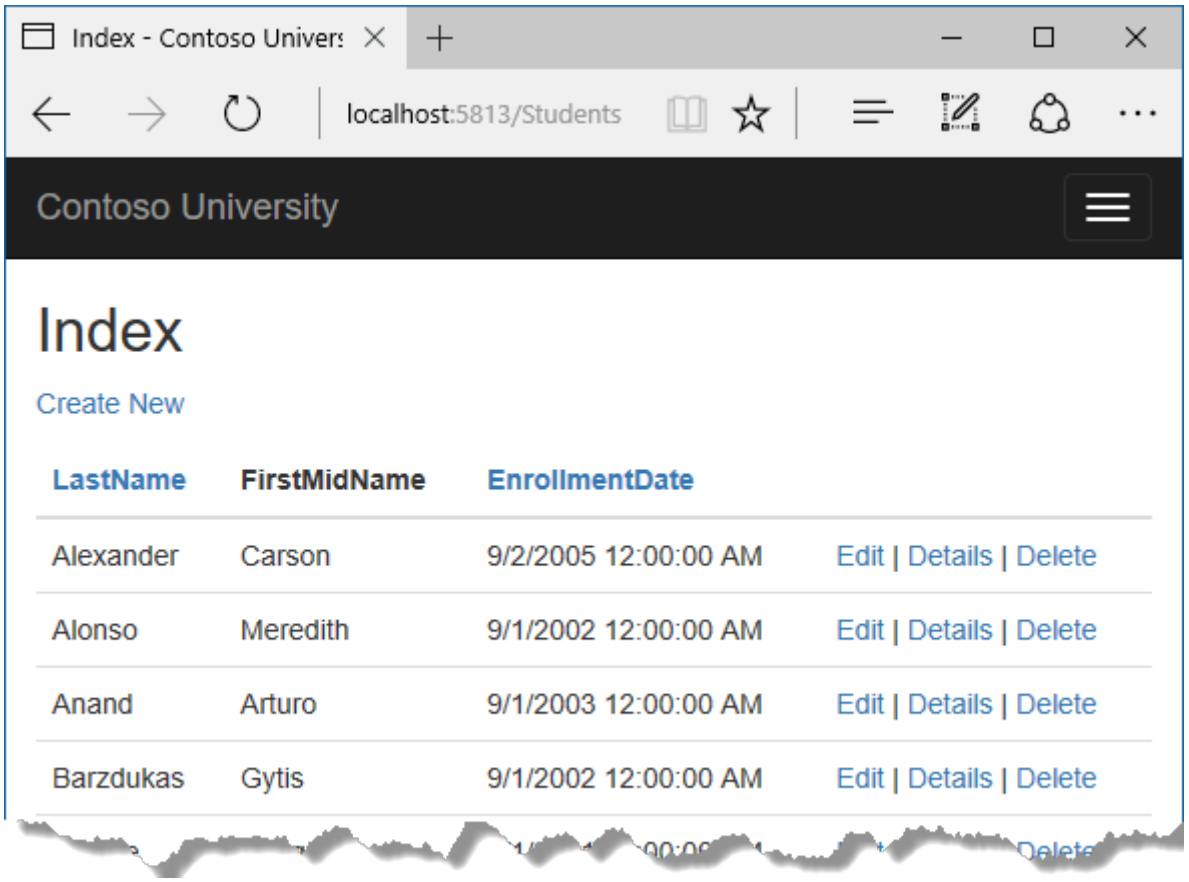
Add column heading hyperlinks to the Student Index view

Replace the code in `Views/Students/Index.cshtml`, with the following code to add column heading hyperlinks. The changed lines are highlighted.

CSHTML

```
@model IEnumerable<ContosoUniversity.Models.Student>

@{
    ViewData["Title"] = "Index";
}



<h2>Index</h2>

<p>
    <a asp-action="Create">Create New</a>
</p>
<table class="table">
    <thead>
        <tr>
                <th>
                    <a asp-action="Index" asp-route-
sortOrder="@ViewData["NameSortParm"]">@Html.DisplayNameFor(model =>
model.LastName)</a>
                </th>
```

```
                <th>
                    @Html.DisplayNameFor(model => model.FirstMidName)
                </th>
                <th>
                    <a asp-action="Index" asp-route-
sortOrder="@ViewData["DateSortParm"]">@Html.DisplayNameFor(model =>
model.EnrollmentDate)</a>
                </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
@foreach (var item in Model) {
        <tr>
            <td>
                @Html.DisplayFor(modelItem => item.LastName)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.FirstMidName)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.EnrollmentDate)
            </td>
            <td>
                <a asp-action="Edit" asp-route-id="@item.ID">Edit</a> |
                <a asp-action="Details" asp-route-id="@item.ID">Details</a>
|
                <a asp-action="Delete" asp-route-id="@item.ID">Delete</a>
            </td>
        </tr>
}
    </tbody>
</table>
```

This code uses the information in `ViewData` properties to set up hyperlinks with the appropriate query string values.

Run the app, select the **Students** tab, and click the **Last Name** and **Enrollment Date** column headings to verify that sorting works.

Add a Search box

To add filtering to the Students Index page, you'll add a text box and a submit button to the view and make corresponding changes in the `Index` method. The text box will let you enter a string to search for in the first name and last name fields.

Add filtering functionality to the Index method

In `StudentsController.cs`, replace the `Index` method with the following code (the changes are highlighted).

C#

```
public async Task<IActionResult> Index(string sortOrder, string
searchString)
{
    ViewData["NameSortParm"] = String.IsNullOrEmpty(sortOrder) ? "name_desc"
: "";
    ViewData["DateSortParm"] = sortOrder == "Date" ? "date_desc" : "Date";
    ViewData["CurrentFilter"] = searchString;

    var students = from s in _context.Students
                   select s;
```

```
    if (!String.IsNullOrEmpty(searchString))
    {
        students = students.Where(s => s.LastName.Contains(searchString)
                               || s.FirstMidName.Contains(searchString));
    }
    switch (sortOrder)
    {
        case "name_desc":
            students = students.OrderByDescending(s => s.LastName);
            break;
        case "Date":
            students = students.OrderBy(s => s.EnrollmentDate);
            break;
        case "date_desc":
            students = students.OrderByDescending(s => s.EnrollmentDate);
            break;
        default:
            students = students.OrderBy(s => s.LastName);
            break;
    }
    return View(await students.AsNoTracking().ToListAsync());
}
```

You've added a `searchString` parameter to the `Index` method. The search string value is received from a text box that you'll add to the Index view. You've also added to the LINQ statement a where clause that selects only students whose first name or last name contains the search string. The statement that adds the where clause is executed only if there's a value to search for.

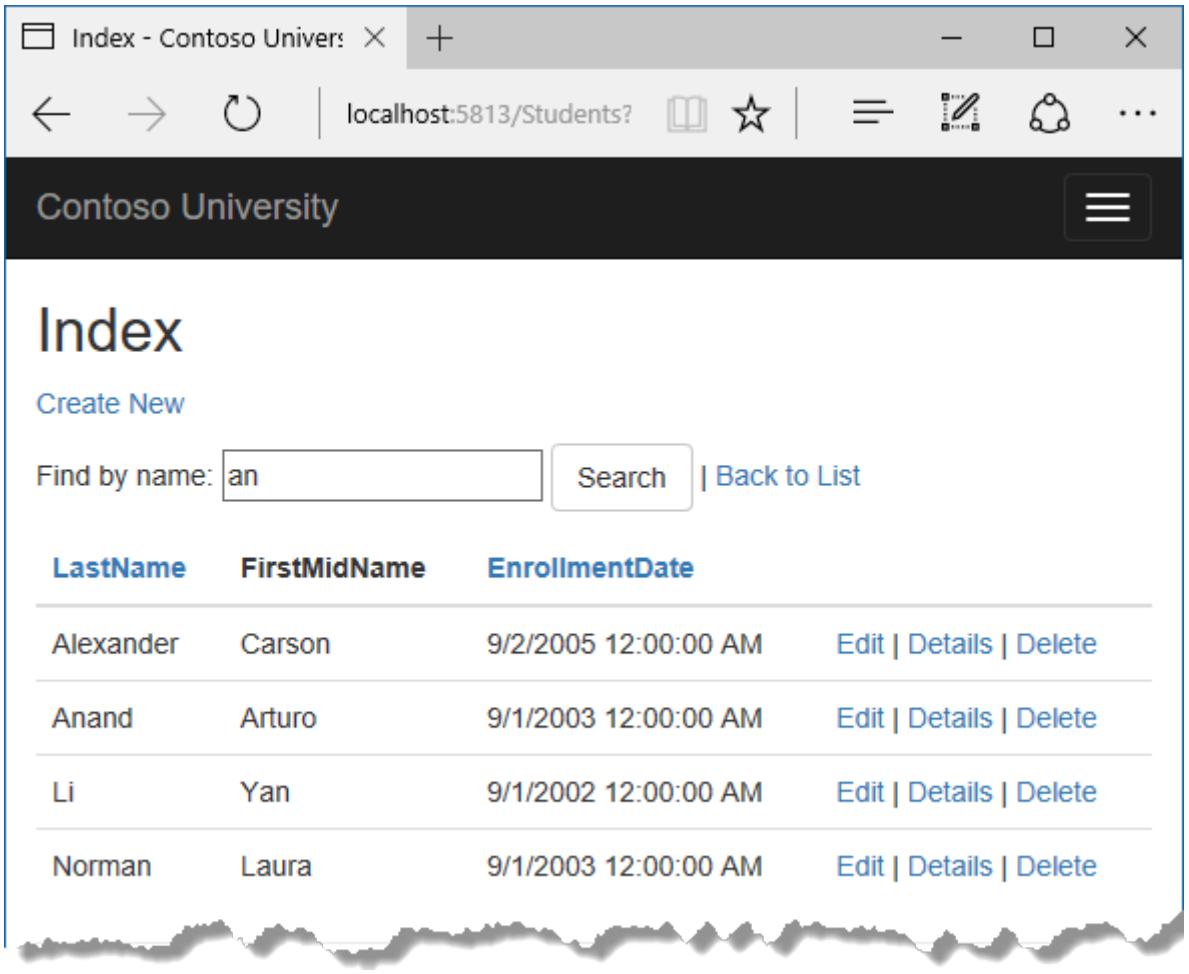
> ⓘ **Note**
>
> Here you are calling the `Where` method on an `IQueryable` object, and the filter will be processed on the server. In some scenarios you might be calling the `Where` method as an extension method on an in-memory collection. (For example, suppose you change the reference to `_context.Students` so that instead of an EF `DbSet` it references a repository method that returns an `IEnumerable` collection.) The result would normally be the same but in some cases may be different.
>
> For example, the .NET Framework implementation of the `Contains` method performs a case-sensitive comparison by default, but in SQL Server this is determined by the collation setting of the SQL Server instance. That setting defaults to case-insensitive. You could call the `ToUpper` method to make the test explicitly case-insensitive: *Where(s => s.LastName.ToUpper().Contains(searchString.ToUpper())*. That would ensure that results stay the same if you change the code later to use a repository which returns an `IEnumerable` collection instead of an `IQueryable` object. (When you call the `Contains` method on an `IEnumerable` collection, you get the

.NET Framework implementation; when you call it on an `IQueryable` object, you get the database provider implementation.) However, there's a performance penalty for this solution. The `ToUpper` code would put a function in the WHERE clause of the TSQL SELECT statement. That would prevent the optimizer from using an index. Given that SQL is mostly installed as case-insensitive, it's best to avoid the `ToUpper` code until you migrate to a case-sensitive data store.

Add a Search Box to the Student Index View

In `Views/Student/Index.cshtml`, add the highlighted code immediately before the opening table tag in order to create a caption, a text box, and a **Search** button.

CSHTML



```
<p>
    <a asp-action="Create">Create New</a>
</p>

<form asp-action="Index" method="get">
    <div class="form-actions no-color">
        <p>
            <label>Find by name: <input type="text" name="SearchString"
value="@ViewData["CurrentFilter"]" /></label>
            <input type="submit" value="Search" class="btn btn-default" /> |
            <a asp-action="Index">Back to Full List</a>
        </p>
    </div>
</form>

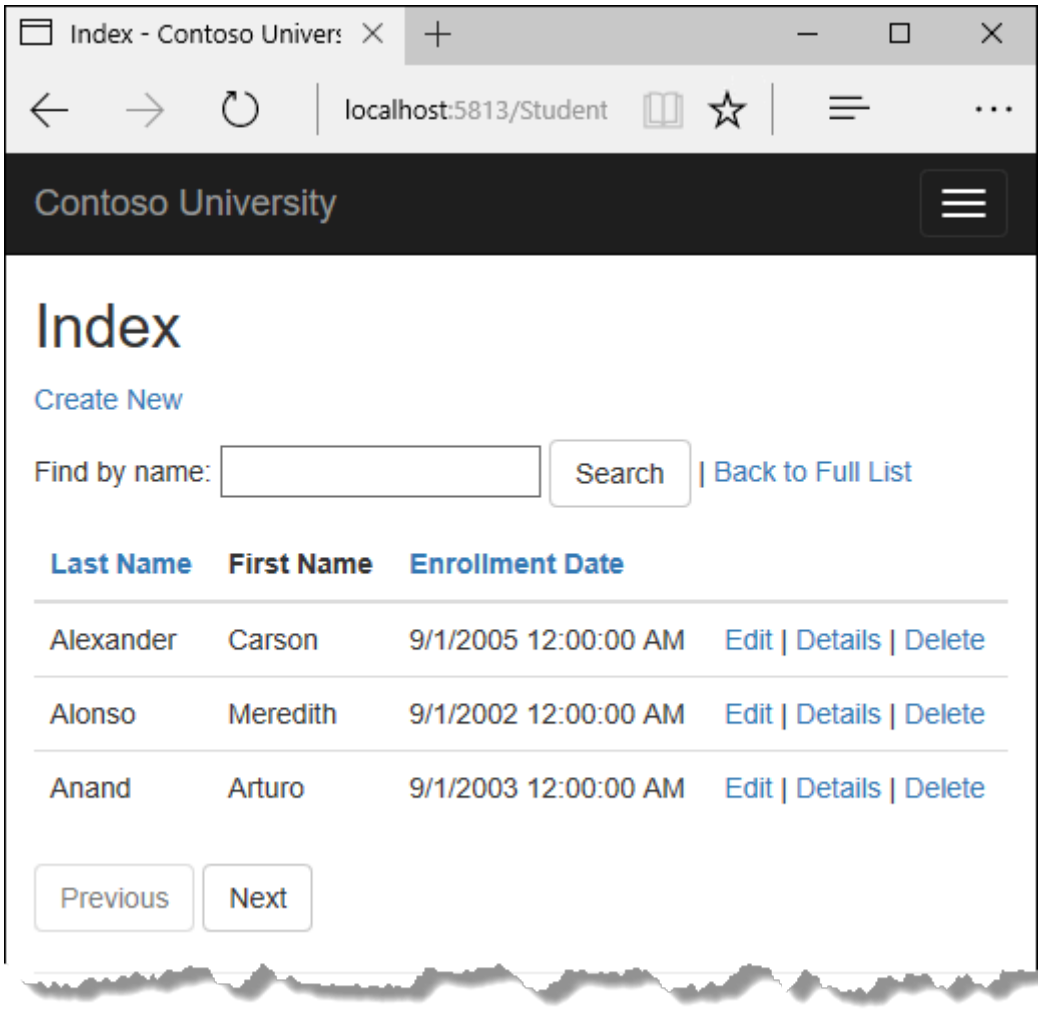
<table class="table">
```

This code uses the `<form>` tag helper to add the search text box and button. By default, the `<form>` tag helper submits form data with a POST, which means that parameters are passed in the HTTP message body and not in the URL as query strings. When you specify HTTP GET, the form data is passed in the URL as query strings, which enables users to bookmark the URL. The W3C guidelines recommend that you should use GET when the action doesn't result in an update.

Run the app, select the **Students** tab, enter a search string, and click Search to verify that filtering is working.

Notice that the URL contains the search string.

```
HTML
```



```
http://localhost:5813/Students?SearchString=an
```

If you bookmark this page, you'll get the filtered list when you use the bookmark. Adding `method="get"` to the `form` tag is what caused the query string to be generated.

At this stage, if you click a column heading sort link you'll lose the filter value that you entered in the **Search** box. You'll fix that in the next section.

Add paging to Students Index

To add paging to the Students Index page, you'll create a `PaginatedList` class that uses `Skip` and `Take` statements to filter data on the server instead of always retrieving all rows of the table. Then you'll make additional changes in the `Index` method and add paging buttons to the `Index` view. The following illustration shows the paging buttons.

In the project folder, create `PaginatedList.cs`, and then replace the template code with the following code.

C#

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;
using Microsoft.EntityFrameworkCore;

namespace ContosoUniversity
{
    public class PaginatedList<T> : List<T>
    {
        public int PageIndex { get; private set; }
        public int TotalPages { get; private set; }

        public PaginatedList(List<T> items, int count, int pageIndex, int
pageSize)
        {
            PageIndex = pageIndex;
            TotalPages = (int)Math.Ceiling(count / (double)pageSize);

            this.AddRange(items);
        }
```

```
        public bool HasPreviousPage => PageIndex > 1;

        public bool HasNextPage => PageIndex < TotalPages;

        public static async Task<PaginatedList<T>> CreateAsync(IQueryable<T>
source, int pageIndex, int pageSize)
        {
            var count = await source.CountAsync();
            var items = await source.Skip((pageIndex - 1) *
pageSize).Take(pageSize).ToListAsync();
            return new PaginatedList<T>(items, count, pageIndex, pageSize);
        }
    }
}
```

The `CreateAsync` method in this code takes page size and page number and applies the appropriate `Skip` and `Take` statements to the `IQueryable`. When `ToListAsync` is called on the `IQueryable`, it will return a List containing only the requested page. The properties `HasPreviousPage` and `HasNextPage` can be used to enable or disable **Previous** and **Next** paging buttons.

A `CreateAsync` method is used instead of a constructor to create the `PaginatedList<T>` object because constructors can't run asynchronous code.

Add paging to Index method

In `StudentsController.cs`, replace the `Index` method with the following code.

C#

```
public async Task<IActionResult> Index(
    string sortOrder,
    string currentFilter,
    string searchString,
    int? pageNumber)
{
    ViewData["CurrentSort"] = sortOrder;
    ViewData["NameSortParm"] = String.IsNullOrEmpty(sortOrder) ? "name_desc"
: "";
    ViewData["DateSortParm"] = sortOrder == "Date" ? "date_desc" : "Date";
```

```
    if (searchString != null)
    {
        pageNumber = 1;
    }
    else
    {
        searchString = currentFilter;
    }

    ViewData["CurrentFilter"] = searchString;

    var students = from s in _context.Students
                   select s;
    if (!String.IsNullOrEmpty(searchString))
    {
        students = students.Where(s => s.LastName.Contains(searchString)
                               || s.FirstMidName.Contains(searchString));
    }
    switch (sortOrder)
    {
        case "name_desc":
            students = students.OrderByDescending(s => s.LastName);
            break;
        case "Date":
            students = students.OrderBy(s => s.EnrollmentDate);
            break;
        case "date_desc":
            students = students.OrderByDescending(s => s.EnrollmentDate);
            break;
        default:
            students = students.OrderBy(s => s.LastName);
            break;
    }

    int pageSize = 3;
    return View(await
PaginatedList<Student>.CreateAsync(students.AsNoTracking(), pageNumber ?? 1,
pageSize));
}
```

This code adds a page number parameter, a current sort order parameter, and a current filter parameter to the method signature.

C#

```
public async Task<IActionResult> Index(
    string sortOrder,
    string currentFilter,
    string searchString,
    int? pageNumber)
```

The first time the page is displayed, or if the user hasn't clicked a paging or sorting link, all the parameters will be null. If a paging link is clicked, the page variable will contain the page number to display.

The `ViewData` element named CurrentSort provides the view with the current sort order, because this must be included in the paging links in order to keep the sort order the same while paging.

The `ViewData` element named CurrentFilter provides the view with the current filter string. This value must be included in the paging links in order to maintain the filter settings during paging, and it must be restored to the text box when the page is redisplayed.

If the search string is changed during paging, the page has to be reset to 1, because the new filter can result in different data to display. The search string is changed when a value is entered in the text box and the Submit button is pressed. In that case, the `searchString` parameter isn't null.

C#

```
if (searchString != null)
{
    pageNumber = 1;
}
else
{
    searchString = currentFilter;
}
```

At the end of the `Index` method, the `PaginatedList.CreateAsync` method converts the student query to a single page of students in a collection type that supports paging. That single page of students is then passed to the view.

C#

```
return View(await
PaginatedList<Student>.CreateAsync(students.AsNoTracking(), pageNumber ?? 1,
pageSize));
```

The `PaginatedList.CreateAsync` method takes a page number. The two question marks represent the null-coalescing operator. The null-coalescing operator defines a default value for a nullable type; the expression `(pageNumber ?? 1)` means return the value of `pageNumber` if it has a value, or return 1 if `pageNumber` is null.

Add paging links

In `Views/Students/Index.cshtml`, replace the existing code with the following code. The changes are highlighted.

CSHTML

```
@model PaginatedList<ContosoUniversity.Models.Student>

@{
    ViewData["Title"] = "Index";
}

<h2>Index</h2>

<p>
    <a asp-action="Create">Create New</a>
</p>

<form asp-action="Index" method="get">
    <div class="form-actions no-color">
        <p>
            <label>Find by name: <input type="text" name="SearchString"
value="@ViewData["CurrentFilter"]" /></label>
            <input type="submit" value="Search" class="btn btn-default" /> |
            <a asp-action="Index">Back to Full List</a>
        </p>
    </div>
</form>

<table class="table">
    <thead>
        <tr>
            <th>
                <a asp-action="Index" asp-route-
sortOrder="@ViewData["NameSortParm"]" asp-route-
currentFilter="@ViewData["CurrentFilter"]">Last Name</a>
            </th>
            <th>
                First Name
            </th>
            <th>
                <a asp-action="Index" asp-route-
sortOrder="@ViewData["DateSortParm"]" asp-route-
currentFilter="@ViewData["CurrentFilter"]">Enrollment Date</a>
            </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
        @foreach (var item in Model)
        {
            <tr>
```

```
                <td>
                    @Html.DisplayFor(modelItem => item.LastName)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.FirstMidName)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.EnrollmentDate)
                </td>
                <td>
                    <a asp-action="Edit" asp-route-id="@item.ID">Edit</a> |
                    <a asp-action="Details" asp-route-
id="@item.ID">Details</a> |
                    <a asp-action="Delete" asp-route-
id="@item.ID">Delete</a>
                </td>
            </tr>
        }
    </tbody>
</table>
```

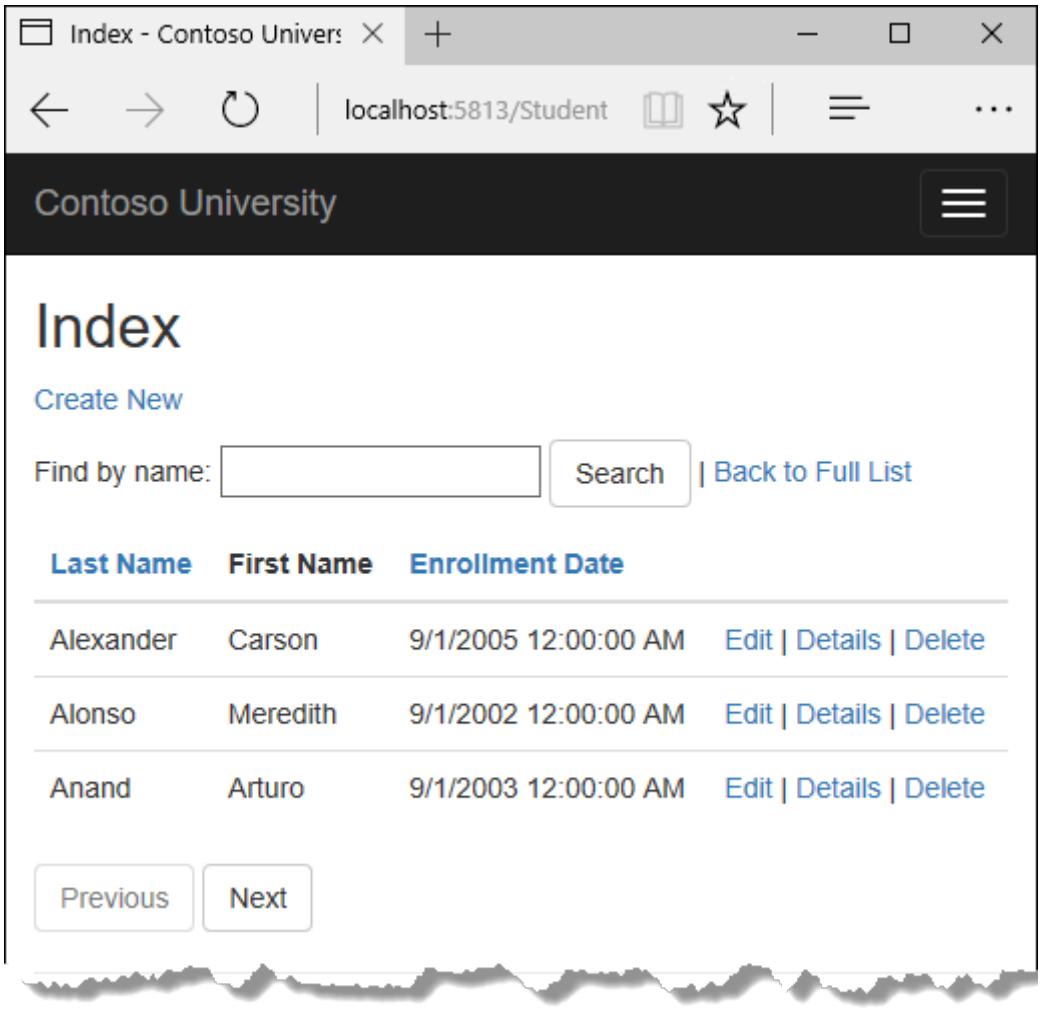
```
@{
    var prevDisabled = !Model.HasPreviousPage ? "disabled" : "";
    var nextDisabled = !Model.HasNextPage ? "disabled" : "";
}

<a asp-action="Index"
   asp-route-sortOrder="@ViewData["CurrentSort"]"
   asp-route-pageNumber="@(Model.PageIndex - 1)"
   asp-route-currentFilter="@ViewData["CurrentFilter"]"
   class="btn btn-default @prevDisabled">
    Previous
</a>
<a asp-action="Index"
   asp-route-sortOrder="@ViewData["CurrentSort"]"
   asp-route-pageNumber="@(Model.PageIndex + 1)"
   asp-route-currentFilter="@ViewData["CurrentFilter"]"
   class="btn btn-default @nextDisabled">
    Next
</a>
```

The `@model` statement at the top of the page specifies that the view now gets a `PaginatedList<T>` object instead of a `List<T>` object.

The column header links use the query string to pass the current search string to the controller so that the user can sort within filter results:

HTML



```
<a asp-action="Index" asp-route-sortOrder="@ViewData["DateSortParm"]" asp-
route-currentFilter ="@ViewData["CurrentFilter"]">Enrollment Date</a>
```

The paging buttons are displayed by tag helpers:

HTML

```
<a asp-action="Index"
   asp-route-sortOrder="@ViewData["CurrentSort"]"
   asp-route-pageNumber="@(Model.PageIndex - 1)"
   asp-route-currentFilter="@ViewData["CurrentFilter"]"
   class="btn btn-default @prevDisabled">
   Previous
</a>
```

Run the app and go to the Students page.

Click the paging links in different sort orders to make sure paging works. Then enter a search string and try paging again to verify that paging also works correctly with sorting and filtering.

Create an About page

For the Contoso University website's **About** page, you'll display how many students have enrolled for each enrollment date. This requires grouping and simple calculations

on the groups. To accomplish this, you'll do the following:

- Create a view model class for the data that you need to pass to the view.
- Create the About method in the Home controller.
- Create the About view.

Create the view model

Create a *SchoolViewModels* folder in the *Models* folder.

In the new folder, add a class file `EnrollmentDateGroup.cs` and replace the template code with the following code:

C#

```
using System;
using System.ComponentModel.DataAnnotations;

namespace ContosoUniversity.Models.SchoolViewModels
{
    public class EnrollmentDateGroup
    {
        [DataType(DataType.Date)]
        public DateTime? EnrollmentDate { get; set; }

        public int StudentCount { get; set; }
    }
}
```

Modify the Home Controller

In `HomeController.cs`, add the following using statements at the top of the file:

C#

```
using Microsoft.EntityFrameworkCore;
using ContosoUniversity.Data;
using ContosoUniversity.Models.SchoolViewModels;
using Microsoft.Extensions.Logging;
```

Add a class variable for the database context immediately after the opening curly brace for the class, and get an instance of the context from ASP.NET Core DI:

C#

```
public class HomeController : Controller
{
    private readonly ILogger<HomeController> _logger;
    private readonly SchoolContext _context;

    public HomeController(ILogger<HomeController> logger, SchoolContext
context)
    {
        _logger = logger;
        _context = context;
    }
```

Add an `About` method with the following code:

C#

```
public async Task<ActionResult> About()
{
    IQueryable<EnrollmentDateGroup> data =
        from student in _context.Students
        group student by student.EnrollmentDate into dateGroup
        select new EnrollmentDateGroup()
        {
            EnrollmentDate = dateGroup.Key,
            StudentCount = dateGroup.Count()
        };
    return View(await data.AsNoTracking().ToListAsync());
}
```

The LINQ statement groups the student entities by enrollment date, calculates the number of entities in each group, and stores the results in a collection of `EnrollmentDateGroup` view model objects.

Create the About View

Add a `Views/Home/About.cshtml` file with the following code:

CSHTML

```
@model
IEnumerable<ContosoUniversity.Models.SchoolViewModels.EnrollmentDateGroup>

@{
    ViewData["Title"] = "Student Body Statistics";
}

<h2>Student Body Statistics</h2>
```

```
<table>
    <tr>
        <th>
            Enrollment Date
        </th>
        <th>
            Students
        </th>
    </tr>

    @foreach (var item in Model)
    {
        <tr>
            <td>
                @Html.DisplayFor(modelItem => item.EnrollmentDate)
            </td>
            <td>
                @item.StudentCount
            </td>
        </tr>
    }
</table>
```

Run the app and go to the About page. The count of students for each enrollment date is displayed in a table.

Get the code

Download or view the completed application.

Next steps

In this tutorial, you:

- ✓ Added column sort links
- ✓ Added a Search box
- ✓ Added paging to Students Index
- ✓ Added paging to Index method
- ✓ Added paging links
- ✓ Created an About page

Advance to the next tutorial to learn how to handle data model changes by using migrations.

Next: Handle data model changes

Tutorial: Part 5, apply migrations to the Contoso University sample

Article • 05/31/2024

In this tutorial, you start using the EF Core migrations feature for managing data model changes. In later tutorials, you'll add more migrations as you change the data model.

In this tutorial, you:

- ✓ Learn about migrations
- ✓ Create an initial migration
- ✓ Examine Up and Down methods
- ✓ Learn about the data model snapshot
- ✓ Apply the migration

Prerequisites

- Sorting, filtering, and paging

About migrations

When you develop a new application, your data model changes frequently, and each time the model changes, it gets out of sync with the database. You started these tutorials by configuring the Entity Framework to create the database if it doesn't exist. Then each time you change the data model -- add, remove, or change entity classes or change your DbContext class -- you can delete the database and EF creates a new one that matches the model, and seeds it with test data.

This method of keeping the database in sync with the data model works well until you deploy the application to production. When the application is running in production it's usually storing data that you want to keep, and you don't want to lose everything each time you make a change such as adding a new column. The EF Core Migrations feature solves this problem by enabling EF to update the database schema instead of creating a new database.

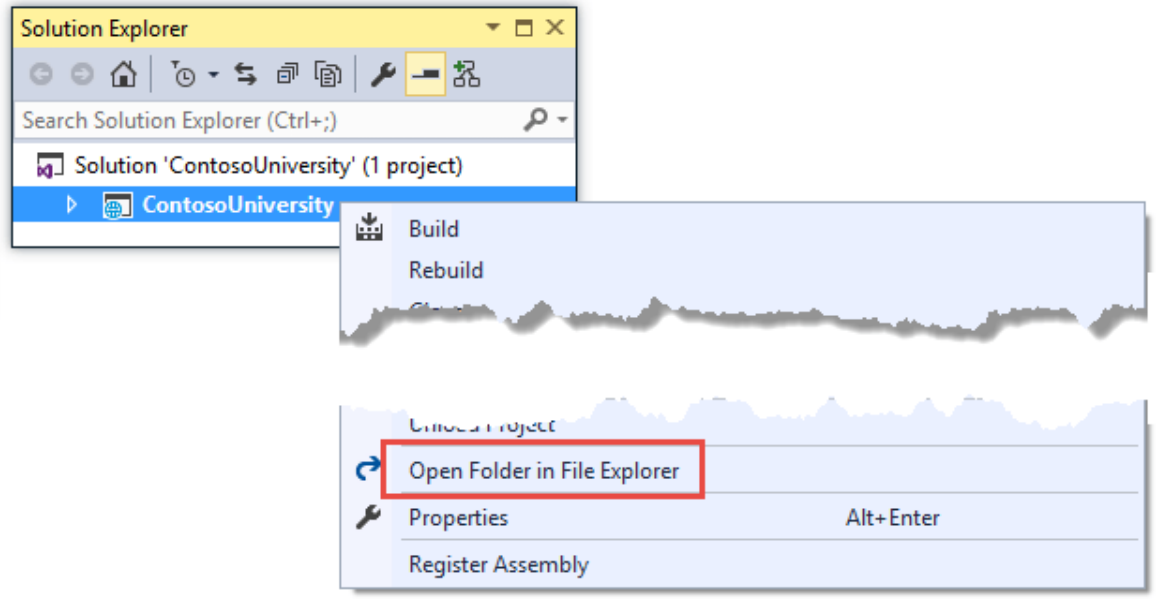
To work with migrations, you can use the **Package Manager Console** (PMC) or the CLI. These tutorials show how to use CLI commands. Information about the PMC is at the end of this tutorial.

Drop the database

Install EF Core tools as a global tool and delete the database:

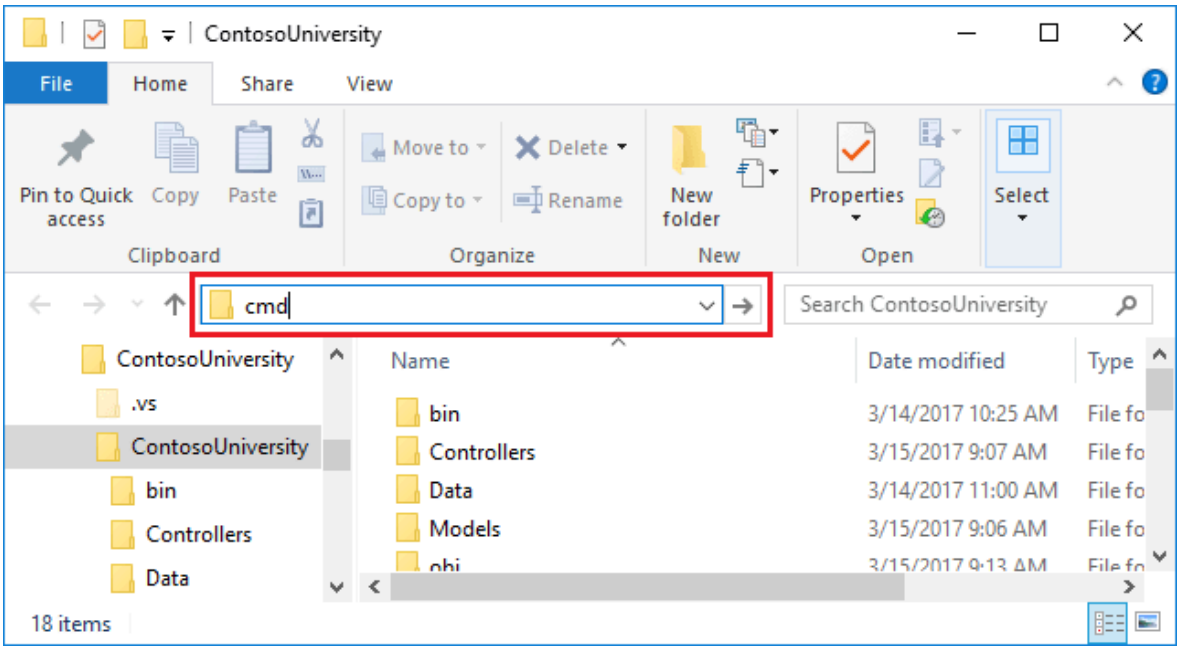
.NET CLI

```
dotnet tool install --global dotnet-ef
dotnet ef database drop
```



> **Note**
>
> By default the architecture of the .NET binaries to install represents the currently running OS architecture. To specify a different OS architecture, see dotnet tool install, --arch option. For more information, see GitHub issue dotnet/AspNetCore.Docs #29262.

The following section explains how to run CLI commands.



Create an initial migration

Save your changes and build the project. Then open a command window and navigate to the project folder. Here's a quick way to do that:

- In **Solution Explorer**, right-click the project and choose **Open Folder in File Explorer** from the context menu.

- Enter "cmd" in the address bar and press Enter.

Enter the following command in the command window:

.NET CLI

```
dotnet ef migrations add InitialCreate
```

In the preceding commands, output similar to the following is displayed:

Console

```
info: Microsoft.EntityFrameworkCore.Infrastructure[10403]
      Entity Framework Core initialized 'SchoolContext' using provider
'Microsoft.EntityFrameworkCore.SqlServer' with options: None
Done. To undo this action, use 'ef migrations remove'
```

If you see an error message "*cannot access the file ... ContosoUniversity.dll because it is being used by another process.*", find the IIS Express icon in the Windows System Tray, and right-click it, then click **ContosoUniversity** > **Stop Site**.

Examine Up and Down methods

When you executed the `migrations add` command, EF generated the code that will create the database from scratch. This code is in the *Migrations* folder, in the file named `<timestamp>_InitialCreate.cs`. The `Up` method of the `InitialCreate` class creates the database tables that correspond to the data model entity sets, and the `Down` method deletes them, as shown in the following example.

C#

```
public partial class InitialCreate : Migration
{
    protected override void Up(MigrationBuilder migrationBuilder)
    {
        migrationBuilder.CreateTable(
            name: "Course",
            columns: table => new
            {
                CourseID = table.Column<int>(nullable: false),
                Credits = table.Column<int>(nullable: false),
                Title = table.Column<string>(nullable: true)
            },
            constraints: table =>
            {
                table.PrimaryKey("PK_Course", x => x.CourseID);
            });

        // Additional code not shown
    }

    protected override void Down(MigrationBuilder migrationBuilder)
    {
        migrationBuilder.DropTable(
            name: "Enrollment");
        // Additional code not shown
    }
}
```

Migrations calls the `Up` method to implement the data model changes for a migration. When you enter a command to roll back the update, Migrations calls the `Down` method.

This code is for the initial migration that was created when you entered the `migrations add InitialCreate` command. The migration name parameter ("InitialCreate" in the example) is used for the file name and can be whatever you want. It's best to choose a word or phrase that summarizes what is being done in the migration. For example, you might name a later migration "AddDepartmentTable".

If you created the initial migration when the database already exists, the database creation code is generated but it doesn't have to run because the database already matches the data model. When you deploy the app to another environment where the database doesn't exist yet, this code will run to create your database, so it's a good idea to test it first. That's why you dropped the database earlier -- so that migrations can create a new one from scratch.

The data model snapshot

Migrations creates a *snapshot* of the current database schema in `Migrations/SchoolContextModelSnapshot.cs`. When you add a migration, EF determines what changed by comparing the data model to the snapshot file.

Use the dotnet ef migrations remove command to remove a migration. `dotnet ef migrations remove` deletes the migration and ensures the snapshot is correctly reset. If `dotnet ef migrations remove` fails, use `dotnet ef migrations remove -v` to get more information on the failure.

See EF Core Migrations in Team Environments for more information about how the snapshot file is used.

Apply the migration

In the command window, enter the following command to create the database and tables in it.

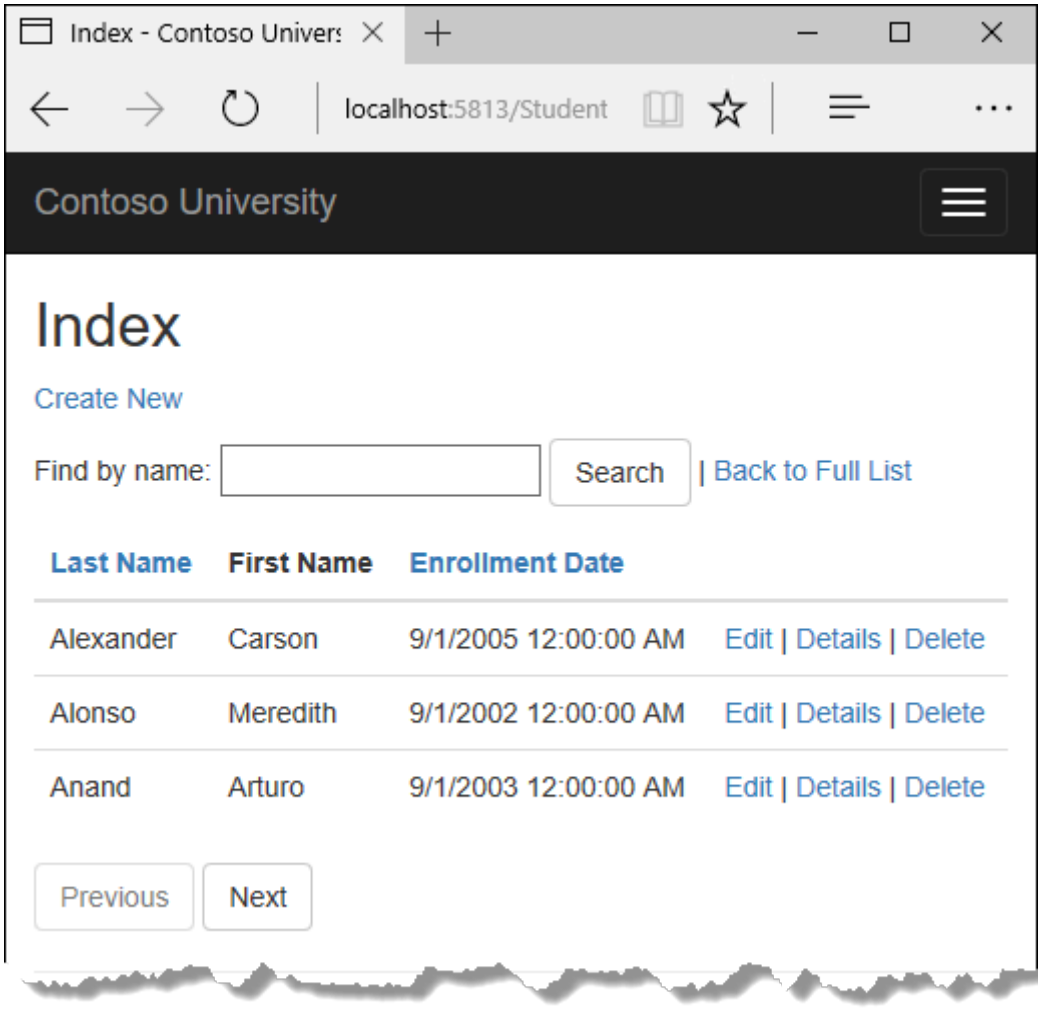
.NET CLI

```
dotnet ef database update
```

The output from the command is similar to the `migrations add` command, except that you see logs for the SQL commands that set up the database. Most of the logs are omitted in the following sample output. If you prefer not to see this level of detail in log messages, you can change the log level in the `appsettings.Development.json` file. For more information, see Logging in .NET Core and ASP.NET Core.

text

```
info: Microsoft.EntityFrameworkCore.Infrastructure[10403]
      Entity Framework Core initialized 'SchoolContext' using provider
'Microsoft.EntityFrameworkCore.SqlServer' with options: None
info: Microsoft.EntityFrameworkCore.Database.Command[20101]
      Executed DbCommand (274ms) [Parameters=[], CommandType='Text',
CommandTimeout='60']
      CREATE DATABASE [ContosoUniversity2];
info: Microsoft.EntityFrameworkCore.Database.Command[20101]
      Executed DbCommand (60ms) [Parameters=[], CommandType='Text',
CommandTimeout='60']
      IF SERVERPROPERTY('EngineEdition') <> 5
      BEGIN
          ALTER DATABASE [ContosoUniversity2] SET READ_COMMITTED_SNAPSHOT
ON;
      END;
info: Microsoft.EntityFrameworkCore.Database.Command[20101]
      Executed DbCommand (15ms) [Parameters=[], CommandType='Text',
```



```
CommandTimeout='30']
      CREATE TABLE [__EFMigrationsHistory] (
          [MigrationId] nvarchar(150) NOT NULL,
          [ProductVersion] nvarchar(32) NOT NULL,
          CONSTRAINT [PK___EFMigrationsHistory] PRIMARY KEY ([MigrationId])
      );

<logs omitted for brevity>

info: Microsoft.EntityFrameworkCore.Database.Command[20101]
      Executed DbCommand (3ms) [Parameters=[], CommandType='Text',
CommandTimeout='30']
      INSERT INTO [__EFMigrationsHistory] ([MigrationId], [ProductVersion])
      VALUES (N'20190327172701_InitialCreate', N'5.0-rtm');
Done.
```

Use **SQL Server Object Explorer** to inspect the database as you did in the first tutorial. You'll notice the addition of an __EFMigrationsHistory table that keeps track of which migrations have been applied to the database. View the data in that table and you'll see one row for the first migration. (The last log in the preceding CLI output example shows the INSERT statement that creates this row.)

Run the application to verify that everything still works the same as before.

Compare CLI and PMC

The EF tooling for managing migrations is available from .NET CLI commands or from PowerShell cmdlets in the Visual Studio **Package Manager Console** (PMC) window. This tutorial shows how to use the CLI, but you can use the PMC if you prefer.

The EF commands for the PMC commands are in the Microsoft.EntityFrameworkCore.Tools package. This package is included in the Microsoft.AspNetCore.App metapackage, so you don't need to add a package reference if your app has a package reference for `Microsoft.AspNetCore.App`.

Important: This isn't the same package as the one you install for the CLI by editing the `.csproj` file. The name of this one ends in `Tools`, unlike the CLI package name which ends in `Tools.DotNet`.

For more information about the CLI commands, see .NET CLI.

For more information about the PMC commands, see Package Manager Console (Visual Studio).

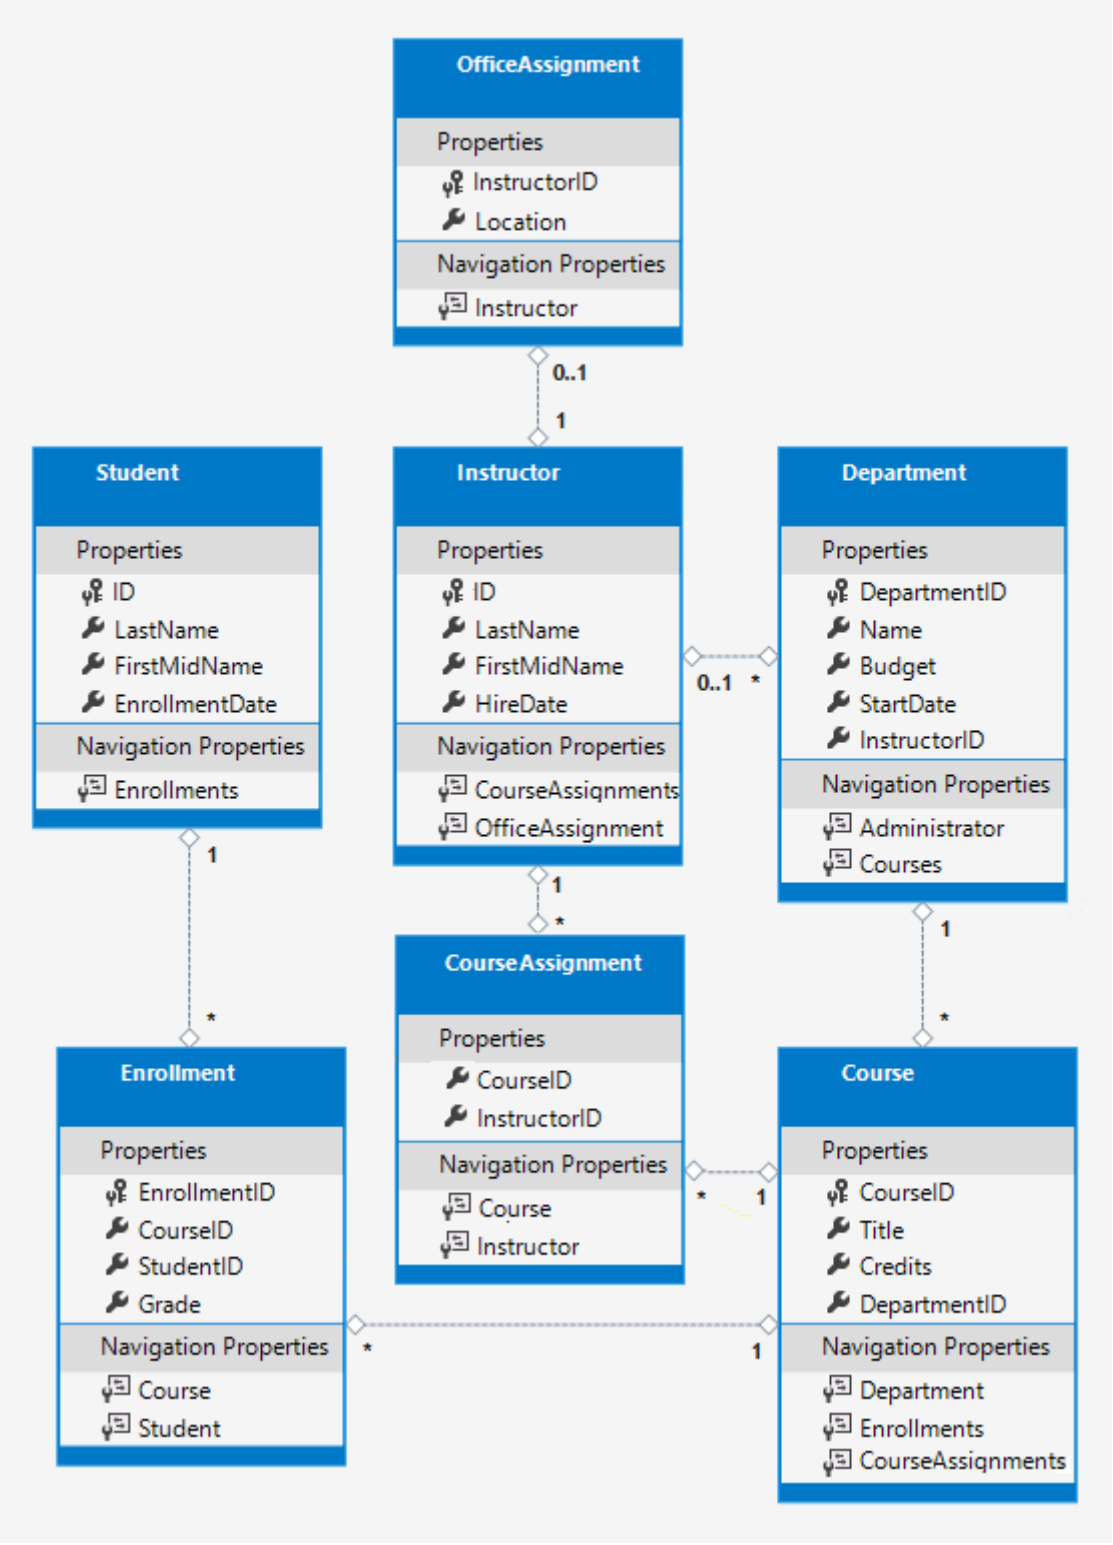
Next step

Advance to the next tutorial to begin looking at more advanced topics about expanding the data model. Along the way you'll create and apply additional migrations.



Create and apply additional migrations

Tutorial: Create a complex data model - ASP.NET MVC with EF Core

Article • 04/10/2024

In the previous tutorials, you worked with a simple data model that was composed of three entities. In this tutorial, you'll add more entities and relationships and you'll customize the data model by specifying formatting, validation, and database mapping rules.

When you're finished, the entity classes will make up the completed data model that's shown in the following illustration:

In this tutorial, you:

- ✓ Customize the Data model
- ✓ Make changes to Student entity
- ✓ Create Instructor entity
- ✓ Create OfficeAssignment entity
- ✓ Modify Course entity
- ✓ Create Department entity
- ✓ Modify Enrollment entity
- ✓ Update the database context

- ✓ Seed database with test data
- ✓ Add a migration
- ✓ Change the connection string
- ✓ Update the database

Prerequisites

- Using EF Core migrations

Customize the Data model

In this section you'll see how to customize the data model by using attributes that specify formatting, validation, and database mapping rules. Then in several of the following sections you'll create the complete School data model by adding attributes to the classes you already created and creating new classes for the remaining entity types in the model.

The DataType attribute

For student enrollment dates, all of the web pages currently display the time along with the date, although all you care about for this field is the date. By using data annotation attributes, you can make one code change that will fix the display format in every view that shows the data. To see an example of how to do that, you'll add an attribute to the `EnrollmentDate` property in the `Student` class.

In `Models/Student.cs`, add a `using` statement for the `System.ComponentModel.DataAnnotations` namespace and add `DataType` and `DisplayFormat` attributes to the `EnrollmentDate` property, as shown in the following example:

C#

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;

namespace ContosoUniversity.Models
{
    public class Student
    {
        public int ID { get; set; }
        public string LastName { get; set; }
        public string FirstMidName { get; set; }
```

```
        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}",
ApplyFormatInEditMode = true)]
        public DateTime EnrollmentDate { get; set; }

        public ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

The `DataType` attribute is used to specify a data type that's more specific than the database intrinsic type. In this case we only want to keep track of the date, not the date and time. The `DataType` Enumeration provides for many data types, such as Date, Time, PhoneNumber, Currency, EmailAddress, and more. The `DataType` attribute can also enable the application to automatically provide type-specific features. For example, a `mailto:` link can be created for `DataType.EmailAddress`, and a date selector can be provided for `DataType.Date` in browsers that support HTML5. The `DataType` attribute emits HTML 5 `data-` (pronounced data dash) attributes that HTML 5 browsers can understand. The `DataType` attributes don't provide any validation.

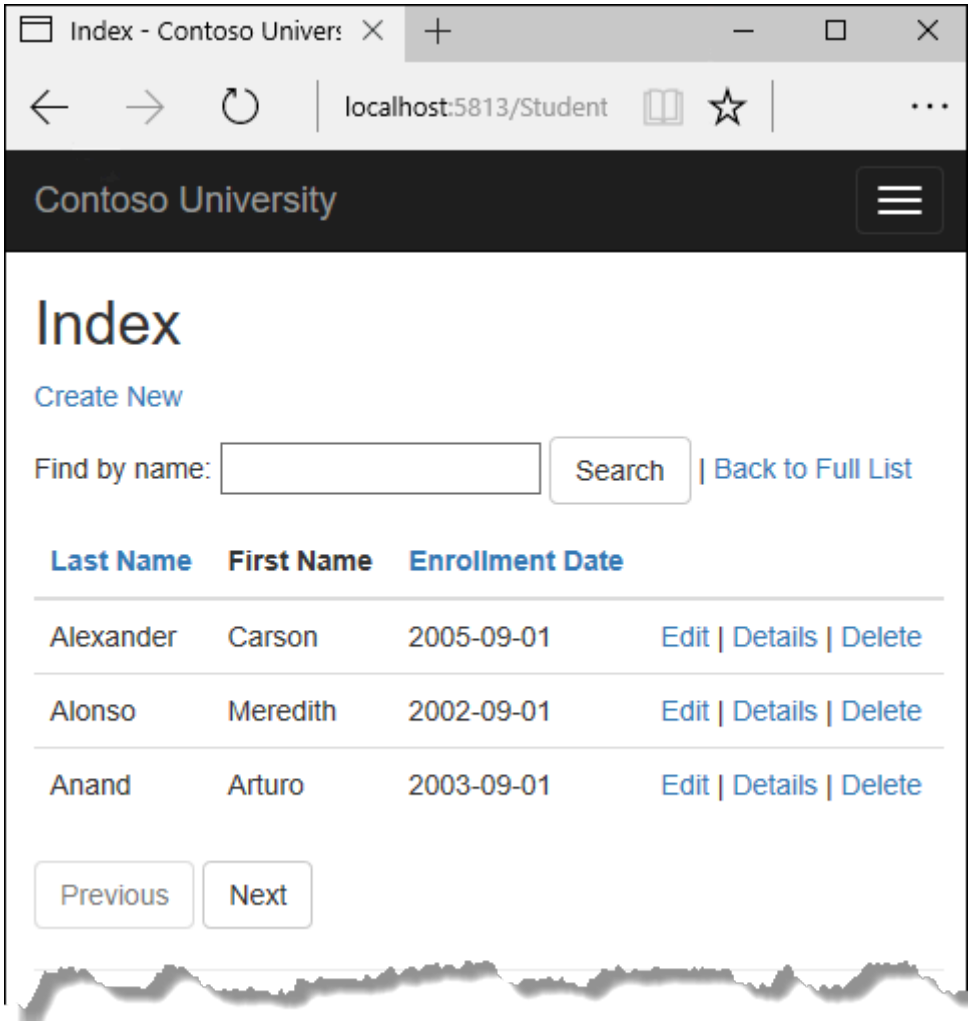
`DataType.Date` doesn't specify the format of the date that's displayed. By default, the data field is displayed according to the default formats based on the server's CultureInfo.

The `DisplayFormat` attribute is used to explicitly specify the date format:

C#

```
[DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode =
true)]
```

The `ApplyFormatInEditMode` setting specifies that the formatting should also be applied when the value is displayed in a text box for editing. (You might not want that for some fields -- for example, for currency values, you might not want the currency symbol in the text box for editing.)



You can use the `DisplayFormat` attribute by itself, but it's generally a good idea to use the `DataType` attribute also. The `DataType` attribute conveys the semantics of the data as opposed to how to render it on a screen, and provides the following benefits that you don't get with `DisplayFormat`:

- The browser can enable HTML5 features (for example to show a calendar control, the locale-appropriate currency symbol, email links, some client-side input validation, etc.).

- By default, the browser will render data using the correct format based on your locale.

For more information, see the <input> tag helper documentation.

Run the app, go to the Students Index page and notice that times are no longer displayed for the enrollment dates. The same will be true for any view that uses the Student model.

The StringLength attribute

You can also specify data validation rules and validation error messages using attributes. The `StringLength` attribute sets the maximum length in the database and provides client side and server side validation for ASP.NET Core MVC. You can also specify the minimum string length in this attribute, but the minimum value has no impact on the database schema.

Suppose you want to ensure that users don't enter more than 50 characters for a name. To add this limitation, add `StringLength` attributes to the `LastName` and `FirstMidName` properties, as shown in the following example:

C#

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;

namespace ContosoUniversity.Models
{
    public class Student
    {
        public int ID { get; set; }
        [StringLength(50)]
        public string LastName { get; set; }
        [StringLength(50)]
        public string FirstMidName { get; set; }
        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}",
ApplyFormatInEditMode = true)]
        public DateTime EnrollmentDate { get; set; }

        public ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

The `StringLength` attribute won't prevent a user from entering white space for a name. You can use the `RegularExpression` attribute to apply restrictions to the input. For example, the following code requires the first character to be upper case and the remaining characters to be alphabetical:

C#

```
[RegularExpression(@"^[A-Z]+[a-zA-Z]*$")]
```

The `MaxLength` attribute provides functionality similar to the `StringLength` attribute but doesn't provide client side validation.

The database model has now changed in a way that requires a change in the database schema. You'll use migrations to update the schema without losing any data that you may have added to the database by using the application UI.

Save your changes and build the project. Then open the command window in the project folder and enter the following commands:

.NET CLI

```
dotnet ef migrations add MaxLengthOnNames
```

.NET CLI

```
dotnet ef database update
```

The `migrations add` command warns that data loss may occur, because the change makes the maximum length shorter for two columns. Migrations creates a file named `<timeStamp>_MaxLengthOnNames.cs`. This file contains code in the `Up` method that will update the database to match the current data model. The `database update` command ran that code.

The timestamp prefixed to the migrations file name is used by Entity Framework to order the migrations. You can create multiple migrations before running the update-database command, and then all of the migrations are applied in the order in which they were created.

Run the app, select the **Students** tab, click **Create New**, and try to enter either name longer than 50 characters. The application should prevent you from doing this.

The Column attribute

You can also use attributes to control how your classes and properties are mapped to the database. Suppose you had used the name `FirstMidName` for the first-name field because the field might also contain a middle name. But you want the database column to be named `FirstName`, because users who will be writing ad-hoc queries against the database are accustomed to that name. To make this mapping, you can use the `Column` attribute.

The `Column` attribute specifies that when the database is created, the column of the `Student` table that maps to the `FirstMidName` property will be named `FirstName`. In other words, when your code refers to `Student.FirstMidName`, the data will come from or be updated in the `FirstName` column of the `Student` table. If you don't specify column names, they're given the same name as the property name.

In the `Student.cs` file, add a `using` statement for `System.ComponentModel.DataAnnotations.Schema` and add the column name attribute to the `FirstMidName` property, as shown in the following highlighted code:

C#

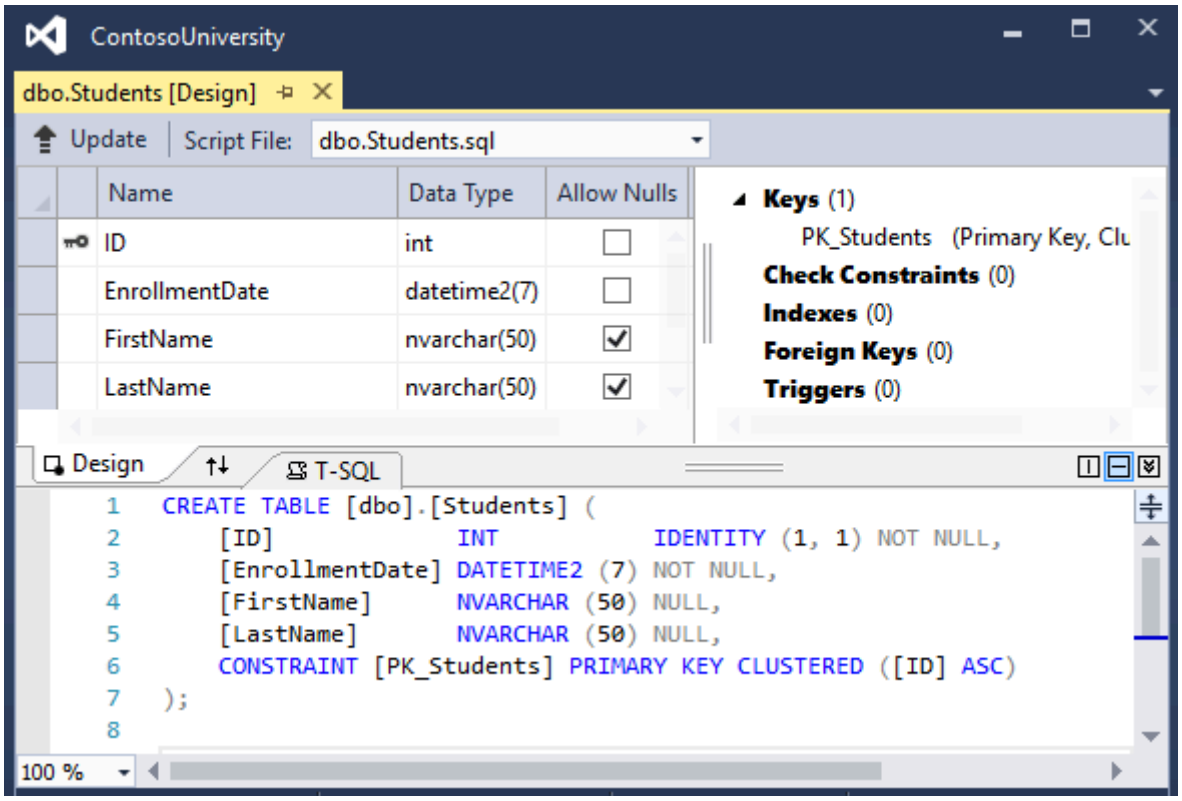
```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;
```

```
namespace ContosoUniversity.Models
{
    public class Student
    {
        public int ID { get; set; }
        [StringLength(50)]
        public string LastName { get; set; }
        [StringLength(50)]
        [Column("FirstName")]
        public string FirstMidName { get; set; }
        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}",
ApplyFormatInEditMode = true)]
        public DateTime EnrollmentDate { get; set; }

        public ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

The addition of the `Column` attribute changes the model backing the `SchoolContext`, so it won't match the database.

Save your changes and build the project. Then open the command window in the project folder and enter the following commands to create another migration:

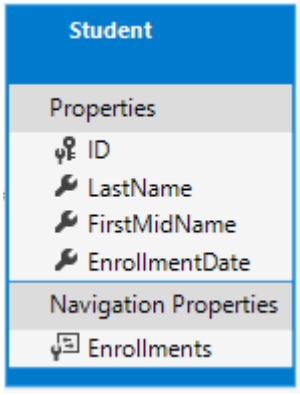


.NET CLI

```
dotnet ef migrations add ColumnFirstName
```

.NET CLI

```
dotnet ef database update
```



In **SQL Server Object Explorer**, open the Student table designer by double-clicking the **Student** table.

Before you applied the first two migrations, the name columns were of type nvarchar(MAX). They're now nvarchar(50) and the column name has changed from FirstMidName to FirstName.

> ⓘ Note
>
> If you try to compile before you finish creating all of the entity classes in the following sections, you might get compiler errors.

Changes to Student entity

In `Models/Student.cs`, replace the code you added earlier with the following code. The changes are highlighted.

C#

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Student
    {
        public int ID { get; set; }
        [Required]
        [StringLength(50)]
        [Display(Name = "Last Name")]
        public string LastName { get; set; }
        [Required]
        [StringLength(50)]
        [Column("FirstName")]
        [Display(Name = "First Name")]
        public string FirstMidName { get; set; }
        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}",
ApplyFormatInEditMode = true)]
        [Display(Name = "Enrollment Date")]
        public DateTime EnrollmentDate { get; set; }
        [Display(Name = "Full Name")]
        public string FullName
        {
            get
            {
                return LastName + ", " + FirstMidName;
            }
        }

        public ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

The Required attribute

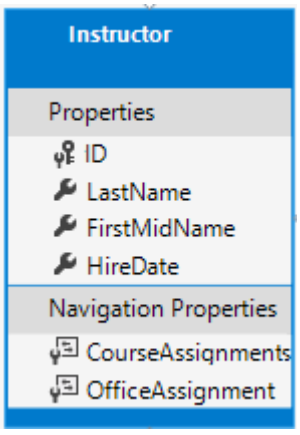
The `Required` attribute makes the name properties required fields. The `Required` attribute isn't needed for non-nullable types such as value types (DateTime, int, double, float, etc.). Types that can't be null are automatically treated as required fields.

The `Required` attribute must be used with `MinimumLength` for the `MinimumLength` to be enforced.

C#

```
[Display(Name = "Last Name")]
[Required]
```

```
[StringLength(50, MinimumLength=2)]
public string LastName { get; set; }
```



The Display attribute

The `Display` attribute specifies that the caption for the text boxes should be "First Name", "Last Name", "Full Name", and "Enrollment Date" instead of the property name in each instance (which has no space dividing the words).

The FullName calculated property

`FullName` is a calculated property that returns a value that's created by concatenating two other properties. Therefore it has only a get accessor, and no `FullName` column will be generated in the database.

Create Instructor entity

Create `Models/Instructor.cs`, replacing the template code with the following code:

C#

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Instructor
    {
        public int ID { get; set; }

        [Required]
        [Display(Name = "Last Name")]
```

```
        [StringLength(50)]
        public string LastName { get; set; }

        [Required]
        [Column("FirstName")]
        [Display(Name = "First Name")]
        [StringLength(50)]
        public string FirstMidName { get; set; }

        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}",
ApplyFormatInEditMode = true)]
        [Display(Name = "Hire Date")]
        public DateTime HireDate { get; set; }

        [Display(Name = "Full Name")]
        public string FullName
        {
            get { return LastName + ", " + FirstMidName; }
        }

        public ICollection<CourseAssignment> CourseAssignments { get; set; }
        public OfficeAssignment OfficeAssignment { get; set; }
    }
}
```

Notice that several properties are the same in the Student and Instructor entities. In the Implementing Inheritance tutorial later in this series, you'll refactor this code to eliminate the redundancy.

You can put multiple attributes on one line, so you could also write the `HireDate` attributes as follows:

C#

```
[DataType(DataType.Date),Display(Name = "Hire
Date"),DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}",
ApplyFormatInEditMode = true)]
```

The CourseAssignments and OfficeAssignment navigation properties

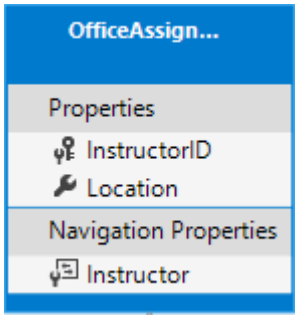
The `CourseAssignments` and `OfficeAssignment` properties are navigation properties.

An instructor can teach any number of courses, so `CourseAssignments` is defined as a collection.

C#

```
public ICollection<CourseAssignment> CourseAssignments { get; set; }
```

If a navigation property can hold multiple entities, its type must be a list in which entries can be added, deleted, and updated. You can specify `ICollection<T>` or a type such as `List<T>` or `HashSet<T>`. If you specify `ICollection<T>`, EF creates a `HashSet<T>` collection by default.



The reason why these are `CourseAssignment` entities is explained below in the section about many-to-many relationships.

Contoso University business rules state that an instructor can only have at most one office, so the `OfficeAssignment` property holds a single OfficeAssignment entity (which may be null if no office is assigned).

C#

```
public OfficeAssignment OfficeAssignment { get; set; }
```

Create OfficeAssignment entity

Create `Models/OfficeAssignment.cs` with the following code:

C#

```
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class OfficeAssignment
    {
        [Key]
        public int InstructorID { get; set; }
        [StringLength(50)]
        [Display(Name = "Office Location")]
        public string Location { get; set; }
```

```
        public Instructor Instructor { get; set; }
    }
}
```

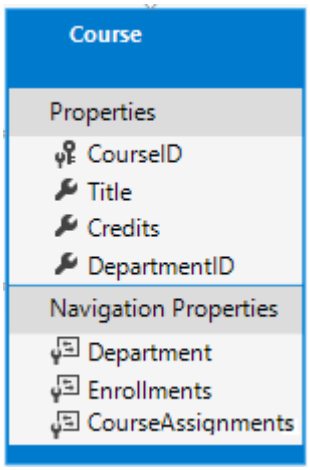
The Key attribute

There's a one-to-zero-or-one relationship between the `Instructor` and the `OfficeAssignment` entities. An office assignment only exists in relation to the instructor it's assigned to, and therefore its primary key is also its foreign key to the `Instructor` entity. But the Entity Framework can't automatically recognize `InstructorID` as the primary key of this entity because its name doesn't follow the `ID` or `classnameID` naming convention. Therefore, the `Key` attribute is used to identify it as the key:

C#

```
[Key]
public int InstructorID { get; set; }
```

You can also use the `Key` attribute if the entity does have its own primary key but you want to name the property something other than classnameID or ID.



By default, EF treats the key as non-database-generated because the column is for an identifying relationship.

The Instructor navigation property

The Instructor entity has a nullable `OfficeAssignment` navigation property (because an instructor might not have an office assignment), and the OfficeAssignment entity has a non-nullable `Instructor` navigation property (because an office assignment can't exist without an instructor -- `InstructorID` is non-nullable). When an Instructor entity has a related OfficeAssignment entity, each entity will have a reference to the other one in its navigation property.

You could put a `[Required]` attribute on the Instructor navigation property to specify that there must be a related instructor, but you don't have to do that because the `InstructorID` foreign key (which is also the key to this table) is non-nullable.

Modify Course entity

In `Models/Course.cs`, replace the code you added earlier with the following code. The changes are highlighted.

C#

```
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Course
    {
        [DatabaseGenerated(DatabaseGeneratedOption.None)]
        [Display(Name = "Number")]
        public int CourseID { get; set; }

        [StringLength(50, MinimumLength = 3)]
        public string Title { get; set; }

        [Range(0, 5)]
        public int Credits { get; set; }

        public int DepartmentID { get; set; }

        public Department Department { get; set; }
        public ICollection<Enrollment> Enrollments { get; set; }
        public ICollection<CourseAssignment> CourseAssignments { get; set; }
    }
}
```

The course entity has a foreign key property `DepartmentID` which points to the related Department entity and it has a `Department` navigation property.

The Entity Framework doesn't require you to add a foreign key property to your data model when you have a navigation property for a related entity. EF automatically creates foreign keys in the database wherever they're needed and creates shadow properties for

them. But having the foreign key in the data model can make updates simpler and more efficient. For example, when you fetch a `Course` entity to edit, the `Department` entity is null if you don't load it, so when you update the `Course` entity, you would have to first fetch the `Department` entity. When the foreign key property `DepartmentID` is included in the data model, you don't need to fetch the `Department` entity before you update.

The DatabaseGenerated attribute

The `DatabaseGenerated` attribute with the `None` parameter on the `CourseID` property specifies that primary key values are provided by the user rather than generated by the database.

C#

```
[DatabaseGenerated(DatabaseGeneratedOption.None)]
[Display(Name = "Number")]
public int CourseID { get; set; }
```

By default, Entity Framework assumes that primary key values are generated by the database. That's what you want in most scenarios. However, for `Course` entities, you'll use a user-specified course number such as a 1000 series for one department, a 2000 series for another department, and so on.

The `DatabaseGenerated` attribute can also be used to generate default values, as in the case of database columns used to record the date a row was created or updated. For more information, see Generated Properties.

Foreign key and navigation properties

The foreign key properties and navigation properties in the `Course` entity reflect the following relationships:

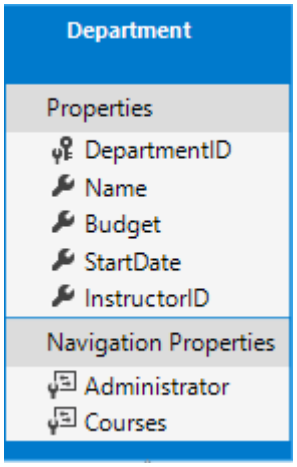
A course is assigned to one department, so there's a `DepartmentID` foreign key and a `Department` navigation property for the reasons mentioned above.

C#

```
public int DepartmentID { get; set; }
public Department Department { get; set; }
```

A course can have any number of students enrolled in it, so the `Enrollments` navigation property is a collection:

C#



```
public ICollection<Enrollment> Enrollments { get; set; }
```

A course may be taught by multiple instructors, so the `CourseAssignments` navigation property is a collection (the type `CourseAssignment` is explained later):

C#

```
public ICollection<CourseAssignment> CourseAssignments { get; set; }
```

Create Department entity

Create `Models/Department.cs` with the following code:

C#

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Department
    {
        public int DepartmentID { get; set; }

        [StringLength(50, MinimumLength = 3)]
        public string Name { get; set; }

        [DataType(DataType.Currency)]
        [Column(TypeName = "money")]
        public decimal Budget { get; set; }

        [DataType(DataType.Date)]
```

```
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}",
ApplyFormatInEditMode = true)]
        [Display(Name = "Start Date")]
        public DateTime StartDate { get; set; }

        public int? InstructorID { get; set; }

        public Instructor Administrator { get; set; }
        public ICollection<Course> Courses { get; set; }
    }
}
```

The Column attribute

Earlier you used the `Column` attribute to change column name mapping. In the code for the `Department` entity, the `Column` attribute is being used to change SQL data type mapping so that the column will be defined using the SQL Server `money` type in the database:

C#

```
[Column(TypeName="money")]
public decimal Budget { get; set; }
```

Column mapping is generally not required, because the Entity Framework chooses the appropriate SQL Server data type based on the CLR type that you define for the property. The CLR `decimal` type maps to a SQL Server `decimal` type. But in this case you know that the column will be holding currency amounts, and the money data type is more appropriate for that.

Foreign key and navigation properties

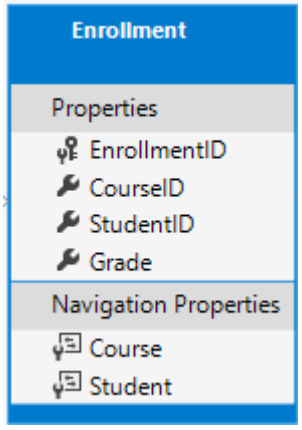
The foreign key and navigation properties reflect the following relationships:

A department may or may not have an administrator, and an administrator is always an instructor. Therefore the `InstructorID` property is included as the foreign key to the Instructor entity, and a question mark is added after the `int` type designation to mark the property as nullable. The navigation property is named `Administrator` but holds an Instructor entity:

C#

```
public int? InstructorID { get; set; }
```

```
public Instructor Administrator { get; set; }
```



A department may have many courses, so there's a Courses navigation property:

C#

```
public ICollection<Course> Courses { get; set; }
```

> **Note**
>
> By convention, the Entity Framework enables cascade delete for non-nullable foreign keys and for many-to-many relationships. This can result in circular cascade delete rules, which will cause an exception when you try to add a migration. For example, if you didn't define the `Department.InstructorID` property as nullable, EF would configure a cascade delete rule to delete the department when you delete the instructor, which isn't what you want to have happen. If your business rules required the `InstructorID` property to be non-nullable, you would have to use the following fluent API statement to disable cascade delete on the relationship:
>
> C#
>
> ```
> modelBuilder.Entity<Department>()
>     .HasOne(d => d.Administrator)
>     .WithMany()
>     .OnDelete(DeleteBehavior.Restrict)
> ```

Modify Enrollment entity

In `Models/Enrollment.cs`, replace the code you added earlier with the following code:

C#

```
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public enum Grade
    {
        A, B, C, D, F
    }

    public class Enrollment
    {
        public int EnrollmentID { get; set; }
        public int CourseID { get; set; }
        public int StudentID { get; set; }
        [DisplayFormat(NullDisplayText = "No grade")]
        public Grade? Grade { get; set; }

        public Course Course { get; set; }
        public Student Student { get; set; }
    }
}
```

Foreign key and navigation properties

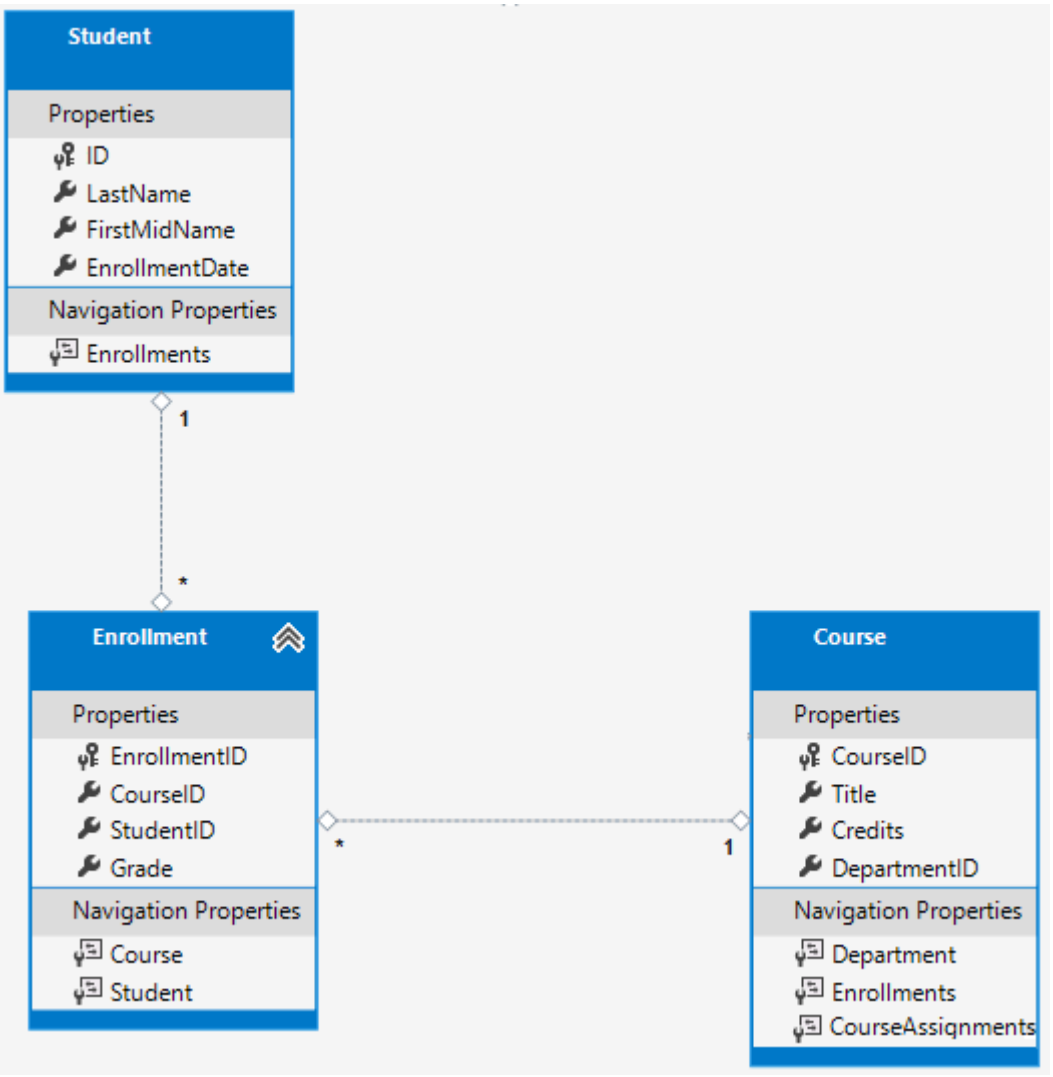
The foreign key properties and navigation properties reflect the following relationships:

An enrollment record is for a single course, so there's a `CourseID` foreign key property and a `Course` navigation property:

C#

```
public int CourseID { get; set; }
public Course Course { get; set; }
```

An enrollment record is for a single student, so there's a `StudentID` foreign key property and a `Student` navigation property:



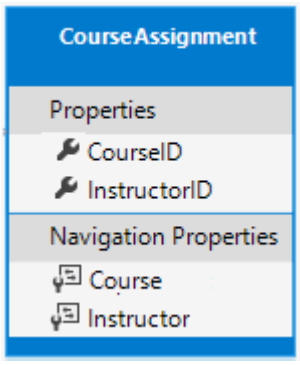
C#

```
public int StudentID { get; set; }
public Student Student { get; set; }
```

Many-to-Many relationships

There's a many-to-many relationship between the `Student` and `Course` entities, and the `Enrollment` entity functions as a many-to-many join table *with payload* in the database. "With payload" means that the `Enrollment` table contains additional data besides foreign keys for the joined tables (in this case, a primary key and a `Grade` property).

The following illustration shows what these relationships look like in an entity diagram. (This diagram was generated using the Entity Framework Power Tools for EF 6.x; creating the diagram isn't part of the tutorial, it's just being used here as an illustration.)



Each relationship line has a 1 at one end and an asterisk (*) at the other, indicating a one-to-many relationship.

If the `Enrollment` table didn't include grade information, it would only need to contain the two foreign keys `CourseID` and `StudentID`. In that case, it would be a many-to-many join table without payload (or a pure join table) in the database. The `Instructor` and `Course` entities have that kind of many-to-many relationship, and your next step is to create an entity class to function as a join table without payload.

EF Core supports implicit join tables for many-to-many relationships, but this tutoral has not been updated to use an implicit join table. See Many-to-Many Relationships, the

Razor Pages version of this tutorial which has been updated.

The CourseAssignment entity

Create `Models/CourseAssignment.cs` with the following code:

C#

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class CourseAssignment
    {
        public int InstructorID { get; set; }
        public int CourseID { get; set; }
        public Instructor Instructor { get; set; }
        public Course Course { get; set; }
    }
}
```

Join entity names

A join table is required in the database for the Instructor-to-Courses many-to-many relationship, and it has to be represented by an entity set. It's common to name a join entity `EntityName1EntityName2`, which in this case would be `CourseInstructor`. However, we recommend that you choose a name that describes the relationship. Data models start out simple and grow, with no-payload joins frequently getting payloads later. If you start with a descriptive entity name, you won't have to change the name later. Ideally, the join entity would have its own natural (possibly single word) name in the business domain. For example, Books and Customers could be linked through Ratings. For this relationship, `CourseAssignment` is a better choice than `CourseInstructor`.

Composite key

Since the foreign keys are not nullable and together uniquely identify each row of the table, there's no need for a separate primary key. The `InstructorID` and `CourseID` properties should function as a composite primary key. The only way to identify composite primary keys to EF is by using the *fluent API* (it can't be done by using attributes). You'll see how to configure the composite primary key in the next section.

The composite key ensures that while you can have multiple rows for one course, and multiple rows for one instructor, you can't have multiple rows for the same instructor and course. The `Enrollment` join entity defines its own primary key, so duplicates of this sort are possible. To prevent such duplicates, you could add a unique index on the foreign key fields, or configure `Enrollment` with a primary composite key similar to `CourseAssignment`. For more information, see Indexes.

Update the database context

Add the following highlighted code to the `Data/SchoolContext.cs` file:

C#

```
using ContosoUniversity.Models;
using Microsoft.EntityFrameworkCore;

namespace ContosoUniversity.Data
{
    public class SchoolContext : DbContext
    {
        public SchoolContext(DbContextOptions<SchoolContext> options) :
base(options)
        {
        }

        public DbSet<Course> Courses { get; set; }
        public DbSet<Enrollment> Enrollments { get; set; }
        public DbSet<Student> Students { get; set; }
        public DbSet<Department> Departments { get; set; }
        public DbSet<Instructor> Instructors { get; set; }
        public DbSet<OfficeAssignment> OfficeAssignments { get; set; }
        public DbSet<CourseAssignment> CourseAssignments { get; set; }

        protected override void OnModelCreating(ModelBuilder modelBuilder)
        {
            modelBuilder.Entity<Course>().ToTable("Course");
            modelBuilder.Entity<Enrollment>().ToTable("Enrollment");
            modelBuilder.Entity<Student>().ToTable("Student");
```

```
            modelBuilder.Entity<Department>().ToTable("Department");
            modelBuilder.Entity<Instructor>().ToTable("Instructor");
            modelBuilder.Entity<OfficeAssignment>
().ToTable("OfficeAssignment");
            modelBuilder.Entity<CourseAssignment>
().ToTable("CourseAssignment");

            modelBuilder.Entity<CourseAssignment>()
                .HasKey(c => new { c.CourseID, c.InstructorID });
        }
    }
}
```

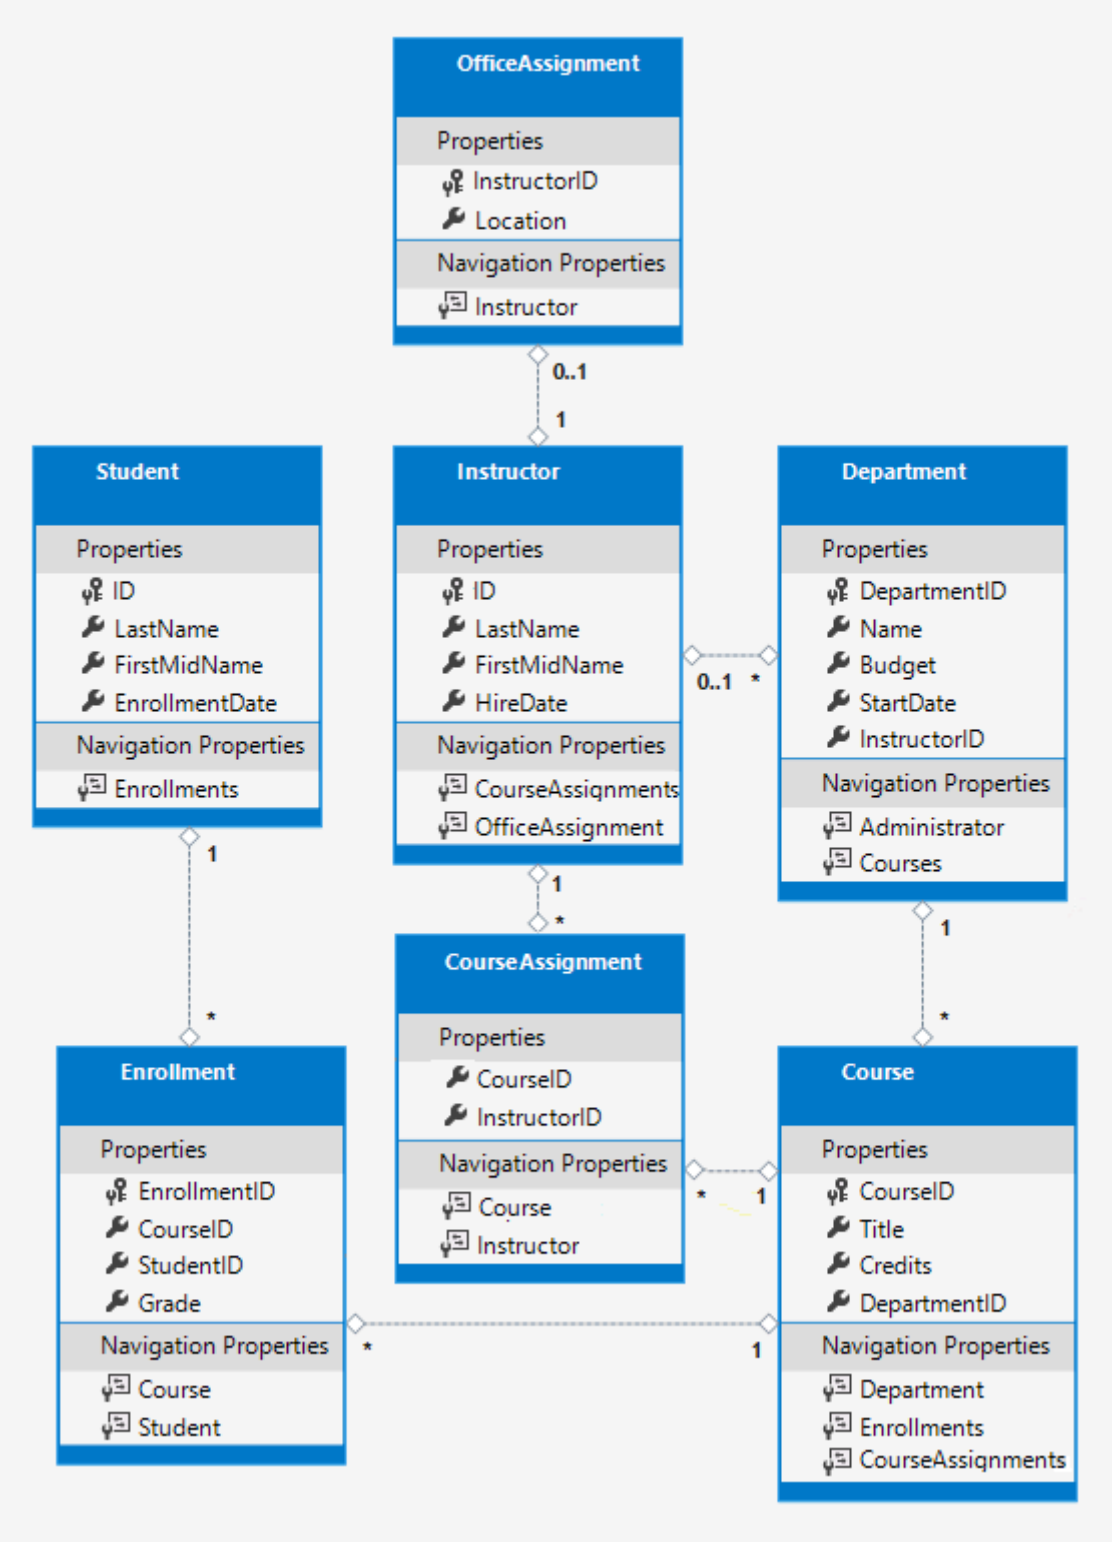
This code adds the new entities and configures the CourseAssignment entity's composite primary key.

About a fluent API alternative

The code in the `OnModelCreating` method of the `DbContext` class uses the *fluent API* to configure EF behavior. The API is called "fluent" because it's often used by stringing a series of method calls together into a single statement, as in this example from the EF Core documentation:

C#

```
protected override void OnModelCreating(ModelBuilder modelBuilder)
{
    modelBuilder.Entity<Blog>()
        .Property(b => b.Url)
        .IsRequired();
}
```



In this tutorial, you're using the fluent API only for database mapping that you can't do with attributes. However, you can also use the fluent API to specify most of the formatting, validation, and mapping rules that you can do by using attributes. Some attributes such as `MinimumLength` can't be applied with the fluent API. As mentioned previously, `MinimumLength` doesn't change the schema, it only applies a client and server side validation rule.

Some developers prefer to use the fluent API exclusively so that they can keep their entity classes "clean." You can mix attributes and fluent API if you want, and there are a few customizations that can only be done by using fluent API, but in general the recommended practice is to choose one of these two approaches and use that consistently as much as possible. If you do use both, note that wherever there's a conflict, Fluent API overrides attributes.

For more information about attributes vs. fluent API, see Methods of configuration.

Entity Diagram Showing Relationships

The following illustration shows the diagram that the Entity Framework Power Tools create for the completed School model.

Besides the one-to-many relationship lines (1 to *), you can see here the one-to-zero-or-one relationship line (1 to 0..1) between the `Instructor` and `OfficeAssignment`

entities and the zero-or-one-to-many relationship line (0..1 to *) between the Instructor and Department entities.

Seed database with test data

Replace the code in the `Data/DbInitializer.cs` file with the following code in order to provide seed data for the new entities you've created.

C#

```
using System;
using System.Linq;
using Microsoft.EntityFrameworkCore;
using Microsoft.Extensions.DependencyInjection;
using ContosoUniversity.Models;

namespace ContosoUniversity.Data
{
    public static class DbInitializer
    {
        public static void Initialize(SchoolContext context)
        {
            //context.Database.EnsureCreated();

            // Look for any students.
            if (context.Students.Any())
            {
                return;   // DB has been seeded
            }

            var students = new Student[]
            {
                new Student { FirstMidName = "Carson",   LastName =
"Alexander",
                    EnrollmentDate = DateTime.Parse("2010-09-01") },
                new Student { FirstMidName = "Meredith", LastName =
"Alonso",
                    EnrollmentDate = DateTime.Parse("2012-09-01") },
                new Student { FirstMidName = "Arturo",   LastName = "Anand",
                    EnrollmentDate = DateTime.Parse("2013-09-01") },
                new Student { FirstMidName = "Gytis",    LastName =
"Barzdukas",
                    EnrollmentDate = DateTime.Parse("2012-09-01") },
                new Student { FirstMidName = "Yan",      LastName = "Li",
                    EnrollmentDate = DateTime.Parse("2012-09-01") },
                new Student { FirstMidName = "Peggy",    LastName =
"Justice",
                    EnrollmentDate = DateTime.Parse("2011-09-01") },
                new Student { FirstMidName = "Laura",    LastName =
"Norman",
                    EnrollmentDate = DateTime.Parse("2013-09-01") },
```

```
                new Student { FirstMidName = "Nino",     LastName =
"Olivetto",
                    EnrollmentDate = DateTime.Parse("2005-09-01") }
            };

            foreach (Student s in students)
            {
                context.Students.Add(s);
            }
            context.SaveChanges();

            var instructors = new Instructor[]
            {
                new Instructor { FirstMidName = "Kim",     LastName =
"Abercrombie",
                    HireDate = DateTime.Parse("1995-03-11") },
                new Instructor { FirstMidName = "Fadi",    LastName =
"Fakhouri",
                    HireDate = DateTime.Parse("2002-07-06") },
                new Instructor { FirstMidName = "Roger",   LastName =
"Harui",
                    HireDate = DateTime.Parse("1998-07-01") },
                new Instructor { FirstMidName = "Candace", LastName =
"Kapoor",
                    HireDate = DateTime.Parse("2001-01-15") },
                new Instructor { FirstMidName = "Roger",   LastName =
"Zheng",
                    HireDate = DateTime.Parse("2004-02-12") }
            };

            foreach (Instructor i in instructors)
            {
                context.Instructors.Add(i);
            }
            context.SaveChanges();

            var departments = new Department[]
            {
                new Department { Name = "English",     Budget = 350000,
                    StartDate = DateTime.Parse("2007-09-01"),
                    InstructorID  = instructors.Single( i => i.LastName ==
"Abercrombie").ID },
                new Department { Name = "Mathematics", Budget = 100000,
                    StartDate = DateTime.Parse("2007-09-01"),
                    InstructorID  = instructors.Single( i => i.LastName ==
"Fakhouri").ID },
                new Department { Name = "Engineering", Budget = 350000,
                    StartDate = DateTime.Parse("2007-09-01"),
                    InstructorID  = instructors.Single( i => i.LastName ==
"Harui").ID },
                new Department { Name = "Economics",   Budget = 100000,
                    StartDate = DateTime.Parse("2007-09-01"),
                    InstructorID  = instructors.Single( i => i.LastName ==
"Kapoor").ID }
            };
```

```
            foreach (Department d in departments)
            {
                context.Departments.Add(d);
            }
            context.SaveChanges();

            var courses = new Course[]
            {
                new Course {CourseID = 1050, Title = "Chemistry",
Credits = 3,
                    DepartmentID = departments.Single( s => s.Name ==
"Engineering").DepartmentID
                },
                new Course {CourseID = 4022, Title = "Microeconomics",
Credits = 3,
                    DepartmentID = departments.Single( s => s.Name ==
"Economics").DepartmentID
                },
                new Course {CourseID = 4041, Title = "Macroeconomics",
Credits = 3,
                    DepartmentID = departments.Single( s => s.Name ==
"Economics").DepartmentID
                },
                new Course {CourseID = 1045, Title = "Calculus",
Credits = 4,
                    DepartmentID = departments.Single( s => s.Name ==
"Mathematics").DepartmentID
                },
                new Course {CourseID = 3141, Title = "Trigonometry",
Credits = 4,
                    DepartmentID = departments.Single( s => s.Name ==
"Mathematics").DepartmentID
                },
                new Course {CourseID = 2021, Title = "Composition",
Credits = 3,
                    DepartmentID = departments.Single( s => s.Name ==
"English").DepartmentID
                },
                new Course {CourseID = 2042, Title = "Literature",
Credits = 4,
                    DepartmentID = departments.Single( s => s.Name ==
"English").DepartmentID
                },
            };

            foreach (Course c in courses)
            {
                context.Courses.Add(c);
            }
            context.SaveChanges();

            var officeAssignments = new OfficeAssignment[]
            {
                new OfficeAssignment {
```

```
                    InstructorID = instructors.Single( i => i.LastName ==
"Fakhouri").ID,
                    Location = "Smith 17" },
                new OfficeAssignment {
                    InstructorID = instructors.Single( i => i.LastName ==
"Harui").ID,
                    Location = "Gowan 27" },
                new OfficeAssignment {
                    InstructorID = instructors.Single( i => i.LastName ==
"Kapoor").ID,
                    Location = "Thompson 304" },
            };

            foreach (OfficeAssignment o in officeAssignments)
            {
                context.OfficeAssignments.Add(o);
            }
            context.SaveChanges();

            var courseInstructors = new CourseAssignment[]
            {
                new CourseAssignment {
                    CourseID = courses.Single(c => c.Title == "Chemistry"
).CourseID,
                    InstructorID = instructors.Single(i => i.LastName ==
"Kapoor").ID
                    },
                new CourseAssignment {
                    CourseID = courses.Single(c => c.Title == "Chemistry"
).CourseID,
                    InstructorID = instructors.Single(i => i.LastName ==
"Harui").ID
                    },
                new CourseAssignment {
                    CourseID = courses.Single(c => c.Title ==
"Microeconomics" ).CourseID,
                    InstructorID = instructors.Single(i => i.LastName ==
"Zheng").ID
                    },
                new CourseAssignment {
                    CourseID = courses.Single(c => c.Title ==
"Macroeconomics" ).CourseID,
                    InstructorID = instructors.Single(i => i.LastName ==
"Zheng").ID
                    },
                new CourseAssignment {
                    CourseID = courses.Single(c => c.Title == "Calculus"
).CourseID,
                    InstructorID = instructors.Single(i => i.LastName ==
"Fakhouri").ID
                    },
                new CourseAssignment {
                    CourseID = courses.Single(c => c.Title == "Trigonometry"
).CourseID,
                    InstructorID = instructors.Single(i => i.LastName ==
```

```
"Harui").ID
                    },
                new CourseAssignment {
                    CourseID = courses.Single(c => c.Title == "Composition"
).CourseID,
                    InstructorID = instructors.Single(i => i.LastName ==
"Abercrombie").ID
                    },
                new CourseAssignment {
                    CourseID = courses.Single(c => c.Title == "Literature"
).CourseID,
                    InstructorID = instructors.Single(i => i.LastName ==
"Abercrombie").ID
                    },
            };

            foreach (CourseAssignment ci in courseInstructors)
            {
                context.CourseAssignments.Add(ci);
            }
            context.SaveChanges();

            var enrollments = new Enrollment[]
            {
                new Enrollment {
                    StudentID = students.Single(s => s.LastName ==
"Alexander").ID,
                    CourseID = courses.Single(c => c.Title == "Chemistry"
).CourseID,
                    Grade = Grade.A
                },
                    new Enrollment {
                    StudentID = students.Single(s => s.LastName ==
"Alexander").ID,
                    CourseID = courses.Single(c => c.Title ==
"Microeconomics" ).CourseID,
                    Grade = Grade.C
                    },
                    new Enrollment {
                    StudentID = students.Single(s => s.LastName ==
"Alexander").ID,
                    CourseID = courses.Single(c => c.Title ==
"Macroeconomics" ).CourseID,
                    Grade = Grade.B
                    },
                    new Enrollment {
                        StudentID = students.Single(s => s.LastName ==
"Alonso").ID,
                    CourseID = courses.Single(c => c.Title == "Calculus"
).CourseID,
                    Grade = Grade.B
                    },
                    new Enrollment {
                        StudentID = students.Single(s => s.LastName ==
"Alonso").ID,
```

```
                    CourseID = courses.Single(c => c.Title == "Trigonometry"
).CourseID,
                    Grade = Grade.B
                    },
                    new Enrollment {
                    StudentID = students.Single(s => s.LastName ==
"Alonso").ID,
                    CourseID = courses.Single(c => c.Title == "Composition"
).CourseID,
                    Grade = Grade.B
                    },
                    new Enrollment {
                    StudentID = students.Single(s => s.LastName ==
"Anand").ID,
                    CourseID = courses.Single(c => c.Title == "Chemistry"
).CourseID
                    },
                    new Enrollment {
                    StudentID = students.Single(s => s.LastName ==
"Anand").ID,
                    CourseID = courses.Single(c => c.Title ==
"Microeconomics").CourseID,
                    Grade = Grade.B
                    },
                new Enrollment {
                    StudentID = students.Single(s => s.LastName ==
"Barzdukas").ID,
                    CourseID = courses.Single(c => c.Title ==
"Chemistry").CourseID,
                    Grade = Grade.B
                    },
                    new Enrollment {
                    StudentID = students.Single(s => s.LastName == "Li").ID,
                    CourseID = courses.Single(c => c.Title ==
"Composition").CourseID,
                    Grade = Grade.B
                    },
                    new Enrollment {
                    StudentID = students.Single(s => s.LastName ==
"Justice").ID,
                    CourseID = courses.Single(c => c.Title ==
"Literature").CourseID,
                    Grade = Grade.B
                    }
            };

            foreach (Enrollment e in enrollments)
            {
                var enrollmentInDataBase = context.Enrollments.Where(
                    s =>
                            s.Student.ID == e.StudentID &&
                            s.Course.CourseID ==
e.CourseID).SingleOrDefault();
                if (enrollmentInDataBase == null)
                {
```

```
                    context.Enrollments.Add(e);
                }
            }
            context.SaveChanges();
        }
    }
}
```

As you saw in the first tutorial, most of this code simply creates new entity objects and loads sample data into properties as required for testing. Notice how the many-to-many relationships are handled: the code creates relationships by creating entities in the `Enrollments` and `CourseAssignment` join entity sets.

Add a migration

Save your changes and build the project. Then open the command window in the project folder and enter the `migrations add` command (don't do the update-database command yet):

.NET CLI

```
dotnet ef migrations add ComplexDataModel
```

You get a warning about possible data loss.

text

```
An operation was scaffolded that may result in the loss of data. Please
review the migration for accuracy.
Done. To undo this action, use 'ef migrations remove'
```

If you tried to run the `database update` command at this point (don't do it yet), you would get the following error:

> The ALTER TABLE statement conflicted with the FOREIGN KEY constraint "FK_dbo.Course_dbo.Department_DepartmentID". The conflict occurred in database "ContosoUniversity", table "dbo.Department", column 'DepartmentID'.

Sometimes when you execute migrations with existing data, you need to insert stub data into the database to satisfy foreign key constraints. The generated code in the `Up` method adds a non-nullable `DepartmentID` foreign key to the `Course` table. If there are already rows in the Course table when the code runs, the `AddColumn` operation fails

because SQL Server doesn't know what value to put in the column that can't be null. For this tutorial you'll run the migration on a new database, but in a production application you'd have to make the migration handle existing data, so the following directions show an example of how to do that.

To make this migration work with existing data you have to change the code to give the new column a default value, and create a stub department named "Temp" to act as the default department. As a result, existing Course rows will all be related to the "Temp" department after the `Up` method runs.

- Open the `{timestamp}_ComplexDataModel.cs` file.
- Comment out the line of code that adds the DepartmentID column to the Course table.

```
C#

migrationBuilder.AlterColumn<string>(
    name: "Title",
    table: "Course",
    maxLength: 50,
    nullable: true,
    oldClrType: typeof(string),
    oldNullable: true);

//migrationBuilder.AddColumn<int>(
//    name: "DepartmentID",
//    table: "Course",
//    nullable: false,
//    defaultValue: 0);
```

- Add the following highlighted code after the code that creates the Department table:

```
C#

migrationBuilder.CreateTable(
    name: "Department",
    columns: table => new
    {
        DepartmentID = table.Column<int>(nullable: false)
            .Annotation("SqlServer:ValueGenerationStrategy",
SqlServerValueGenerationStrategy.IdentityColumn),
        Budget = table.Column<decimal>(type: "money", nullable: false),
        InstructorID = table.Column<int>(nullable: true),
        Name = table.Column<string>(maxLength: 50, nullable: true),
        StartDate = table.Column<DateTime>(nullable: false)
    },
    constraints: table =>
```

```
    {
        table.PrimaryKey("PK_Department", x => x.DepartmentID);
        table.ForeignKey(
            name: "FK_Department_Instructor_InstructorID",
            column: x => x.InstructorID,
            principalTable: "Instructor",
            principalColumn: "ID",
            onDelete: ReferentialAction.Restrict);
    });

migrationBuilder.Sql("INSERT INTO dbo.Department (Name, Budget,
StartDate) VALUES ('Temp', 0.00, GETDATE())");
// Default value for FK points to department created above, with
// defaultValue changed to 1 in following AddColumn statement.

migrationBuilder.AddColumn<int>(
    name: "DepartmentID",
    table: "Course",
    nullable: false,
    defaultValue: 1);
```

In a production application, you would write code or scripts to add Department rows and relate Course rows to the new Department rows. You would then no longer need the "Temp" department or the default value on the `Course.DepartmentID` column.

Save your changes and build the project.

Change the connection string

You now have new code in the `DbInitializer` class that adds seed data for the new entities to an empty database. To make EF create a new empty database, change the name of the database in the connection string in `appsettings.json` to ContosoUniversity3 or some other name that you haven't used on the computer you're using.

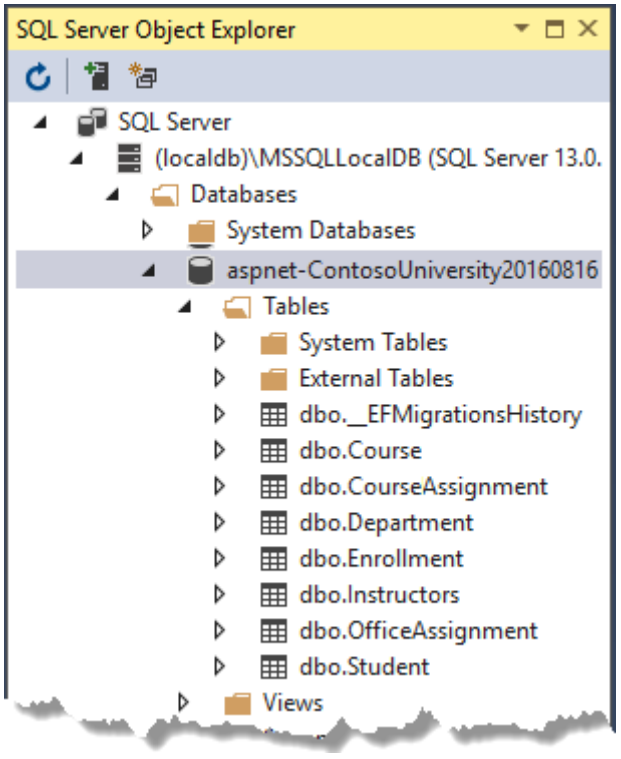
JSON

```
{
  "ConnectionStrings": {
    "DefaultConnection": "Server=
(localdb)\\mssqllocaldb;Database=ContosoUniversity3;Trusted_Connection=True;
MultipleActiveResultSets=true"
  },
```

Save your change to `appsettings.json`.

> **Note**
>
> As an alternative to changing the database name, you can delete the database. Use **SQL Server Object Explorer** (SSOX) or the `database drop` CLI command:
>
> .NET CLI
>
> ```
> dotnet ef database drop
> ```

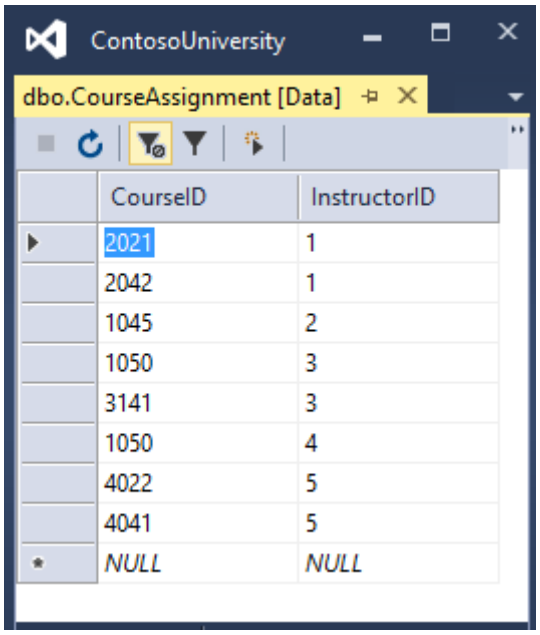
Update the database



After you have changed the database name or deleted the database, run the `database update` command in the command window to execute the migrations.

.NET CLI

```
dotnet ef database update
```



Run the app to cause the `DbInitializer.Initialize` method to run and populate the new database.

Open the database in SSOX as you did earlier, and expand the **Tables** node to see that all of the tables have been created. (If you still have SSOX open from the earlier time, click the **Refresh** button.)

Run the app to trigger the initializer code that seeds the database.

Right-click the **CourseAssignment** table and select **View Data** to verify that it has data in it.

Get the code

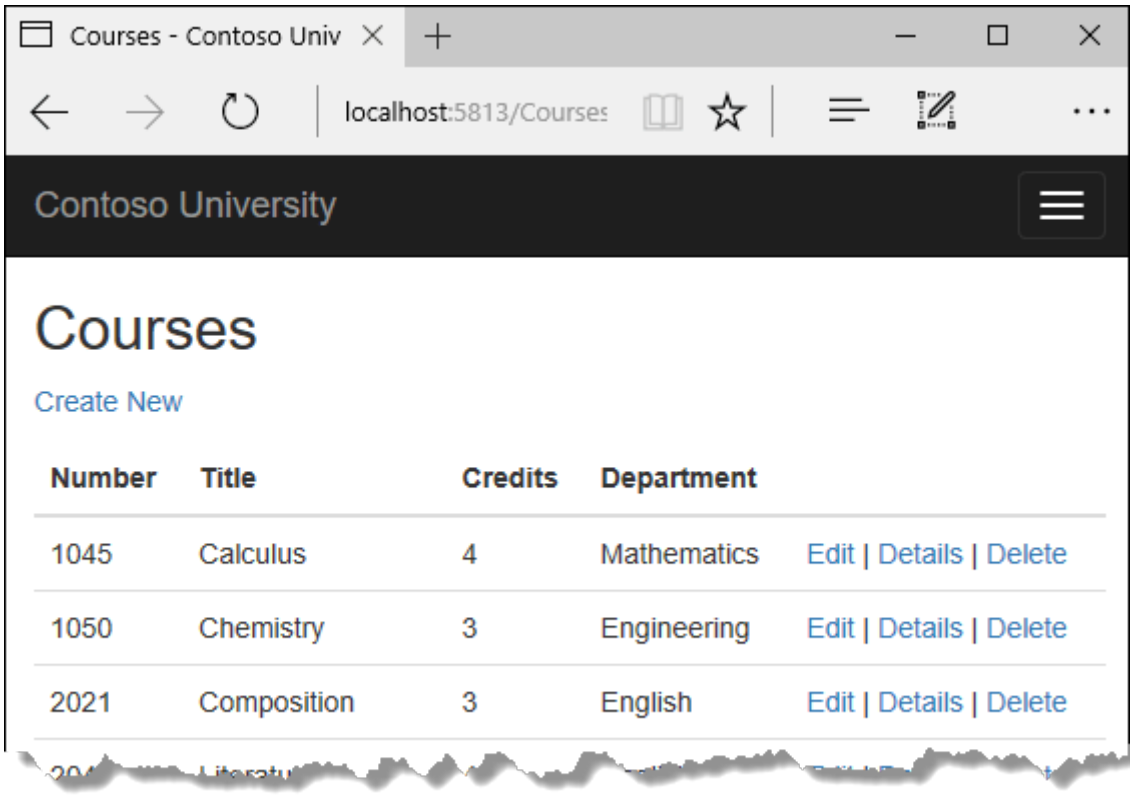
Download or view the completed application.

Next steps

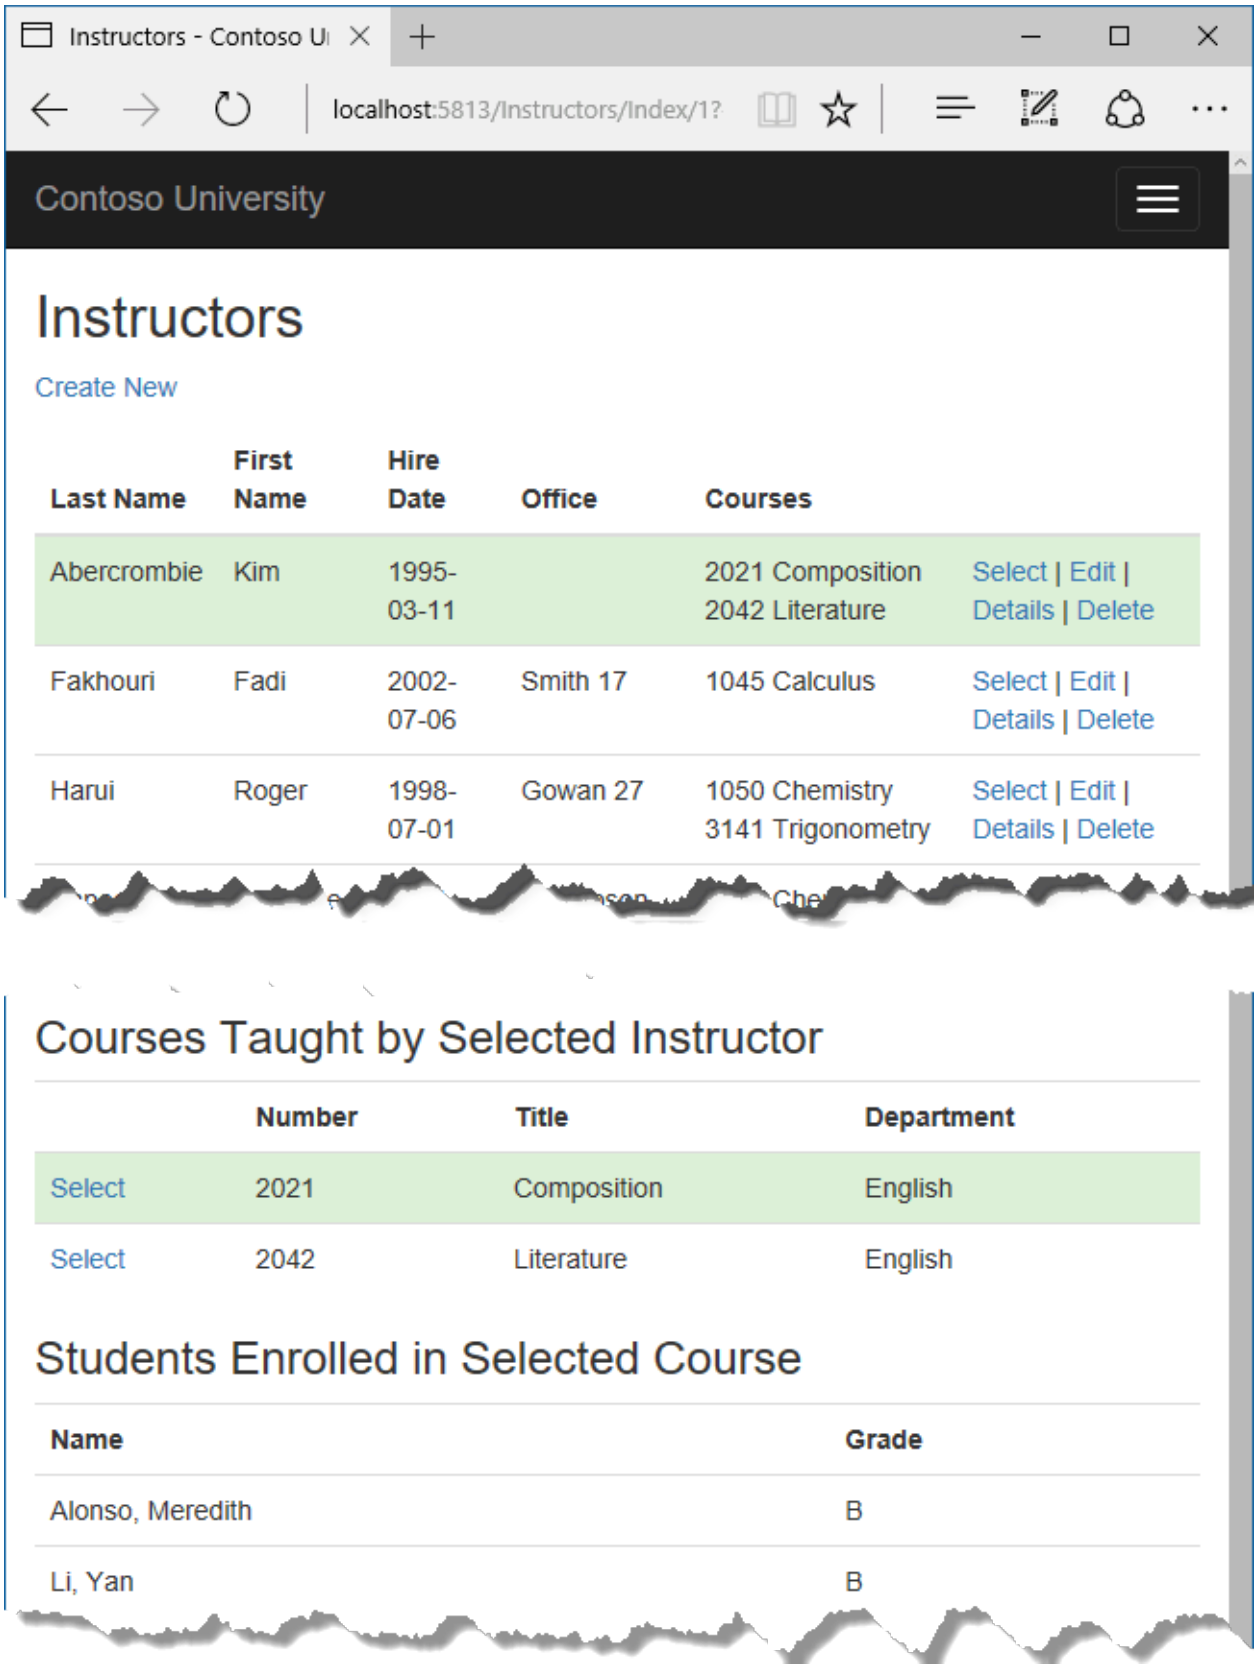
In this tutorial, you:

- ✓ Customized the Data model
- ✓ Made changes to Student entity
- ✓ Created Instructor entity
- ✓ Created OfficeAssignment entity
- ✓ Modified Course entity
- ✓ Created Department entity
- ✓ Modified Enrollment entity
- ✓ Updated the database context
- ✓ Seeded database with test data
- ✓ Added a migration
- ✓ Changed the connection string
- ✓ Updated the database

Advance to the next tutorial to learn more about how to access related data.



Next: Access related data



Tutorial: Read related data - ASP.NET MVC with EF Core

Article • 04/10/2024

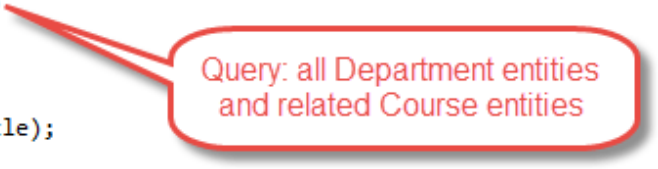
In the previous tutorial, you completed the School data model. In this tutorial, you'll read and display related data -- that is, data that the Entity Framework loads into navigation properties.

The following illustrations show the pages that you'll work with.

In this tutorial, you:

- ✓ Learn how to load related data
- ✓ Create a Courses page
- ✓ Create an Instructors page
- ✓ Learn about explicit loading

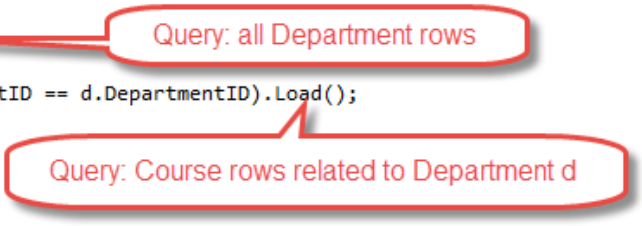
Prerequisites



- Create a complex data model

Learn how to load related data

There are several ways that Object-Relational Mapping (ORM) software such as Entity Framework can load related data into the navigation properties of an entity:



- Eager loading: When the entity is read, related data is retrieved along with it. This typically results in a single join query that retrieves all of the data that's needed. You specify eager loading in Entity Framework Core by using the `Include` and `ThenInclude` methods.

```
var departments = _context.Departments.Include(d => d.Courses);
foreach (Department d in departments)
{
    foreach(Course c in d.Courses)
    {
        courseList.Add(d.Name + c.Title);
    }
}
```

  You can retrieve some of the data in separate queries, and EF "fixes up" the navigation properties. That is, EF automatically adds the separately retrieved entities where they belong in navigation properties of previously retrieved entities. For the query that retrieves related data, you can use the `Load` method instead of a method that returns a list or object, such as `ToList` or `Single`.

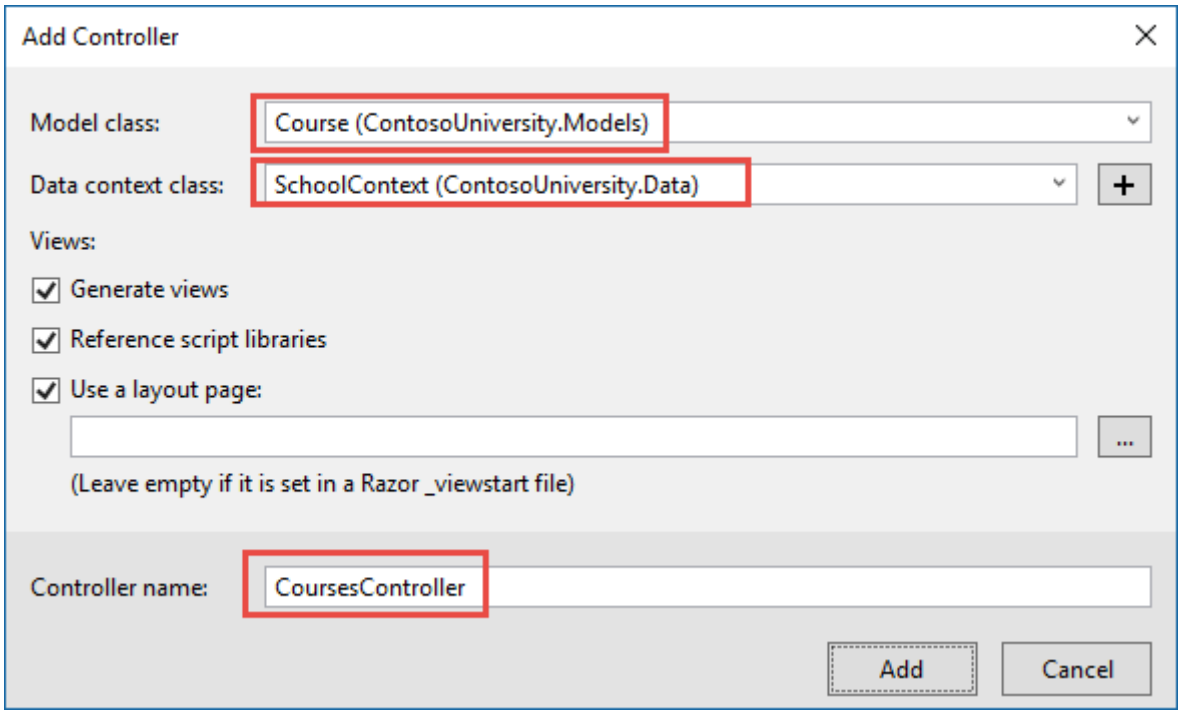
```
var departments = _context.Departments;
foreach (Department d in departments)
{
    _context.Courses.Where(c => c.DepartmentID == d.DepartmentID).Load();
    foreach (Course c in d.Courses)
    {
        courseList.Add(d.Name + c.Title);
    }
}
```

- Explicit loading: When the entity is first read, related data isn't retrieved. You write code that retrieves the related data if it's needed. As in the case of eager loading with separate queries, explicit loading results in multiple queries sent to the database. The difference is that with explicit loading, the code specifies the navigation properties to be loaded. In Entity Framework Core 1.1 you can use the `Load` method to do explicit loading. For example:

- Lazy loading: When the entity is first read, related data isn't retrieved. However, the first time you attempt to access a navigation property, the data required for that navigation property is automatically retrieved. A query is sent to the database each time you try to get data from a navigation property for the first time. Entity Framework Core 1.0 doesn't support lazy loading.

Performance considerations

If you know you need related data for every entity retrieved, eager loading often offers the best performance, because a single query sent to the database is typically more efficient than separate queries for each entity retrieved. For example, suppose that each department has ten related courses. Eager loading of all related data would result in just a single (join) query and a single round trip to the database. A separate query for courses for each department would result in eleven round trips to the database. The extra round trips to the database are especially detrimental to performance when latency is high.



On the other hand, in some scenarios separate queries is more efficient. Eager loading of all related data in one query might cause a very complex join to be generated, which SQL Server can't process efficiently. Or if you need to access an entity's navigation properties only for a subset of a set of the entities you're processing, separate queries might perform better because eager loading of everything up front would retrieve more data than you need. If performance is critical, it's best to test performance both ways in order to make the best choice.

Create a Courses page

The `Course` entity includes a navigation property that contains the `Department` entity of the department that the course is assigned to. To display the name of the assigned department in a list of courses, you need to get the `Name` property from the `Department` entity that's in the `Course.Department` navigation property.

Create a controller named `CoursesController` for the `Course` entity type, using the same options for the **MVC Controller with views, using Entity Framework** scaffolder that you

did earlier for the `StudentsController`, as shown in the following illustration:

Open `CoursesController.cs` and examine the `Index` method. The automatic scaffolding has specified eager loading for the `Department` navigation property by using the `Include` method.

Replace the `Index` method with the following code that uses a more appropriate name for the `IQueryable` that returns Course entities (`courses` instead of `schoolContext`):

C#

```
public async Task<IActionResult> Index()
{
    var courses = _context.Courses
        .Include(c => c.Department)
        .AsNoTracking();
    return View(await courses.ToListAsync());
}
```

Open `Views/Courses/Index.cshtml` and replace the template code with the following code. The changes are highlighted:

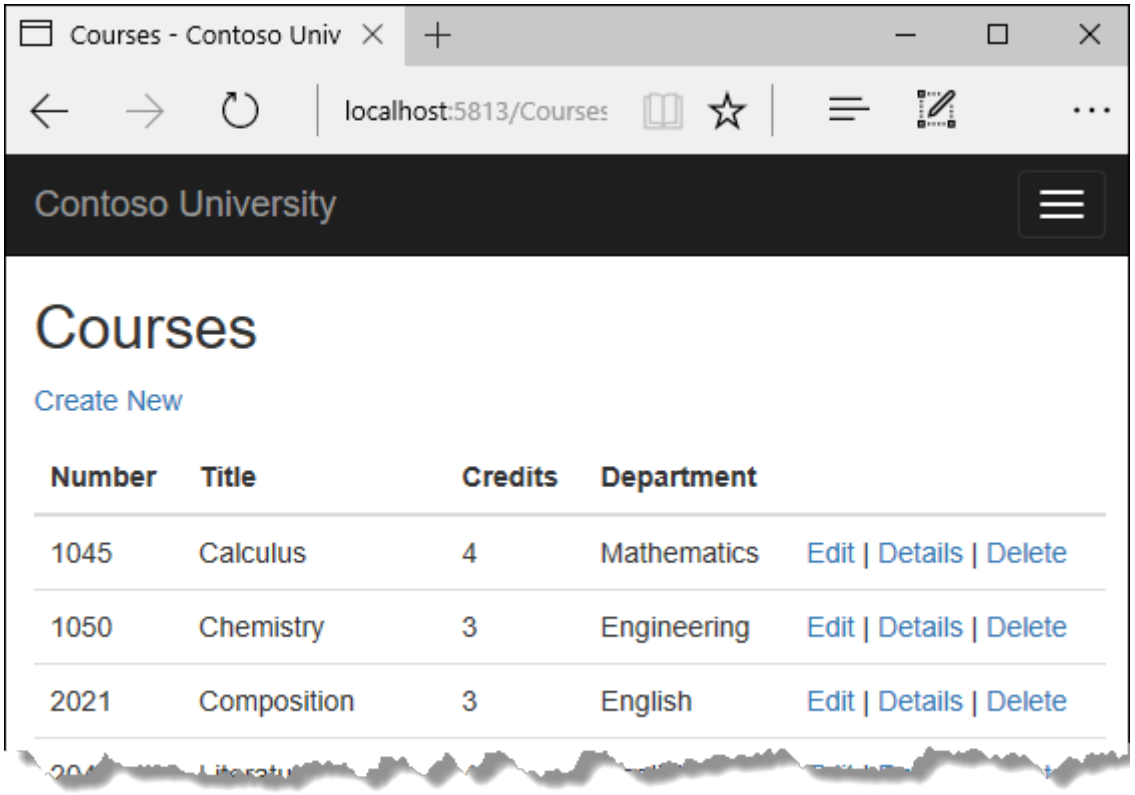
CSHTML

```
@model IEnumerable<ContosoUniversity.Models.Course>

@{
    ViewData["Title"] = "Courses";
}
```

```
<h2>Courses</h2>

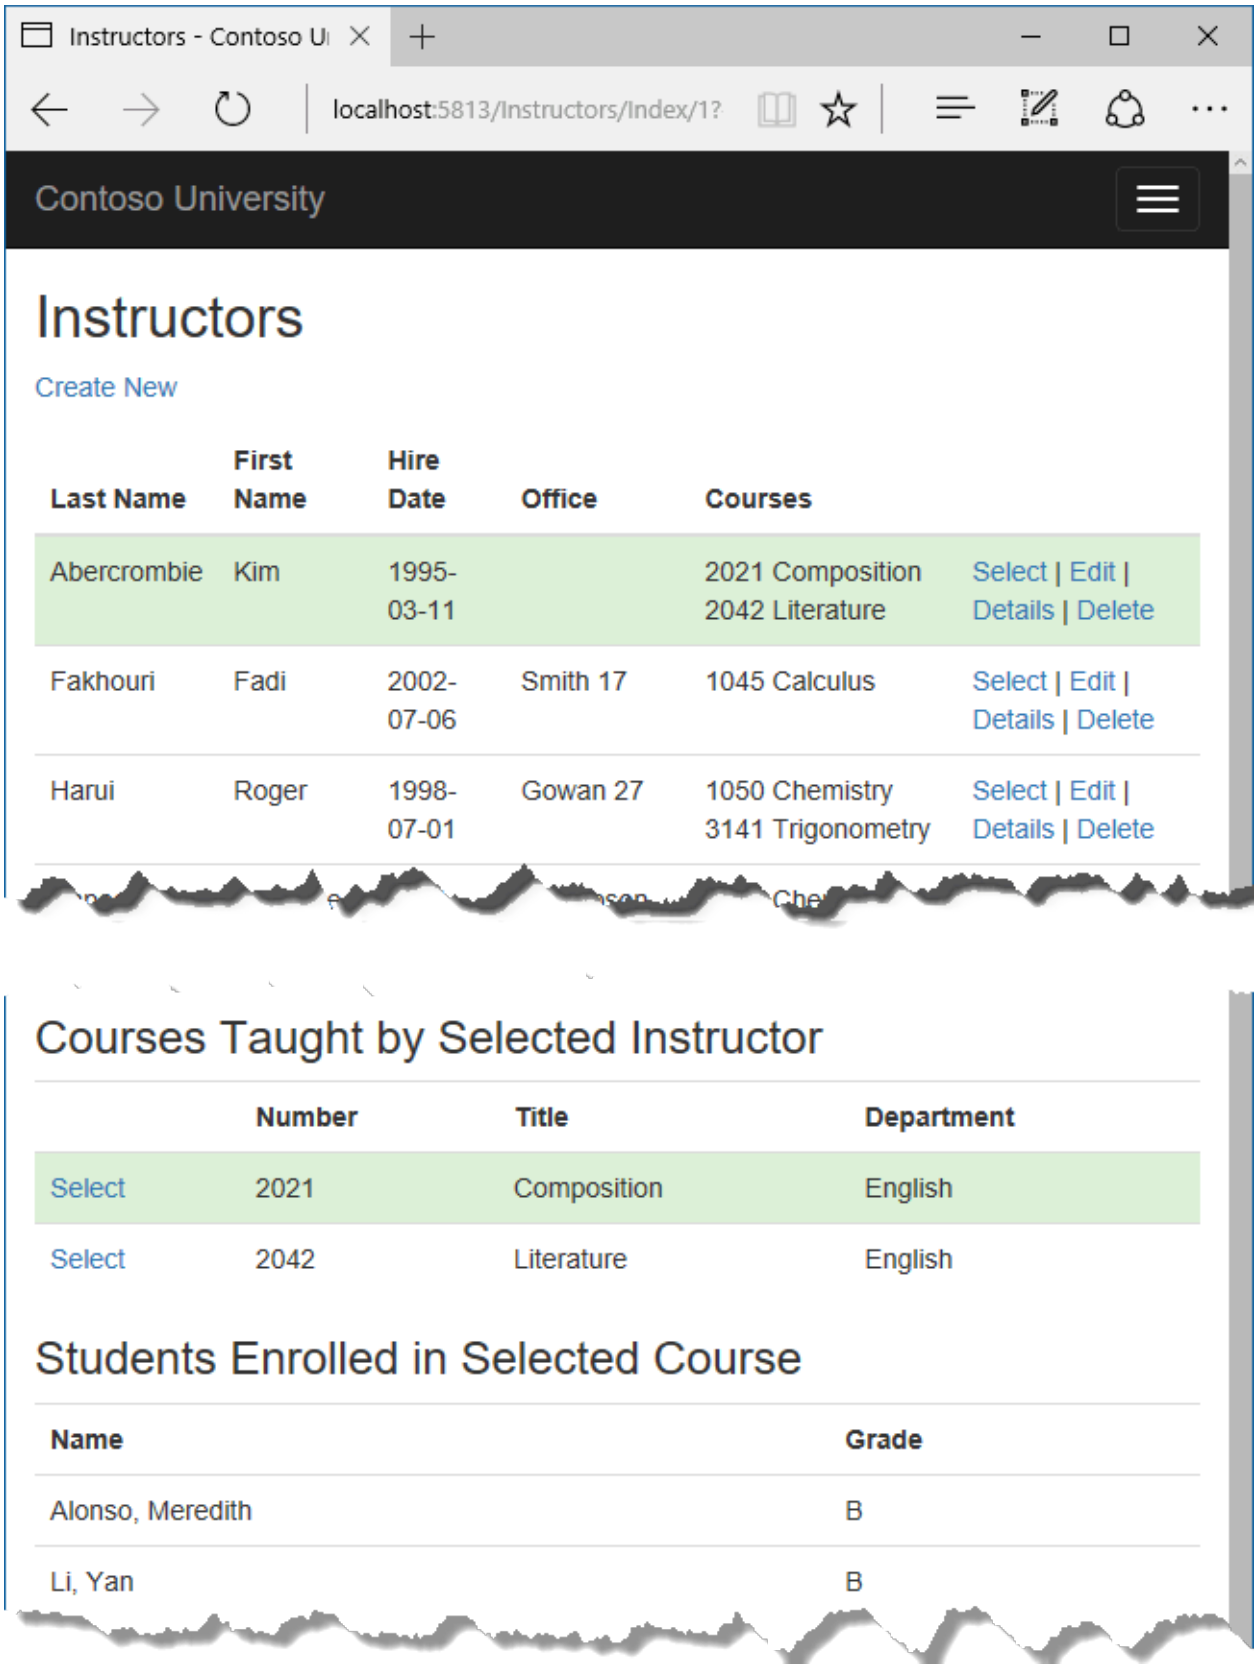
<p>
    <a asp-action="Create">Create New</a>
</p>
<table class="table">
    <thead>
        <tr>
            <th>
                @Html.DisplayNameFor(model => model.CourseID)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Title)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Credits)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Department)
            </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
        @foreach (var item in Model)
        {
            <tr>
                <td>
                    @Html.DisplayFor(modelItem => item.CourseID)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Title)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Credits)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Department.Name)
                </td>
                <td>
                    <a asp-action="Edit" asp-route-
id="@item.CourseID">Edit</a> |
                    <a asp-action="Details" asp-route-
id="@item.CourseID">Details</a> |
                    <a asp-action="Delete" asp-route-
id="@item.CourseID">Delete</a>
                </td>
            </tr>
        }
    </tbody>
</table>
```



You've made the following changes to the scaffolded code:

- Changed the heading from **Index** to **Courses**.
- Added a **Number** column that shows the `CourseID` property value. By default, primary keys aren't scaffolded because normally they're meaningless to end users. However, in this case the primary key is meaningful and you want to show it.
- Changed the **Department** column to display the department name. The code displays the `Name` property of the `Department` entity that's loaded into the `Department` navigation property:

```
HTML



@Html.DisplayFor(modelItem => item.Department.Name)
```

Run the app and select the **Courses** tab to see the list with department names.

Create an Instructors page

In this section, you'll create a controller and view for the `Instructor` entity in order to display the Instructors page:

This page reads and displays related data in the following ways:

- The list of instructors displays related data from the `OfficeAssignment` entity. The `Instructor` and `OfficeAssignment` entities are in a one-to-zero-or-one relationship. You'll use eager loading for the `OfficeAssignment` entities. As explained earlier, eager loading is typically more efficient when you need the

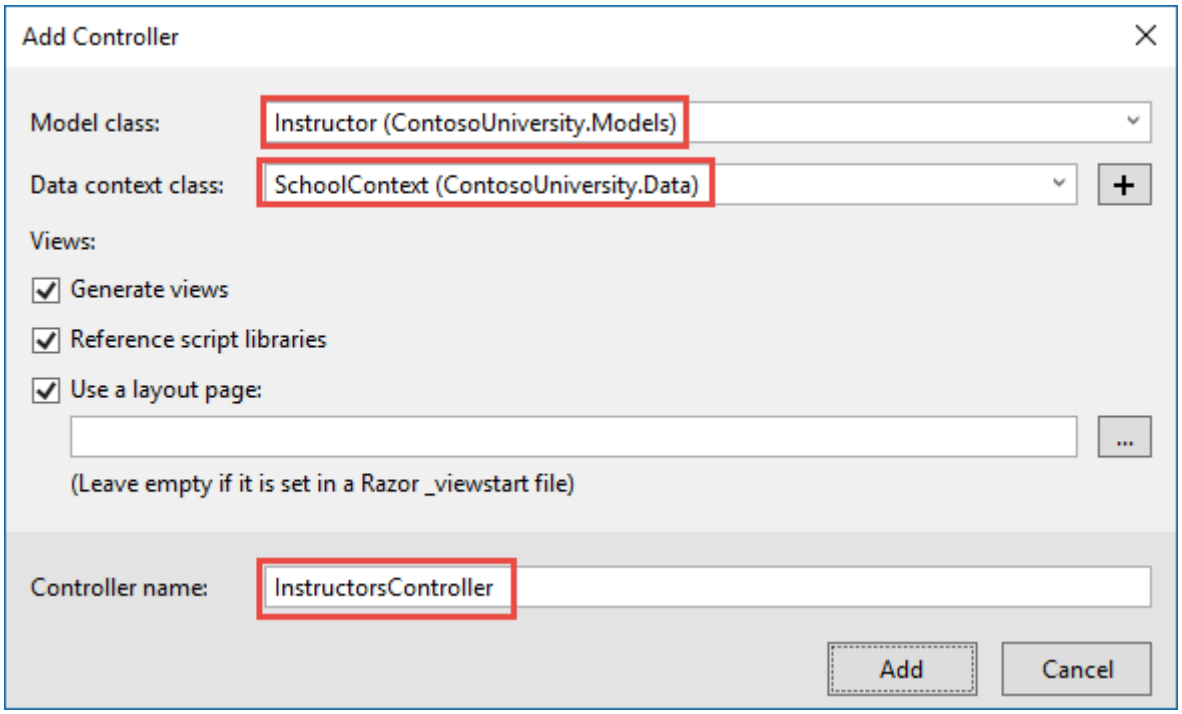
related data for all retrieved rows of the primary table. In this case, you want to display office assignments for all displayed instructors.

- When the user selects an instructor, related `Course` entities are displayed. The `Instructor` and `Course` entities are in a many-to-many relationship. You'll use eager loading for the `Course` entities and their related `Department` entities. In this case, separate queries might be more efficient because you need courses only for the selected instructor. However, this example shows how to use eager loading for navigation properties within entities that are themselves in navigation properties.
- When the user selects a course, related data from the `Enrollments` entity set is displayed. The `Course` and `Enrollment` entities are in a one-to-many relationship. You'll use separate queries for `Enrollment` entities and their related `Student` entities.

Create a view model for the Instructor Index view

The Instructors page shows data from three different tables. Therefore, you'll create a view model that includes three properties, each holding the data for one of the tables.

In the *SchoolViewModels* folder, create `InstructorIndexData.cs` and replace the existing code with the following code:



C#

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;

namespace ContosoUniversity.Models.SchoolViewModels
{
    public class InstructorIndexData
    {
        public IEnumerable<Instructor> Instructors { get; set; }
        public IEnumerable<Course> Courses { get; set; }
        public IEnumerable<Enrollment> Enrollments { get; set; }
    }
}
```

Create the Instructor controller and views

Create an Instructors controller with EF read/write actions as shown in the following illustration:

Open `InstructorsController.cs` and add a using statement for the ViewModels namespace:

C#

```
using ContosoUniversity.Models.SchoolViewModels;
```

Replace the Index method with the following code to do eager loading of related data and put it in the view model.

C#

```
public async Task<IActionResult> Index(int? id, int? courseID)
{
    var viewModel = new InstructorIndexData();
    viewModel.Instructors = await _context.Instructors
          .Include(i => i.OfficeAssignment)
          .Include(i => i.CourseAssignments)
            .ThenInclude(i => i.Course)
                .ThenInclude(i => i.Enrollments)
                    .ThenInclude(i => i.Student)
          .Include(i => i.CourseAssignments)
            .ThenInclude(i => i.Course)
                .ThenInclude(i => i.Department)
          .AsNoTracking()
          .OrderBy(i => i.LastName)
          .ToListAsync();

    if (id != null)
    {
        ViewData["InstructorID"] = id.Value;
        Instructor instructor = viewModel.Instructors.Where(
```

```
            i => i.ID == id.Value).Single();
        viewModel.Courses = instructor.CourseAssignments.Select(s =>
s.Course);
    }

    if (courseID != null)
    {
        ViewData["CourseID"] = courseID.Value;
        viewModel.Enrollments = viewModel.Courses.Where(
            x => x.CourseID == courseID).Single().Enrollments;
    }

    return View(viewModel);
}
```

The method accepts optional route data (`id`) and a query string parameter (`courseID`) that provide the ID values of the selected instructor and selected course. The parameters are provided by the **Select** hyperlinks on the page.

The code begins by creating an instance of the view model and putting in it the list of instructors. The code specifies eager loading for the `Instructor.OfficeAssignment` and the `Instructor.CourseAssignments` navigation properties. Within the `CourseAssignments` property, the `Course` property is loaded, and within that, the `Enrollments` and `Department` properties are loaded, and within each `Enrollment` entity the `Student` property is loaded.

C#

```
viewModel.Instructors = await _context.Instructors
      .Include(i => i.OfficeAssignment)
      .Include(i => i.CourseAssignments)
        .ThenInclude(i => i.Course)
            .ThenInclude(i => i.Enrollments)
                .ThenInclude(i => i.Student)
      .Include(i => i.CourseAssignments)
        .ThenInclude(i => i.Course)
            .ThenInclude(i => i.Department)
      .AsNoTracking()
      .OrderBy(i => i.LastName)
      .ToListAsync();
```

Since the view always requires the `OfficeAssignment` entity, it's more efficient to fetch that in the same query. Course entities are required when an instructor is selected in the web page, so a single query is better than multiple queries only if the page is displayed more often with a course selected than without.

The code repeats `CourseAssignments` and `Course` because you need two properties from `Course`. The first string of `ThenInclude` calls gets `CourseAssignment.Course`, `Course.Enrollments`, and `Enrollment.Student`.

You can read more about including multiple levels of related data here.

C#

```
viewModel.Instructors = await _context.Instructors
      .Include(i => i.OfficeAssignment)
      .Include(i => i.CourseAssignments)
        .ThenInclude(i => i.Course)
            .ThenInclude(i => i.Enrollments)
                .ThenInclude(i => i.Student)
      .Include(i => i.CourseAssignments)
        .ThenInclude(i => i.Course)
            .ThenInclude(i => i.Department)
      .AsNoTracking()
      .OrderBy(i => i.LastName)
      .ToListAsync();
```

At that point in the code, another `ThenInclude` would be for navigation properties of `Student`, which you don't need. But calling `Include` starts over with `Instructor` properties, so you have to go through the chain again, this time specifying `Course.Department` instead of `Course.Enrollments`.

C#

```
viewModel.Instructors = await _context.Instructors
      .Include(i => i.OfficeAssignment)
      .Include(i => i.CourseAssignments)
        .ThenInclude(i => i.Course)
            .ThenInclude(i => i.Enrollments)
                .ThenInclude(i => i.Student)
      .Include(i => i.CourseAssignments)
        .ThenInclude(i => i.Course)
            .ThenInclude(i => i.Department)
      .AsNoTracking()
      .OrderBy(i => i.LastName)
      .ToListAsync();
```

The following code executes when an instructor was selected. The selected instructor is retrieved from the list of instructors in the view model. The view model's `Courses` property is then loaded with the `Course` entities from that instructor's `CourseAssignments` navigation property.

C#

```
if (id != null)
{
    ViewData["InstructorID"] = id.Value;
    Instructor instructor = viewModel.Instructors.Where(
        i => i.ID == id.Value).Single();
    viewModel.Courses = instructor.CourseAssignments.Select(s => s.Course);
}
```

The `Where` method returns a collection, but in this case the criteria passed to that method result in only a single Instructor entity being returned. The `Single` method converts the collection into a single `Instructor` entity, which gives you access to that entity's `CourseAssignments` property. The `CourseAssignments` property contains `CourseAssignment` entities, from which you want only the related `Course` entities.

You use the `Single` method on a collection when you know the collection will have only one item. The `Single` method throws an exception if the collection passed to it's empty or if there's more than one item. An alternative is `SingleOrDefault`, which returns a default value (null in this case) if the collection is empty. However, in this case that would still result in an exception (from trying to find a `Courses` property on a null reference), and the exception message would less clearly indicate the cause of the problem. When you call the `Single` method, you can also pass in the Where condition instead of calling the `Where` method separately:

C#

```
.Single(i => i.ID == id.Value)
```

Instead of:

C#

```
.Where(i => i.ID == id.Value).Single()
```

Next, if a course was selected, the selected course is retrieved from the list of courses in the view model. Then the view model's `Enrollments` property is loaded with the Enrollment entities from that course's `Enrollments` navigation property.

C#

```
if (courseID != null)
{
    ViewData["CourseID"] = courseID.Value;
    viewModel.Enrollments = viewModel.Courses.Where(
```

```
        x => x.CourseID == courseID).Single().Enrollments;
}
```

Tracking vs no-tracking

No-tracking queries are useful when the results are used in a read-only scenario. They're generally quicker to execute because there's no need to set up the change tracking information. If the entities retrieved from the database don't need to be updated, then a no-tracking query is likely to perform better than a tracking query.

In some cases a tracking query is more efficient than a no-tracking query. For more information, see Tracking vs. No-Tracking Queries.

Modify the Instructor Index view

In `Views/Instructors/Index.cshtml`, replace the template code with the following code. The changes are highlighted.

CSHTML

```
@model ContosoUniversity.Models.SchoolViewModels.InstructorIndexData

@{
    ViewData["Title"] = "Instructors";
}

<h2>Instructors</h2>

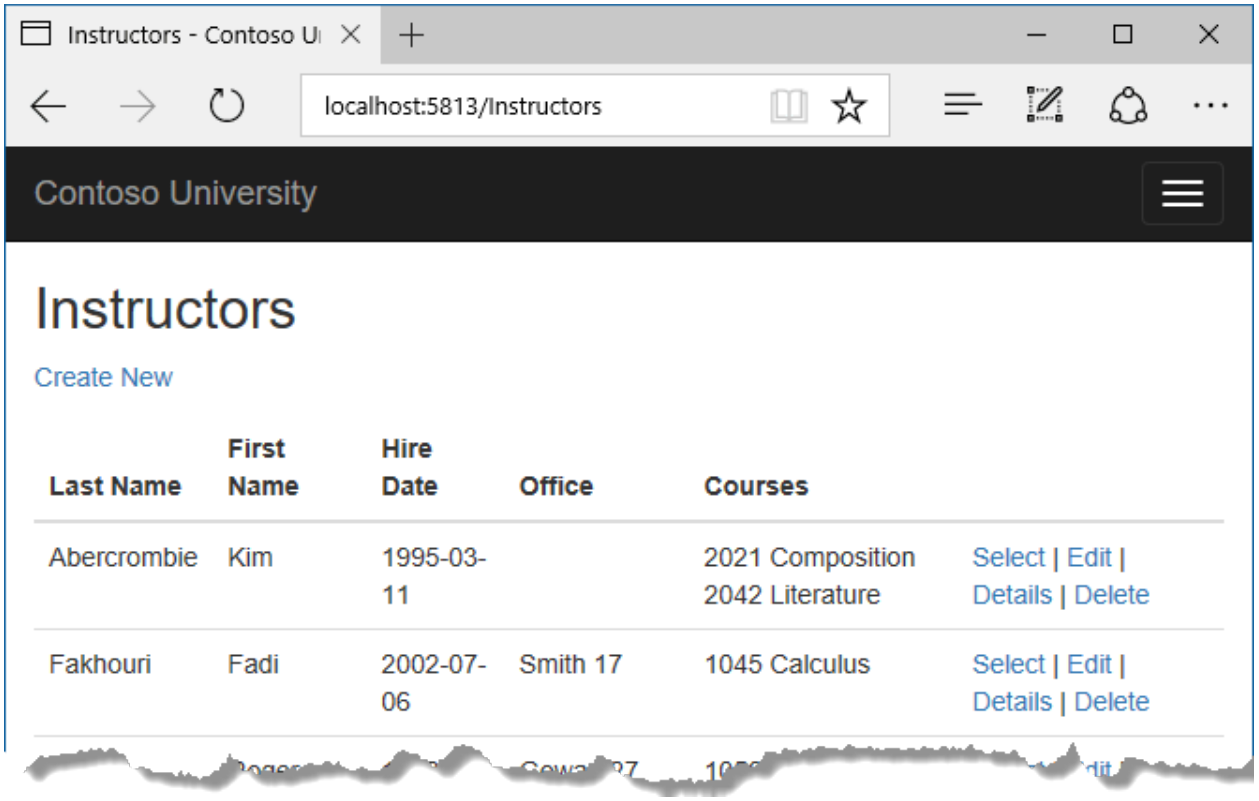
<p>
    <a asp-action="Create">Create New</a>
</p>
<table class="table">
    <thead>
        <tr>
            <th>Last Name</th>
            <th>First Name</th>
            <th>Hire Date</th>
            <th>Office</th>
            <th>Courses</th>
            <th></th>
        </tr>
    </thead>
    <tbody>
        @foreach (var item in Model.Instructors)
        {
```

```
            string selectedRow = "";
            if (item.ID == (int?)ViewData["InstructorID"])
            {
                selectedRow = "table-success";
            }
            <tr class="@selectedRow">
                <td>
                    @Html.DisplayFor(modelItem => item.LastName)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.FirstMidName)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.HireDate)
                </td>
                <td>
                    @if (item.OfficeAssignment != null)
                    {
                        @item.OfficeAssignment.Location
                    }
                </td>
                <td>
                    @foreach (var course in item.CourseAssignments)
                    {
                        @course.Course.CourseID @course.Course.Title <br />
                    }
                </td>
                <td>
                    <a asp-action="Index" asp-route-id="@item.ID">Select</a>
|
                    <a asp-action="Edit" asp-route-id="@item.ID">Edit</a> |
                    <a asp-action="Details" asp-route-
id="@item.ID">Details</a> |
                    <a asp-action="Delete" asp-route-
id="@item.ID">Delete</a>
                </td>
            </tr>
        }
    </tbody>
</table>
```

You've made the following changes to the existing code:

- Changed the model class to `InstructorIndexData`.
- Changed the page title from **Index** to **Instructors**.
- Added an **Office** column that displays `item.OfficeAssignment.Location` only if `item.OfficeAssignment` isn't null. (Because this is a one-to-zero-or-one relationship, there might not be a related OfficeAssignment entity.)

CSHTML



```
@if (item.OfficeAssignment != null)
{
    @item.OfficeAssignment.Location
}
```

- Added a **Courses** column that displays courses taught by each instructor. For more information, see the Explicit line transition section of the Razor syntax article.
- Added code that conditionally adds a Bootstrap CSS class to the `tr` element of the selected instructor. This class sets a background color for the selected row.
- Added a new hyperlink labeled **Select** immediately before the other links in each row, which causes the selected instructor's ID to be sent to the `Index` method.

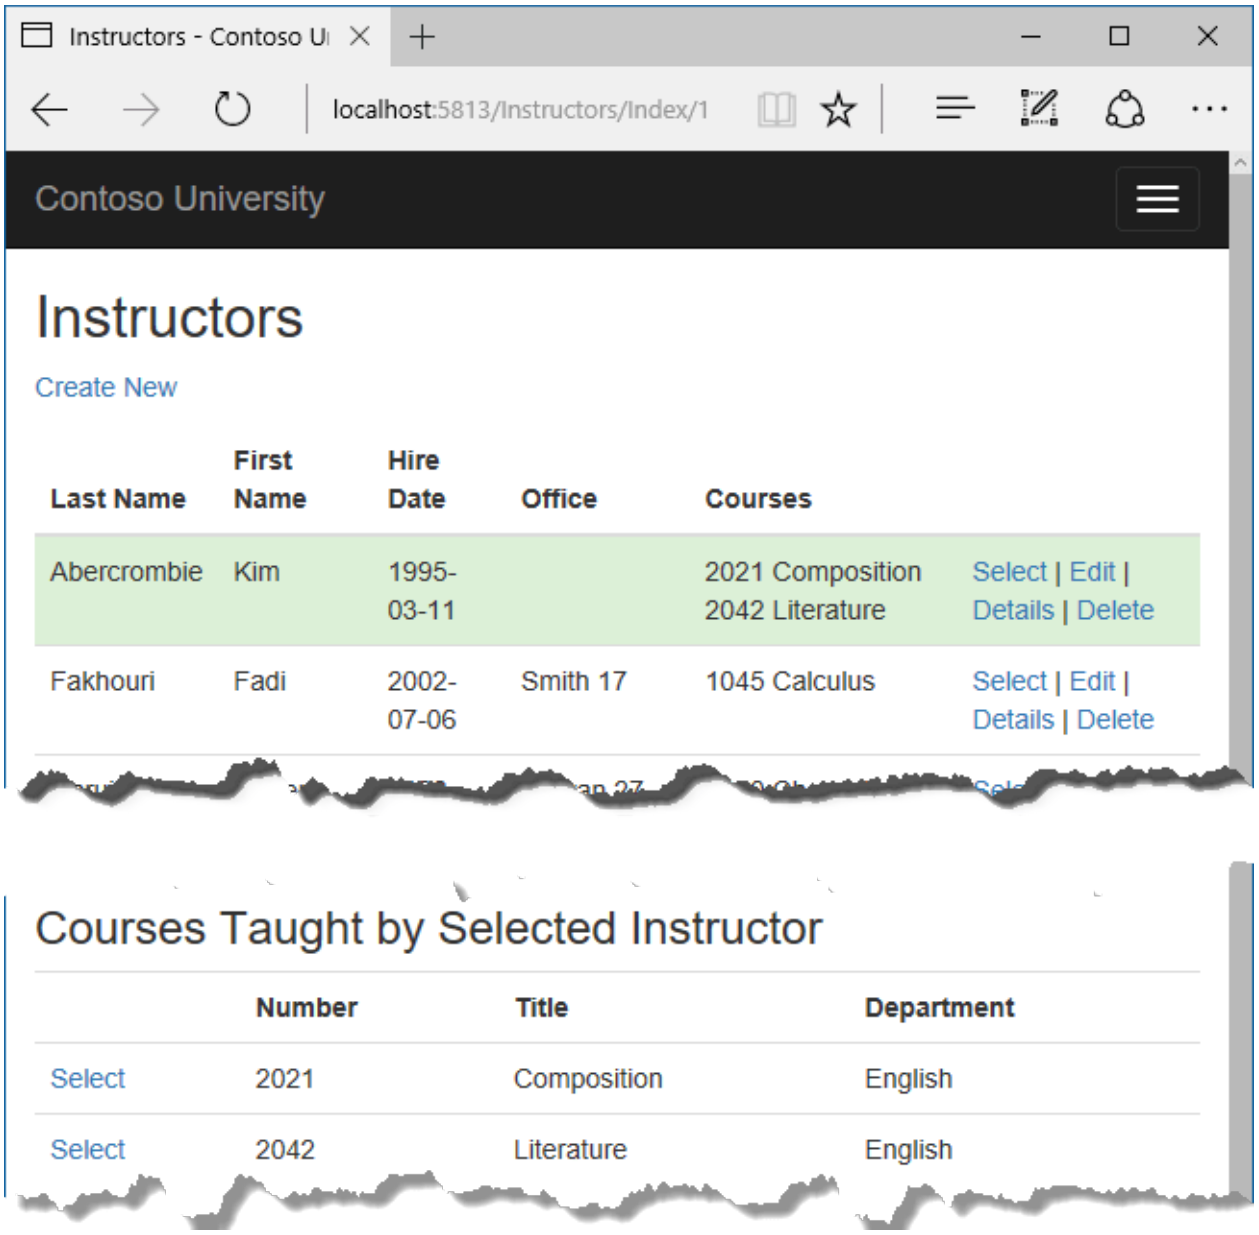
CSHTML

```
<a asp-action="Index" asp-route-id="@item.ID">Select</a> |
```

Run the app and select the **Instructors** tab. The page displays the Location property of related OfficeAssignment entities and an empty table cell when there's no related OfficeAssignment entity.

In the `Views/Instructors/Index.cshtml` file, after the closing table element (at the end of the file), add the following code. This code displays a list of courses related to an instructor when an instructor is selected.

CSHTML



```
@if (Model.Courses != null)
{
    <h3>Courses Taught by Selected Instructor</h3>
    <table class="table">
        <tr>
            <th></th>
            <th>Number</th>
            <th>Title</th>
            <th>Department</th>
        </tr>

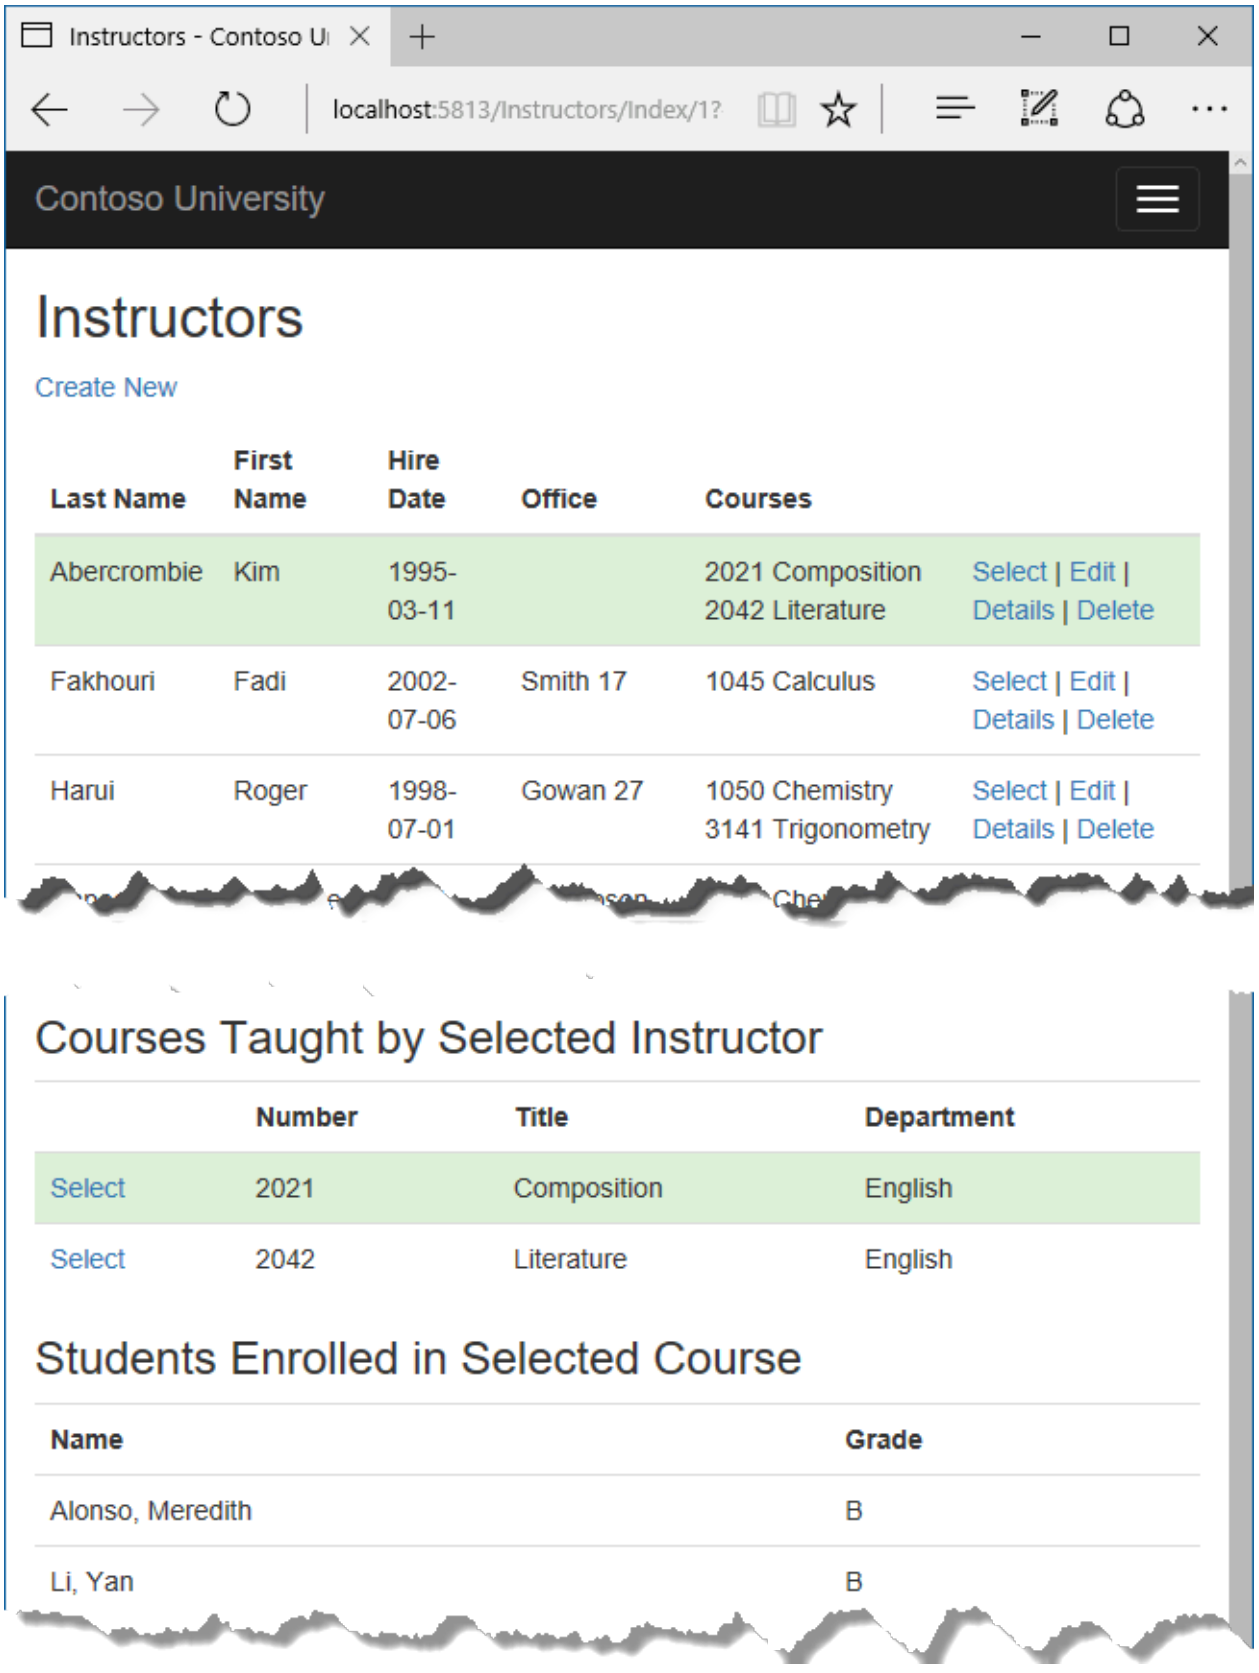
        @foreach (var item in Model.Courses)
        {
            string selectedRow = "";
            if (item.CourseID == (int?)ViewData["CourseID"])
            {
                selectedRow = "success";
            }
            <tr class="@selectedRow">
                <td>
                    @Html.ActionLink("Select", "Index", new { courseID =
item.CourseID })
                </td>
                <td>
                    @item.CourseID
                </td>
                <td>
                    @item.Title
                </td>
                <td>
                    @item.Department.Name
                </td>
            </tr>
        }

    </table>
}
```

This code reads the `Courses` property of the view model to display a list of courses. It also provides a **Select** hyperlink that sends the ID of the selected course to the `Index` action method.

Refresh the page and select an instructor. Now you see a grid that displays courses assigned to the selected instructor, and for each course you see the name of the assigned department.

After the code block you just added, add the following code. This displays a list of the students who are enrolled in a course when that course is selected.



CSHTML

```
@if (Model.Enrollments != null)
{
    <h3>
        Students Enrolled in Selected Course
    </h3>
    <table class="table">
        <tr>
            <th>Name</th>
            <th>Grade</th>
        </tr>
        @foreach (var item in Model.Enrollments)
        {
            <tr>
                <td>
                    @item.Student.FullName
```

```
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Grade)
                </td>
            </tr>
        }
    </table>
}
```

This code reads the `Enrollments` property of the view model in order to display a list of students enrolled in the course.

Refresh the page again and select an instructor. Then select a course to see the list of enrolled students and their grades.

About explicit loading

When you retrieved the list of instructors in `InstructorsController.cs`, you specified eager loading for the `CourseAssignments` navigation property.

Suppose you expected users to only rarely want to see enrollments in a selected instructor and course. In that case, you might want to load the enrollment data only if

it's requested. To see an example of how to do explicit loading, replace the `Index` method with the following code, which removes eager loading for `Enrollments` and loads that property explicitly. The code changes are highlighted.

C#

```
public async Task<IActionResult> Index(int? id, int? courseID)
{
    var viewModel = new InstructorIndexData();
    viewModel.Instructors = await _context.Instructors
          .Include(i => i.OfficeAssignment)
          .Include(i => i.CourseAssignments)
            .ThenInclude(i => i.Course)
                .ThenInclude(i => i.Department)
          .OrderBy(i => i.LastName)
          .ToListAsync();

    if (id != null)
    {
        ViewData["InstructorID"] = id.Value;
        Instructor instructor = viewModel.Instructors.Where(
            i => i.ID == id.Value).Single();
        viewModel.Courses = instructor.CourseAssignments.Select(s =>
s.Course);
    }

    if (courseID != null)
    {
        ViewData["CourseID"] = courseID.Value;
        var selectedCourse = viewModel.Courses.Where(x => x.CourseID ==
courseID).Single();
        await _context.Entry(selectedCourse).Collection(x =>
x.Enrollments).LoadAsync();
        foreach (Enrollment enrollment in selectedCourse.Enrollments)
        {
            await _context.Entry(enrollment).Reference(x =>
x.Student).LoadAsync();
        }
        viewModel.Enrollments = selectedCourse.Enrollments;
    }

    return View(viewModel);
}
```

The new code drops the `ThenInclude` method calls for enrollment data from the code that retrieves instructor entities. It also drops `AsNoTracking`. If an instructor and course are selected, the highlighted code retrieves `Enrollment` entities for the selected course, and `Student` entities for each `Enrollment`.

Run the app, go to the Instructors Index page now and you'll see no difference in what's displayed on the page, although you've changed how the data is retrieved.

Get the code

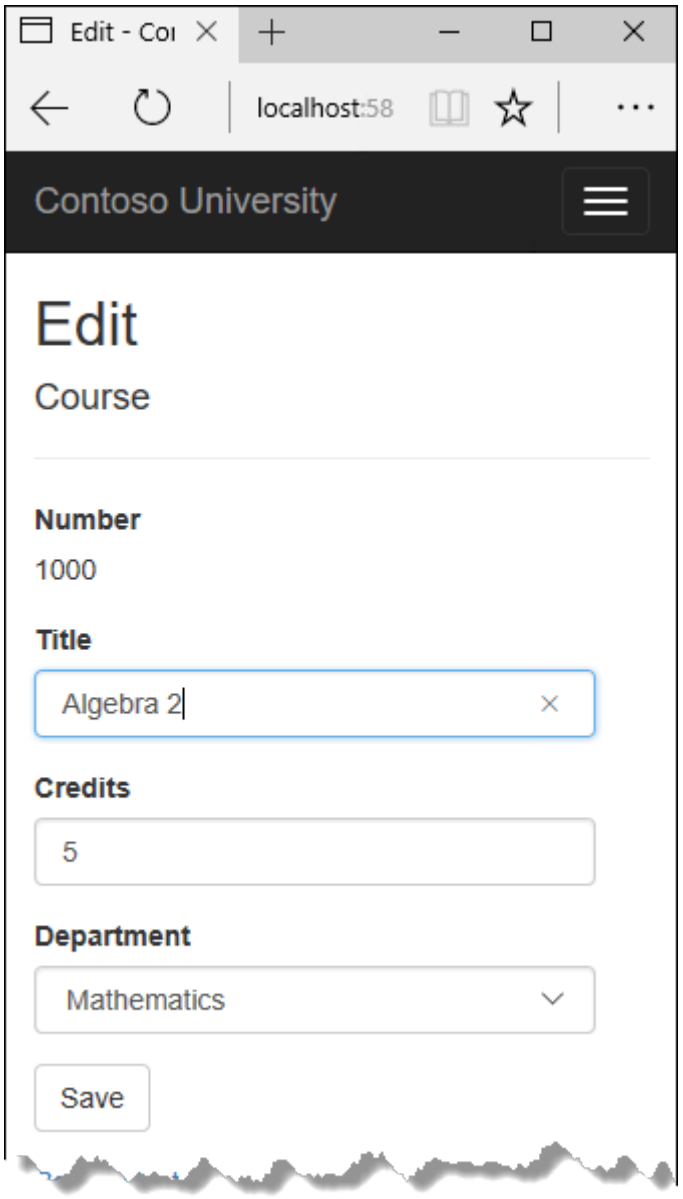
Download or view the completed application.

Next steps

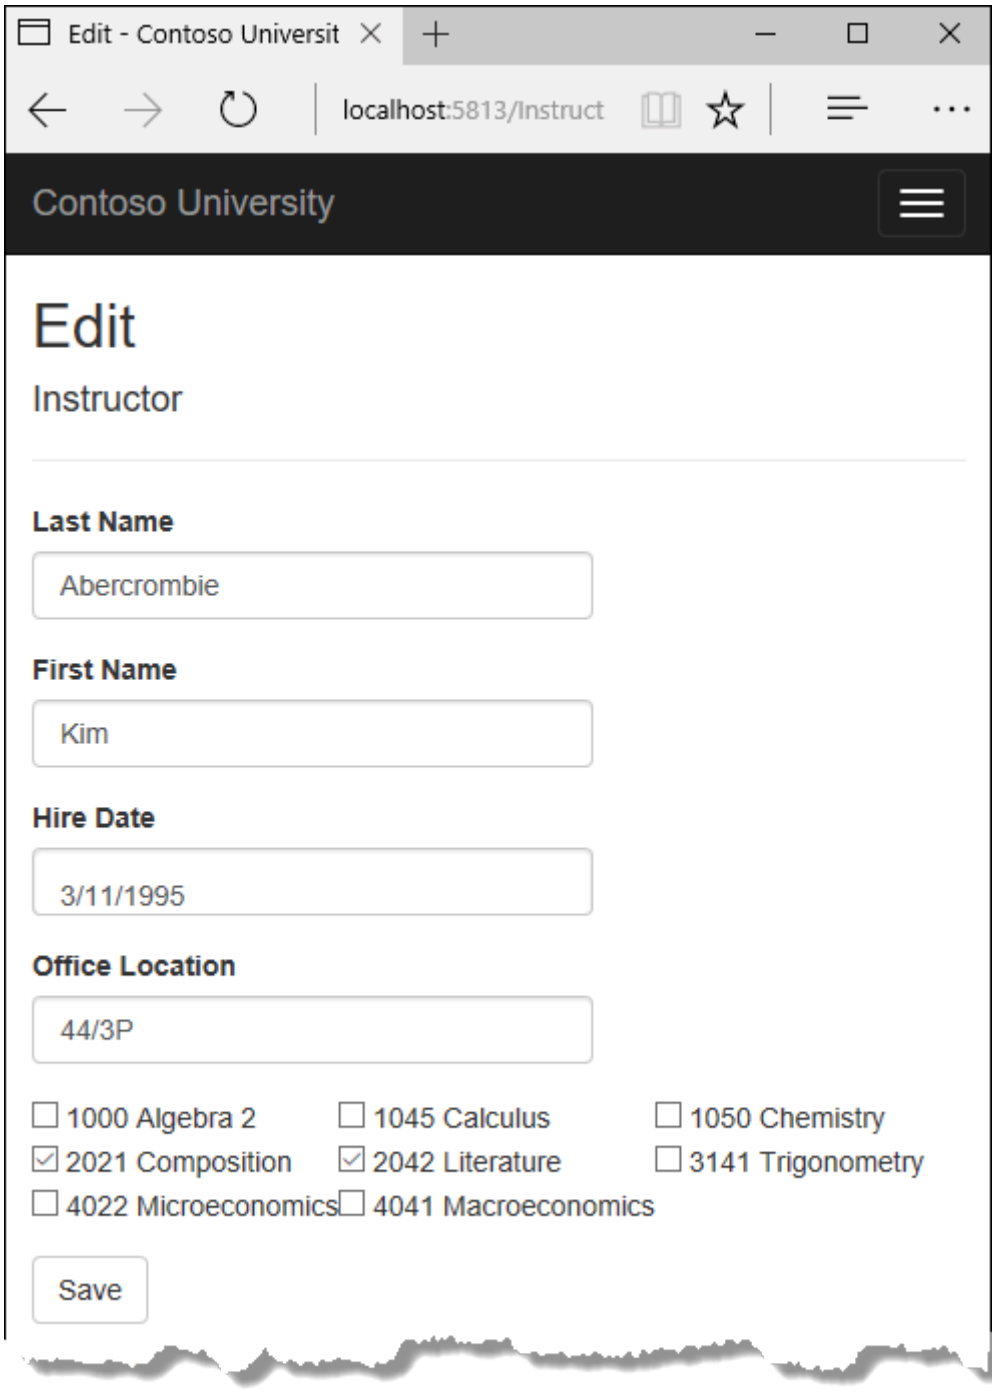
In this tutorial, you:

- ✓ Learned how to load related data
- ✓ Created a Courses page
- ✓ Created an Instructors page
- ✓ Learned about explicit loading

Advance to the next tutorial to learn how to update related data.



Update related data



Tutorial: Update related data - ASP.NET MVC with EF Core

Article • 04/10/2024

In the previous tutorial you displayed related data; in this tutorial you'll update related data by updating foreign key fields and navigation properties.

The following illustrations show some of the pages that you'll work with.

In this tutorial, you:

- ✓ Customize Courses pages
- ✓ Add Instructors Edit page
- ✓ Add courses to Edit page
- ✓ Update Delete page
- ✓ Add office location and courses to Create page

Prerequisites

- Read related data

Customize Courses pages

When a new `Course` entity is created, it must have a relationship to an existing department. To facilitate this, the scaffolded code includes controller methods and Create and Edit views that include a drop-down list for selecting the department. The drop-down list sets the `Course.DepartmentID` foreign key property, and that's all the Entity Framework needs in order to load the `Department` navigation property with the appropriate `Department` entity. You'll use the scaffolded code, but change it slightly to add error handling and sort the drop-down list.

In `CoursesController.cs`, delete the four Create and Edit methods and replace them with the following code:

C#

```
public IActionResult Create()
{
    PopulateDepartmentsDropDownList();
    return View();
}
```

C#

```
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<IActionResult>
Create([Bind("CourseID,Credits,DepartmentID,Title")] Course course)
{
    if (ModelState.IsValid)
    {
        _context.Add(course);
        await _context.SaveChangesAsync();
        return RedirectToAction(nameof(Index));
    }
    PopulateDepartmentsDropDownList(course.DepartmentID);
    return View(course);
}
```

C#

```
public async Task<IActionResult> Edit(int? id)
{
    if (id == null)
    {
        return NotFound();
    }
```

```
    var course = await _context.Courses
        .AsNoTracking()
        .FirstOrDefaultAsync(m => m.CourseID == id);
    if (course == null)
    {
        return NotFound();
    }
    PopulateDepartmentsDropDownList(course.DepartmentID);
    return View(course);
}
```

C#

```
[HttpPost, ActionName("Edit")]
[ValidateAntiForgeryToken]
public async Task<IActionResult> EditPost(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    var courseToUpdate = await _context.Courses
        .FirstOrDefaultAsync(c => c.CourseID == id);

    if (await TryUpdateModelAsync<Course>(courseToUpdate,
        "",
        c => c.Credits, c => c.DepartmentID, c => c.Title))
    {
        try
        {
            await _context.SaveChangesAsync();
        }
        catch (DbUpdateException /* ex */)
        {
            //Log the error (uncomment ex variable name and write a log.)
            ModelState.AddModelError("", "Unable to save changes. " +
                "Try again, and if the problem persists, " +
                "see your system administrator.");
        }
        return RedirectToAction(nameof(Index));
    }
    PopulateDepartmentsDropDownList(courseToUpdate.DepartmentID);
    return View(courseToUpdate);
}
```

After the `Edit` HttpPost method, create a new method that loads department info for the drop-down list.

C#

```
private void PopulateDepartmentsDropDownList(object selectedDepartment =
null)
{
    var departmentsQuery = from d in _context.Departments
                           orderby d.Name
                           select d;
    ViewBag.DepartmentID = new SelectList(departmentsQuery.AsNoTracking(),
"DepartmentID", "Name", selectedDepartment);
}
```

The `PopulateDepartmentsDropDownList` method gets a list of all departments sorted by name, creates a `SelectList` collection for a drop-down list, and passes the collection to the view in `ViewBag`. The method accepts the optional `selectedDepartment` parameter that allows the calling code to specify the item that will be selected when the drop-down list is rendered. The view will pass the name "DepartmentID" to the `<select>` tag helper, and the helper then knows to look in the `ViewBag` object for a `SelectList` named "DepartmentID".

The HttpGet `Create` method calls the `PopulateDepartmentsDropDownList` method without setting the selected item, because for a new course the department isn't established yet:

C#

```
public IActionResult Create()
{
    PopulateDepartmentsDropDownList();
    return View();
}
```

The HttpGet `Edit` method sets the selected item, based on the ID of the department that's already assigned to the course being edited:

C#

```
public async Task<IActionResult> Edit(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    var course = await _context.Courses
        .AsNoTracking()
        .FirstOrDefaultAsync(m => m.CourseID == id);
    if (course == null)
    {
        return NotFound();
```

```
    }
    PopulateDepartmentsDropDownList(course.DepartmentID);
    return View(course);
}
```

The HttpPost methods for both `Create` and `Edit` also include code that sets the selected item when they redisplay the page after an error. This ensures that when the page is redisplayed to show the error message, whatever department was selected stays selected.

Add .AsNoTracking to Details and Delete methods

To optimize performance of the Course Details and Delete pages, add `AsNoTracking` calls in the `Details` and HttpGet `Delete` methods.

C#

```
public async Task<IActionResult> Details(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    var course = await _context.Courses
        .Include(c => c.Department)
        .AsNoTracking()
        .FirstOrDefaultAsync(m => m.CourseID == id);
    if (course == null)
    {
        return NotFound();
    }

    return View(course);
}
```

C#

```
public async Task<IActionResult> Delete(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    var course = await _context.Courses
        .Include(c => c.Department)
        .AsNoTracking()
        .FirstOrDefaultAsync(m => m.CourseID == id);
```

```
    if (course == null)
    {
        return NotFound();
    }

    return View(course);
}
```

Modify the Course views

In `Views/Courses/Create.cshtml`, add a "Select Department" option to the **Department** drop-down list, change the caption from **DepartmentID** to **Department**, and add a validation message.

CSHTML

```
<div class="form-group">
    <label asp-for="Department" class="control-label"></label>
    <select asp-for="DepartmentID" class="form-control" asp-
items="ViewBag.DepartmentID">
        <option value="">-- Select Department --</option>
    </select>
    <span asp-validation-for="DepartmentID" class="text-danger" />
</div>
```

In `Views/Courses/Edit.cshtml`, make the same change for the Department field that you just did in `Create.cshtml`.

Also in `Views/Courses/Edit.cshtml`, add a course number field before the **Title** field. Because the course number is the primary key, it's displayed, but it can't be changed.

CSHTML

```
<div class="form-group">
    <label asp-for="CourseID" class="control-label"></label>
    <div>@Html.DisplayFor(model => model.CourseID)</div>
</div>
```

There's already a hidden field (`<input type="hidden">`) for the course number in the Edit view. Adding a `<label>` tag helper doesn't eliminate the need for the hidden field because it doesn't cause the course number to be included in the posted data when the user clicks **Save** on the **Edit** page.

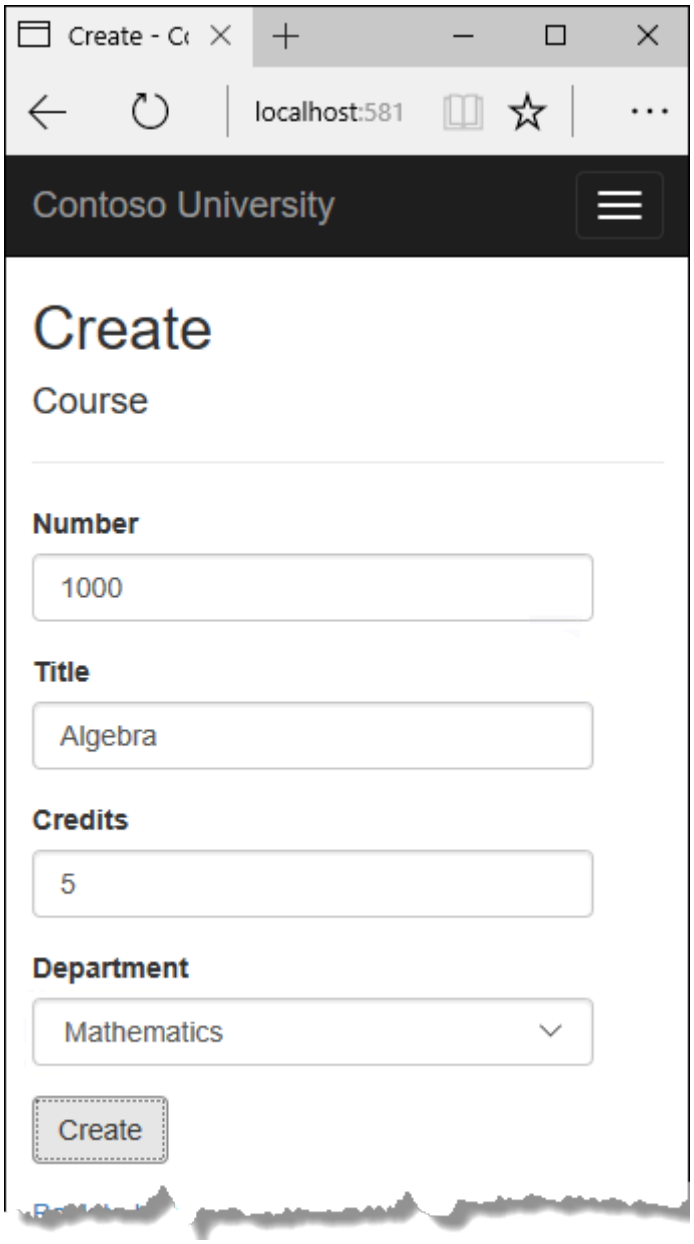
In `Views/Courses/Delete.cshtml`, add a course number field at the top and change department ID to department name.

CSHTML

```
@model ContosoUniversity.Models.Course

@{
    ViewData["Title"] = "Delete";
}

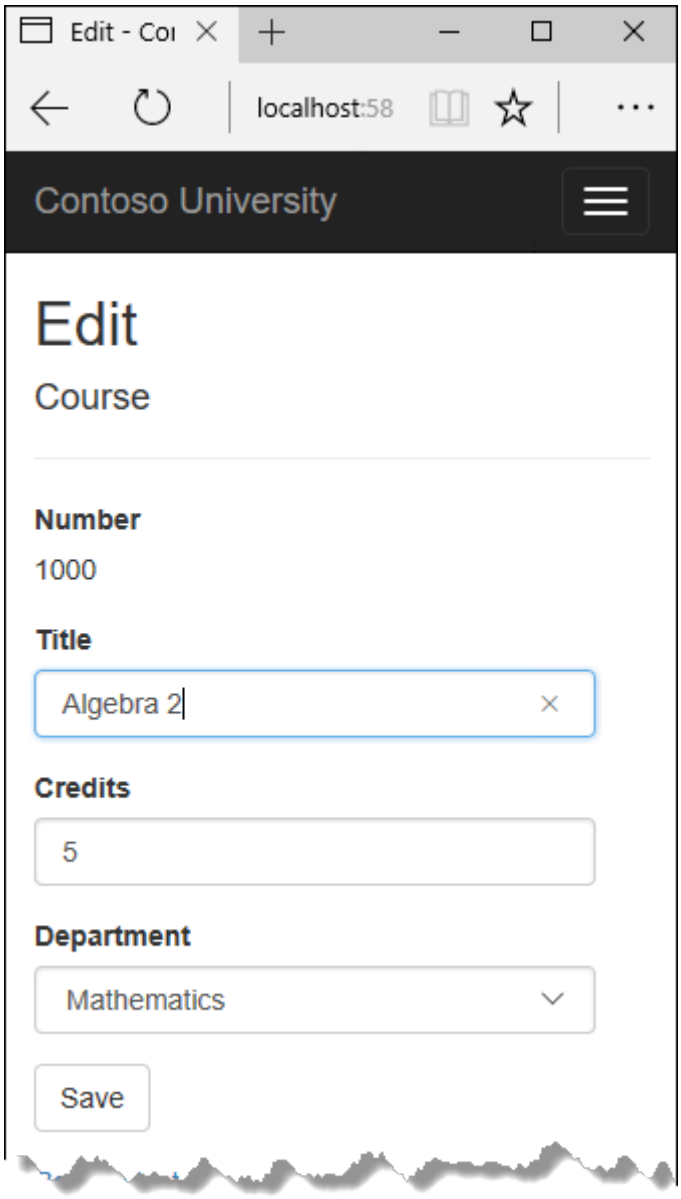
<h2>Delete</h2>



<h3>Are you sure you want to delete this?</h3>
<div>
    <h4>Course</h4>
    <hr />
    <dl class="row">
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.CourseID)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.CourseID)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Title)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Title)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Credits)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Credits)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Department)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Department.Name)
        </dd>
    </dl>

    <form asp-action="Delete">
        <div class="form-actions no-color">
            <input type="submit" value="Delete" class="btn btn-default" /> |
            <a asp-action="Index">Back to List</a>
        </div>
    </form>
</div>
```

In `Views/Courses/Details.cshtml`, make the same change that you just did for `Delete.cshtml`.



Test the Course pages

Run the app, select the **Courses** tab, click **Create New**, and enter data for a new course:

Click **Create**. The Courses Index page is displayed with the new course added to the list. The department name in the Index page list comes from the navigation property, showing that the relationship was established correctly.

Click **Edit** on a course in the Courses Index page.

Change data on the page and click **Save**. The Courses Index page is displayed with the updated course data.

Add Instructors Edit page

When you edit an instructor record, you want to be able to update the instructor's office assignment. The `Instructor` entity has a one-to-zero-or-one relationship with the `OfficeAssignment` entity, which means your code has to handle the following situations:

- If the user clears the office assignment and it originally had a value, delete the `OfficeAssignment` entity.
- If the user enters an office assignment value and it originally was empty, create a new `OfficeAssignment` entity.
- If the user changes the value of an office assignment, change the value in an existing `OfficeAssignment` entity.

Update the Instructors controller

In `InstructorsController.cs`, change the code in the HttpGet `Edit` method so that it loads the Instructor entity's `OfficeAssignment` navigation property and calls `AsNoTracking`:

C#

```
public async Task<IActionResult> Edit(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    var instructor = await _context.Instructors
        .Include(i => i.OfficeAssignment)
        .AsNoTracking()
        .FirstOrDefaultAsync(m => m.ID == id);
    if (instructor == null)
    {
        return NotFound();
    }
    return View(instructor);
}
```

Replace the HttpPost `Edit` method with the following code to handle office assignment updates:

C#

```
[HttpPost, ActionName("Edit")]
[ValidateAntiForgeryToken]
public async Task<IActionResult> EditPost(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    var instructorToUpdate = await _context.Instructors
        .Include(i => i.OfficeAssignment)
        .FirstOrDefaultAsync(s => s.ID == id);

    if (await TryUpdateModelAsync<Instructor>(
        instructorToUpdate,
        "",
        i => i.FirstMidName, i => i.LastName, i => i.HireDate, i =>
i.OfficeAssignment))
    {
```

```
        if
(String.IsNullOrWhiteSpace(instructorToUpdate.OfficeAssignment?.Location))
        {
            instructorToUpdate.OfficeAssignment = null;
        }
        try
        {
            await _context.SaveChangesAsync();
        }
        catch (DbUpdateException /* ex */)
        {
            //Log the error (uncomment ex variable name and write a log.)
            ModelState.AddModelError("", "Unable to save changes. " +
                "Try again, and if the problem persists, " +
                "see your system administrator.");
        }
        return RedirectToAction(nameof(Index));
    }
    return View(instructorToUpdate);
}
```

The code does the following:

- Changes the method name to `EditPost` because the signature is now the same as the HttpGet `Edit` method (the `ActionName` attribute specifies that the `/Edit/` URL is still used).
- Gets the current `Instructor` entity from the database using eager loading for the `OfficeAssignment` navigation property. This is the same as what you did in the HttpGet `Edit` method.
- Updates the retrieved `Instructor` entity with values from the model binder. The `TryUpdateModel` overload enables you to declare the properties you want to include. This prevents over-posting, as explained in the second tutorial.

  C#

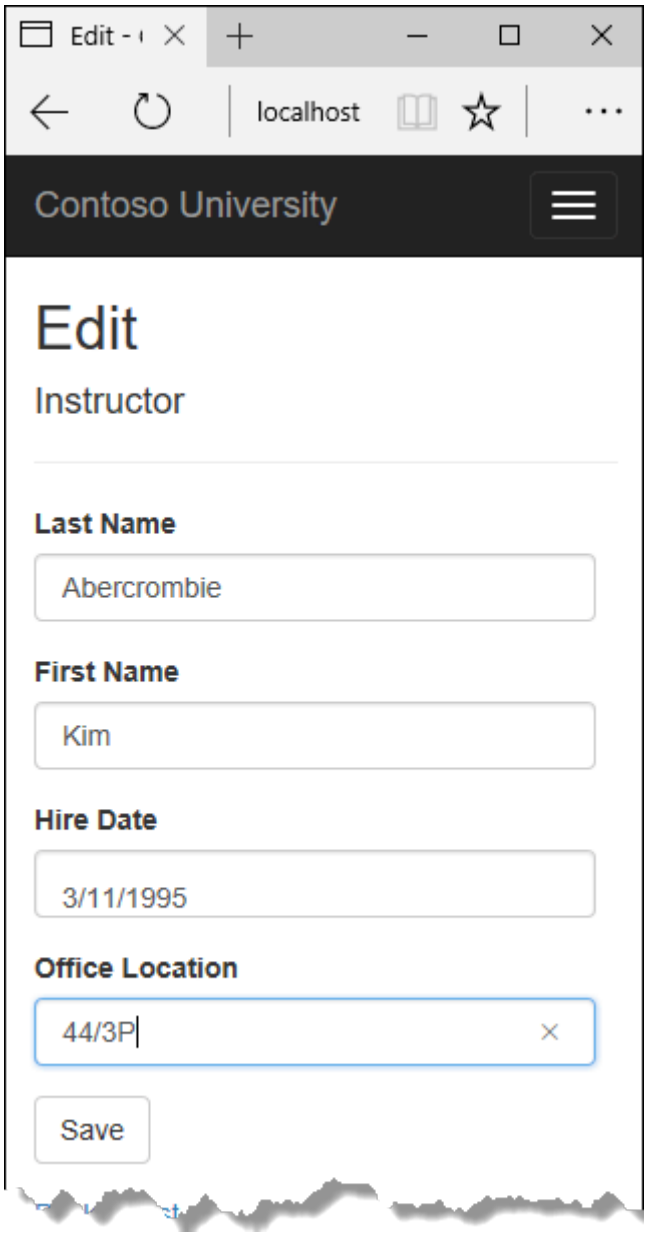
  ```
  if (await TryUpdateModelAsync<Instructor>(
      instructorToUpdate,
      "",
      i => i.FirstMidName, i => i.LastName, i => i.HireDate, i =>
  i.OfficeAssignment))
  ```

- If the office location is blank, sets the `Instructor.OfficeAssignment` property to null so that the related row in the `OfficeAssignment` table will be deleted.

  C#

```
if
(String.IsNullOrWhiteSpace(instructorToUpdate.OfficeAssignment?.Locatio
n))
{
    instructorToUpdate.OfficeAssignment = null;
}
```

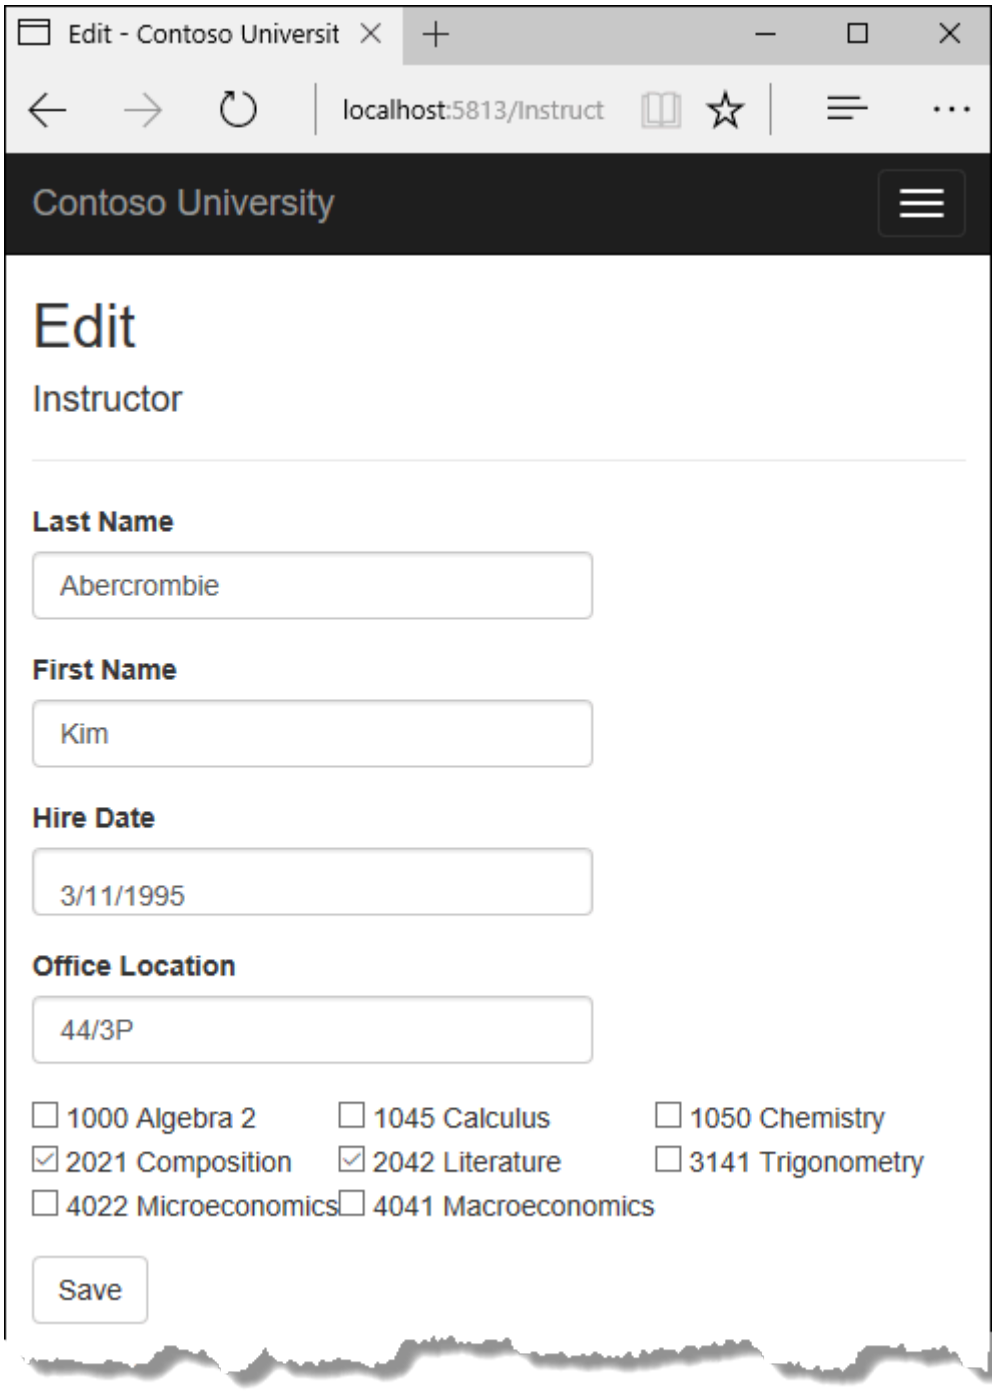
- Saves the changes to the database.



Update the Instructor Edit view

In `Views/Instructors/Edit.cshtml`, add a new field for editing the office location, at the end before the **Save** button:

CSHTML



```
<div class="form-group">
    <label asp-for="OfficeAssignment.Location" class="control-label">
</label>
    <input asp-for="OfficeAssignment.Location" class="form-control" />
    <span asp-validation-for="OfficeAssignment.Location" class="text-danger"
/>
</div>
```

Run the app, select the **Instructors** tab, and then click **Edit** on an instructor. Change the **Office Location** and click **Save**.

Add courses to Edit page

Instructors may teach any number of courses. Now you'll enhance the Instructor Edit page by adding the ability to change course assignments using a group of checkboxes, as shown in the following screen shot:

The relationship between the `Course` and `Instructor` entities is many-to-many. To add and remove relationships, you add and remove entities to and from the `CourseAssignments` join entity set.

The UI that enables you to change which courses an instructor is assigned to is a group of checkboxes. A checkbox for every course in the database is displayed, and the ones that the instructor is currently assigned to are selected. The user can select or clear checkboxes to change course assignments. If the number of courses were much greater, you would probably want to use a different method of presenting the data in the view, but you'd use the same method of manipulating a join entity to create or delete relationships.

Update the Instructors controller

To provide data to the view for the list of checkboxes, you'll use a view model class.

Create `AssignedCourseData.cs` in the *SchoolViewModels* folder and replace the existing code with the following code:

C#

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;

namespace ContosoUniversity.Models.SchoolViewModels
{
    public class AssignedCourseData
    {
        public int CourseID { get; set; }
        public string Title { get; set; }
        public bool Assigned { get; set; }
    }
}
```

In `InstructorsController.cs`, replace the HttpGet `Edit` method with the following code. The changes are highlighted.

C#

```
public async Task<IActionResult> Edit(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    var instructor = await _context.Instructors
        .Include(i => i.OfficeAssignment)
        .Include(i => i.CourseAssignments).ThenInclude(i => i.Course)
        .AsNoTracking()
        .FirstOrDefaultAsync(m => m.ID == id);
    if (instructor == null)
    {
        return NotFound();
    }
    PopulateAssignedCourseData(instructor);
    return View(instructor);
}

private void PopulateAssignedCourseData(Instructor instructor)
{
```

```
    var allCourses = _context.Courses;
    var instructorCourses = new HashSet<int>
(instructor.CourseAssignments.Select(c => c.CourseID));
    var viewModel = new List<AssignedCourseData>();
    foreach (var course in allCourses)
    {
        viewModel.Add(new AssignedCourseData
        {
            CourseID = course.CourseID,
            Title = course.Title,
            Assigned = instructorCourses.Contains(course.CourseID)
        });
    }
    ViewData["Courses"] = viewModel;
}
```

The code adds eager loading for the `Courses` navigation property and calls the new `PopulateAssignedCourseData` method to provide information for the checkbox array using the `AssignedCourseData` view model class.

The code in the `PopulateAssignedCourseData` method reads through all `Course` entities in order to load a list of courses using the view model class. For each course, the code checks whether the course exists in the instructor's `Courses` navigation property. To create efficient lookup when checking whether a course is assigned to the instructor, the courses assigned to the instructor are put into a `HashSet` collection. The `Assigned` property is set to true for courses the instructor is assigned to. The view will use this property to determine which checkboxes must be displayed as selected. Finally, the list is passed to the view in `ViewData`.

Next, add the code that's executed when the user clicks **Save**. Replace the `EditPost` method with the following code, and add a new method that updates the `Courses` navigation property of the Instructor entity.

C#

```
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<IActionResult> Edit(int? id, string[] selectedCourses)
{
    if (id == null)
    {
        return NotFound();
    }

    var instructorToUpdate = await _context.Instructors
        .Include(i => i.OfficeAssignment)
        .Include(i => i.CourseAssignments)
            .ThenInclude(i => i.Course)
```

```
            .FirstOrDefaultAsync(m => m.ID == id);

        if (await TryUpdateModelAsync<Instructor>(
            instructorToUpdate,
            "",
            i => i.FirstMidName, i => i.LastName, i => i.HireDate, i =>
i.OfficeAssignment))
        {
            if
(String.IsNullOrWhiteSpace(instructorToUpdate.OfficeAssignment?.Location))
            {
                instructorToUpdate.OfficeAssignment = null;
            }
            UpdateInstructorCourses(selectedCourses, instructorToUpdate);
            try
            {
                await _context.SaveChangesAsync();
            }
            catch (DbUpdateException /* ex */)
            {
                //Log the error (uncomment ex variable name and write a log.)
                ModelState.AddModelError("", "Unable to save changes. " +
                    "Try again, and if the problem persists, " +
                    "see your system administrator.");
            }
            return RedirectToAction(nameof(Index));
        }
        UpdateInstructorCourses(selectedCourses, instructorToUpdate);
        PopulateAssignedCourseData(instructorToUpdate);
        return View(instructorToUpdate);
    }
```

C#

```
private void UpdateInstructorCourses(string[] selectedCourses, Instructor
instructorToUpdate)
{
    if (selectedCourses == null)
    {
        instructorToUpdate.CourseAssignments = new List<CourseAssignment>();
        return;
    }

    var selectedCoursesHS = new HashSet<string>(selectedCourses);
    var instructorCourses = new HashSet<int>
        (instructorToUpdate.CourseAssignments.Select(c =>
c.Course.CourseID));
    foreach (var course in _context.Courses)
    {
        if (selectedCoursesHS.Contains(course.CourseID.ToString()))
        {
            if (!instructorCourses.Contains(course.CourseID))
            {
                instructorToUpdate.CourseAssignments.Add(new
CourseAssignment { InstructorID = instructorToUpdate.ID, CourseID =
course.CourseID });
            }
        }
        else
        {

            if (instructorCourses.Contains(course.CourseID))
            {
                CourseAssignment courseToRemove =
instructorToUpdate.CourseAssignments.FirstOrDefault(i => i.CourseID ==
course.CourseID);
                _context.Remove(courseToRemove);
            }
        }
    }
}
```

The method signature is now different from the HttpGet `Edit` method, so the method name changes from `EditPost` back to `Edit`.

Since the view doesn't have a collection of Course entities, the model binder can't automatically update the `CourseAssignments` navigation property. Instead of using the model binder to update the `CourseAssignments` navigation property, you do that in the new `UpdateInstructorCourses` method. Therefore, you need to exclude the `CourseAssignments` property from model binding. This doesn't require any change to the code that calls `TryUpdateModel` because you're using the overload that requires explicit approval and `CourseAssignments` isn't in the include list.

If no checkboxes were selected, the code in `UpdateInstructorCourses` initializes the `CourseAssignments` navigation property with an empty collection and returns:

C#

```
private void UpdateInstructorCourses(string[] selectedCourses, Instructor
instructorToUpdate)
{
    if (selectedCourses == null)
    {
        instructorToUpdate.CourseAssignments = new List<CourseAssignment>();
        return;
    }

    var selectedCoursesHS = new HashSet<string>(selectedCourses);
    var instructorCourses = new HashSet<int>
        (instructorToUpdate.CourseAssignments.Select(c =>
c.Course.CourseID));
    foreach (var course in _context.Courses)
    {
        if (selectedCoursesHS.Contains(course.CourseID.ToString()))
        {
            if (!instructorCourses.Contains(course.CourseID))
            {
                instructorToUpdate.CourseAssignments.Add(new
CourseAssignment { InstructorID = instructorToUpdate.ID, CourseID =
course.CourseID });
            }
        }
        else
        {

            if (instructorCourses.Contains(course.CourseID))
            {
                CourseAssignment courseToRemove =
instructorToUpdate.CourseAssignments.FirstOrDefault(i => i.CourseID ==
course.CourseID);
                _context.Remove(courseToRemove);
            }
        }
    }
}
```

The code then loops through all courses in the database and checks each course against the ones currently assigned to the instructor versus the ones that were selected in the view. To facilitate efficient lookups, the latter two collections are stored in `HashSet` objects.

If the checkbox for a course was selected but the course isn't in the `Instructor.CourseAssignments` navigation property, the course is added to the collection

in the navigation property.

C#

```
private void UpdateInstructorCourses(string[] selectedCourses, Instructor
instructorToUpdate)
{
    if (selectedCourses == null)
    {
        instructorToUpdate.CourseAssignments = new List<CourseAssignment>();
        return;
    }

    var selectedCoursesHS = new HashSet<string>(selectedCourses);
    var instructorCourses = new HashSet<int>
        (instructorToUpdate.CourseAssignments.Select(c =>
c.Course.CourseID));
    foreach (var course in _context.Courses)
    {
        if (selectedCoursesHS.Contains(course.CourseID.ToString()))
        {
            if (!instructorCourses.Contains(course.CourseID))
            {
                instructorToUpdate.CourseAssignments.Add(new
CourseAssignment { InstructorID = instructorToUpdate.ID, CourseID =
course.CourseID });
            }
        }
        else
        {

            if (instructorCourses.Contains(course.CourseID))
            {
                CourseAssignment courseToRemove =
instructorToUpdate.CourseAssignments.FirstOrDefault(i => i.CourseID ==
course.CourseID);
                _context.Remove(courseToRemove);
            }
        }
    }
}
```

If the checkbox for a course wasn't selected, but the course is in the `Instructor.CourseAssignments` navigation property, the course is removed from the navigation property.

C#

```
private void UpdateInstructorCourses(string[] selectedCourses, Instructor
instructorToUpdate)
{
    if (selectedCourses == null)
```

```
    {
        instructorToUpdate.CourseAssignments = new List<CourseAssignment>();
        return;
    }

    var selectedCoursesHS = new HashSet<string>(selectedCourses);
    var instructorCourses = new HashSet<int>
        (instructorToUpdate.CourseAssignments.Select(c =>
c.Course.CourseID));
    foreach (var course in _context.Courses)
    {
        if (selectedCoursesHS.Contains(course.CourseID.ToString()))
        {
            if (!instructorCourses.Contains(course.CourseID))
            {
                instructorToUpdate.CourseAssignments.Add(new
CourseAssignment { InstructorID = instructorToUpdate.ID, CourseID =
course.CourseID });
            }
        }
        else
        {

            if (instructorCourses.Contains(course.CourseID))
            {
                CourseAssignment courseToRemove =
instructorToUpdate.CourseAssignments.FirstOrDefault(i => i.CourseID ==
course.CourseID);
                _context.Remove(courseToRemove);
            }
        }
    }
}
```

Update the Instructor views

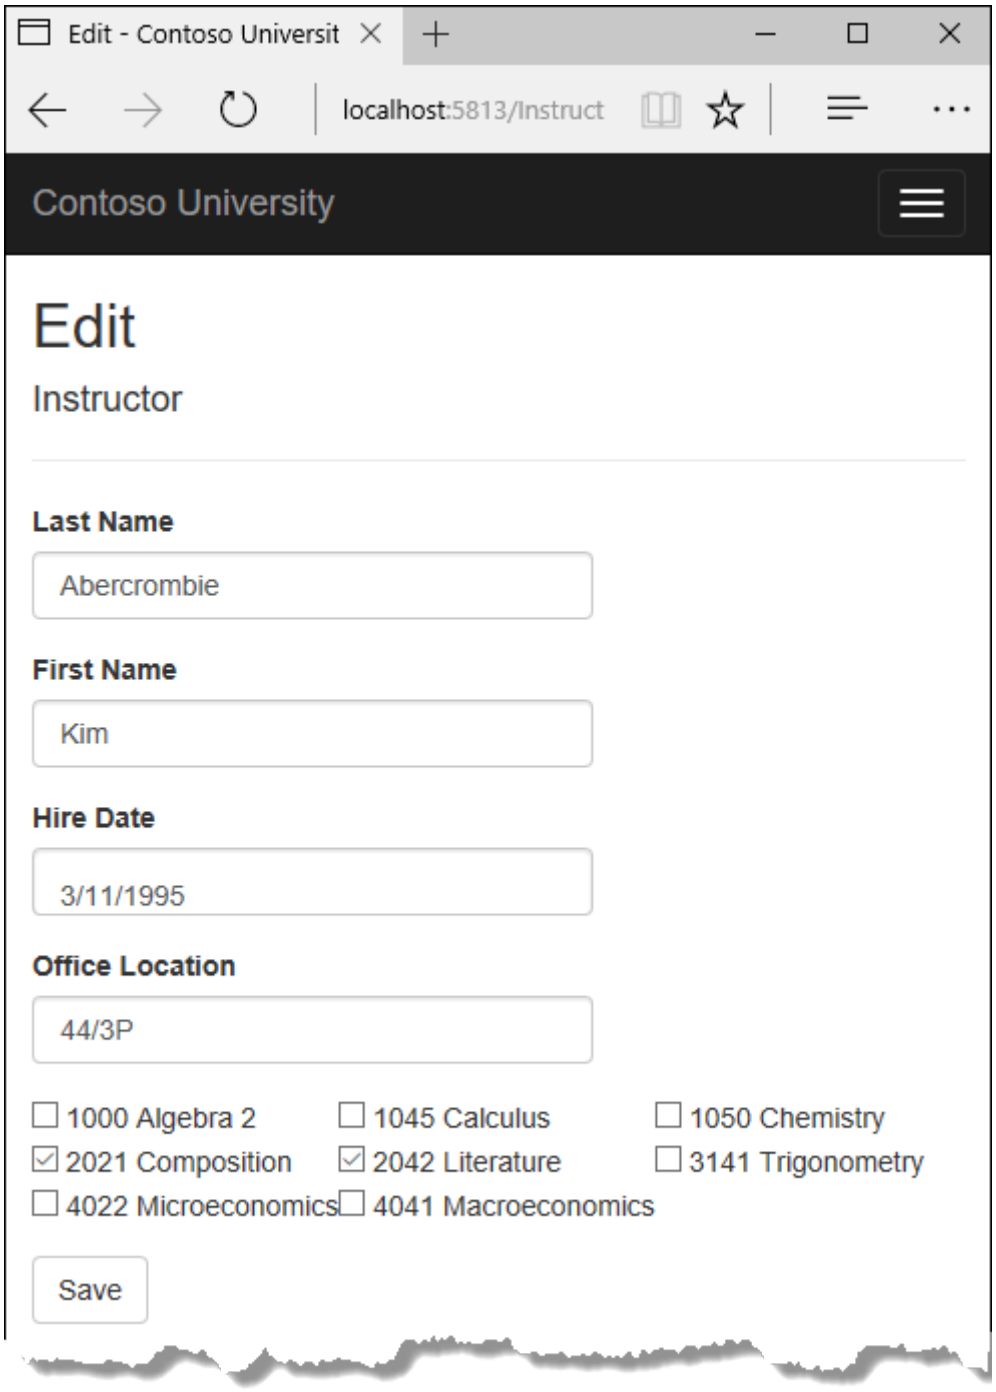
In `Views/Instructors/Edit.cshtml`, add a **Courses** field with an array of checkboxes by adding the following code immediately after the `div` elements for the **Office** field and before the `div` element for the **Save** button.

> ⓘ Note
>
> When you paste the code in Visual Studio, line breaks might be changed in a way that breaks the code. If the code looks different after pasting, press Ctrl+Z one time to undo the automatic formatting. This will fix the line breaks so that they look like what you see here. The indentation doesn't have to be perfect, but the `@:</tr><tr>`, `@:<td>`, `@:</td>`, and `@:</tr>` lines must each be on a single line as shown or you'll get a runtime error. With the block of new code selected, press Tab three

times to line up the new code with the existing code. This problem is fixed in Visual Studio 2019.

CSHTML

```
<div class="form-group">
    <div class="col-md-offset-2 col-md-10">
        <table>
            <tr>
                @{
                    int cnt = 0;



List<ContosoUniversity.Models.SchoolViewModels.AssignedCourseData> courses =
ViewBag.Courses;

                    foreach (var course in courses)
                    {
                        if (cnt++ % 3 == 0)
                        {
                            @:</tr><tr>
                        }
                        @:<td>
                            <input type="checkbox"
                                   name="selectedCourses"
                                   value="@course.CourseID"
                                   @(Html.Raw(course.Assigned ?
"checked=\"checked\"" : "")) />
                                   @course.CourseID @:  @course.Title
                        @:</td>
                    }
                    @:</tr>
                }
        </table>
    </div>
</div>
```

This code creates an HTML table that has three columns. In each column is a checkbox followed by a caption that consists of the course number and title. The checkboxes all have the same name ("selectedCourses"), which informs the model binder that they're to be treated as a group. The value attribute of each checkbox is set to the value of `CourseID`. When the page is posted, the model binder passes an array to the controller that consists of the `CourseID` values for only the checkboxes which are selected.

When the checkboxes are initially rendered, those that are for courses assigned to the instructor have checked attributes, which selects them (displays them checked).

Run the app, select the **Instructors** tab, and click **Edit** on an instructor to see the **Edit** page.

Change some course assignments and click Save. The changes you make are reflected on the Index page.

> ⓘ **Note**
>
> The approach taken here to edit instructor course data works well when there's a limited number of courses. For collections that are much larger, a different UI and a different updating method would be required.

Update Delete page

In `InstructorsController.cs`, delete the `DeleteConfirmed` method and insert the following code in its place.

```
C#

[HttpPost, ActionName("Delete")]
[ValidateAntiForgeryToken]
public async Task<IActionResult> DeleteConfirmed(int id)
{
    Instructor instructor = await _context.Instructors
        .Include(i => i.CourseAssignments)
        .SingleAsync(i => i.ID == id);

    var departments = await _context.Departments
        .Where(d => d.InstructorID == id)
        .ToListAsync();
    departments.ForEach(d => d.InstructorID = null);

    _context.Instructors.Remove(instructor);

    await _context.SaveChangesAsync();
    return RedirectToAction(nameof(Index));
}
```

This code makes the following changes:

- Does eager loading for the `CourseAssignments` navigation property. You have to include this or EF won't know about related `CourseAssignment` entities and won't delete them. To avoid needing to read them here you could configure cascade delete in the database.
- If the instructor to be deleted is assigned as administrator of any departments, removes the instructor assignment from those departments.

Add office location and courses to Create page

In `InstructorsController.cs`, delete the HttpGet and HttpPost `Create` methods, and then add the following code in their place:

```
C#

public IActionResult Create()
{
    var instructor = new Instructor();
    instructor.CourseAssignments = new List<CourseAssignment>();
    PopulateAssignedCourseData(instructor);
    return View();
}
```

```
// POST: Instructors/Create
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<IActionResult>
Create([Bind("FirstMidName,HireDate,LastName,OfficeAssignment")] Instructor
instructor, string[] selectedCourses)
{
    if (selectedCourses != null)
    {
        instructor.CourseAssignments = new List<CourseAssignment>();
        foreach (var course in selectedCourses)
        {
            var courseToAdd = new CourseAssignment { InstructorID =
instructor.ID, CourseID = int.Parse(course) };
            instructor.CourseAssignments.Add(courseToAdd);
        }
    }
    if (ModelState.IsValid)
    {
        _context.Add(instructor);
        await _context.SaveChangesAsync();
        return RedirectToAction(nameof(Index));
    }
    PopulateAssignedCourseData(instructor);
    return View(instructor);
}
```

This code is similar to what you saw for the `Edit` methods except that initially no courses are selected. The HttpGet `Create` method calls the `PopulateAssignedCourseData` method not because there might be courses selected but in order to provide an empty collection for the `foreach` loop in the view (otherwise the view code would throw a null reference exception).

The HttpPost `Create` method adds each selected course to the `CourseAssignments` navigation property before it checks for validation errors and adds the new instructor to the database. Courses are added even if there are model errors so that when there are model errors (for an example, the user keyed an invalid date), and the page is redisplayed with an error message, any course selections that were made are automatically restored.

Notice that in order to be able to add courses to the `CourseAssignments` navigation property you have to initialize the property as an empty collection:

C#

```
instructor.CourseAssignments = new List<CourseAssignment>();
```

As an alternative to doing this in controller code, you could do it in the `Instructor` model by changing the property getter to automatically create the collection if it doesn't exist, as shown in the following example:

C#

```
private ICollection<CourseAssignment> _courseAssignments;
public ICollection<CourseAssignment> CourseAssignments
{
    get
    {
        return _courseAssignments ?? (_courseAssignments = new
List<CourseAssignment>());
    }
    set
    {
        _courseAssignments = value;
    }
}
```

If you modify the `CourseAssignments` property in this way, you can remove the explicit property initialization code in the controller.

In `Views/Instructor/Create.cshtml`, add an office location text box and checkboxes for courses before the Submit button. As in the case of the Edit page, fix the formatting if Visual Studio reformats the code when you paste it.

CSHTML

```
<div class="form-group">
    <label asp-for="OfficeAssignment.Location" class="control-label">
</label>
    <input asp-for="OfficeAssignment.Location" class="form-control" />
    <span asp-validation-for="OfficeAssignment.Location" class="text-danger"
/>
</div>

<div class="form-group">
    <div class="col-md-offset-2 col-md-10">
        <table>
            <tr>
                @{
                    int cnt = 0;

List<ContosoUniversity.Models.SchoolViewModels.AssignedCourseData> courses =
ViewBag.Courses;

                    foreach (var course in courses)
                    {
                        if (cnt++ % 3 == 0)
```

```
                        {
                            @:</tr><tr>
                        }
                        @:<td>
                            <input type="checkbox"
                                   name="selectedCourses"
                                   value="@course.CourseID"
                                   @(Html.Raw(course.Assigned ?
"checked=\"checked\"" : "")) />
                                   @course.CourseID @:  @course.Title
                            @:</td>
                    }
                    @:</tr>
                }
        </table>
    </div>
</div>
```

Test by running the app and creating an instructor.

Handling Transactions

As explained in the CRUD tutorial, the Entity Framework implicitly implements transactions. For scenarios where you need more control -- for example, if you want to include operations done outside of Entity Framework in a transaction -- see Transactions.

Get the code

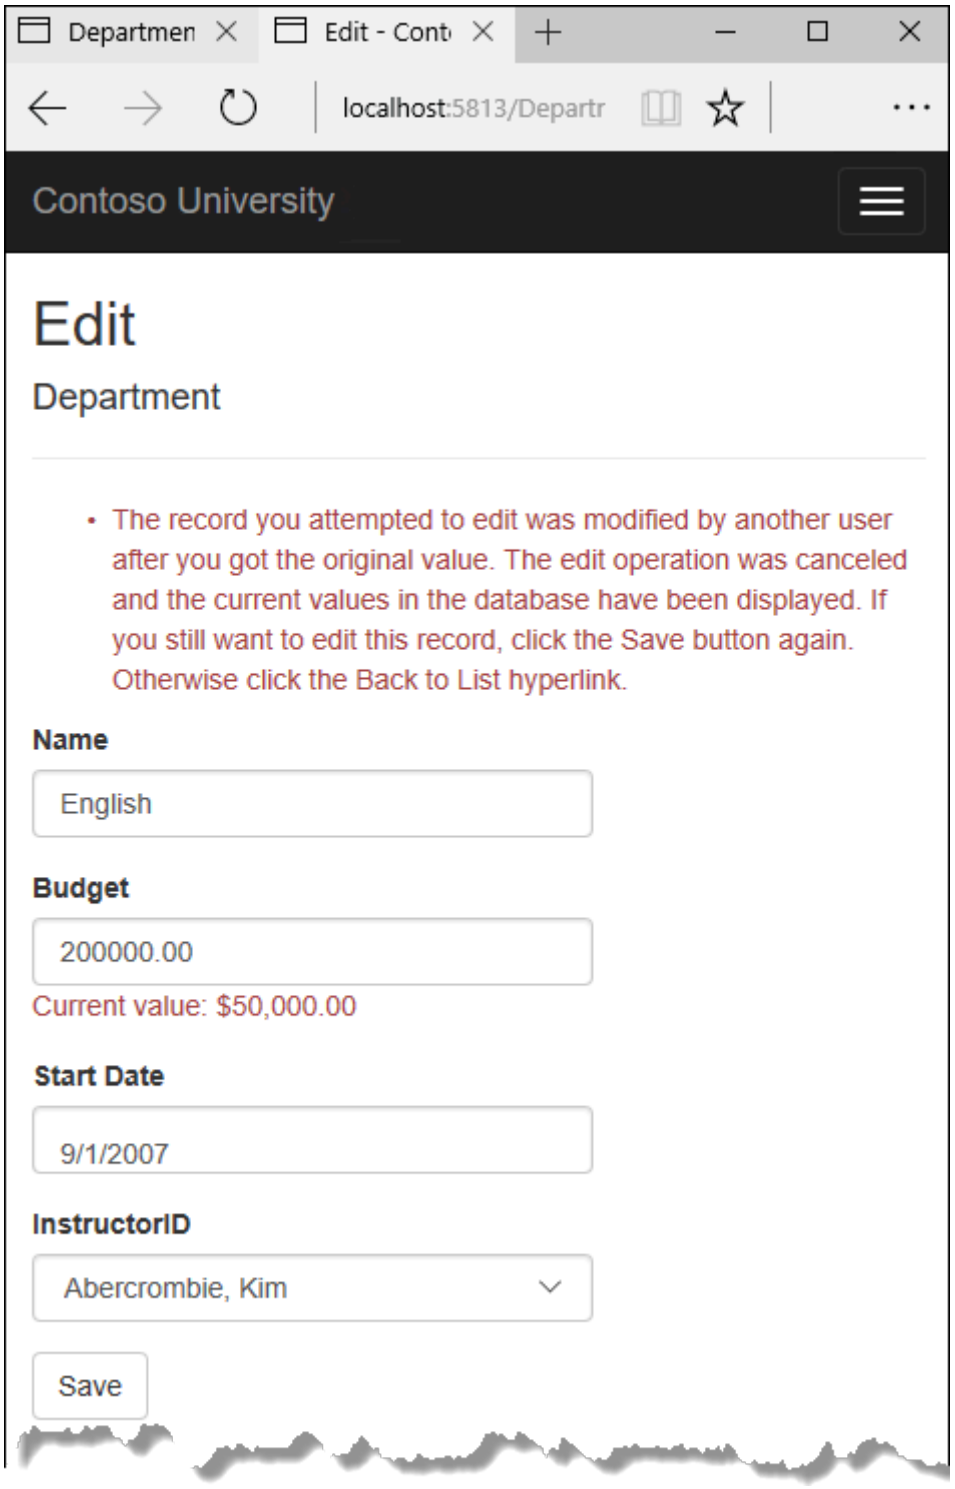
Download or view the completed application.

Next steps

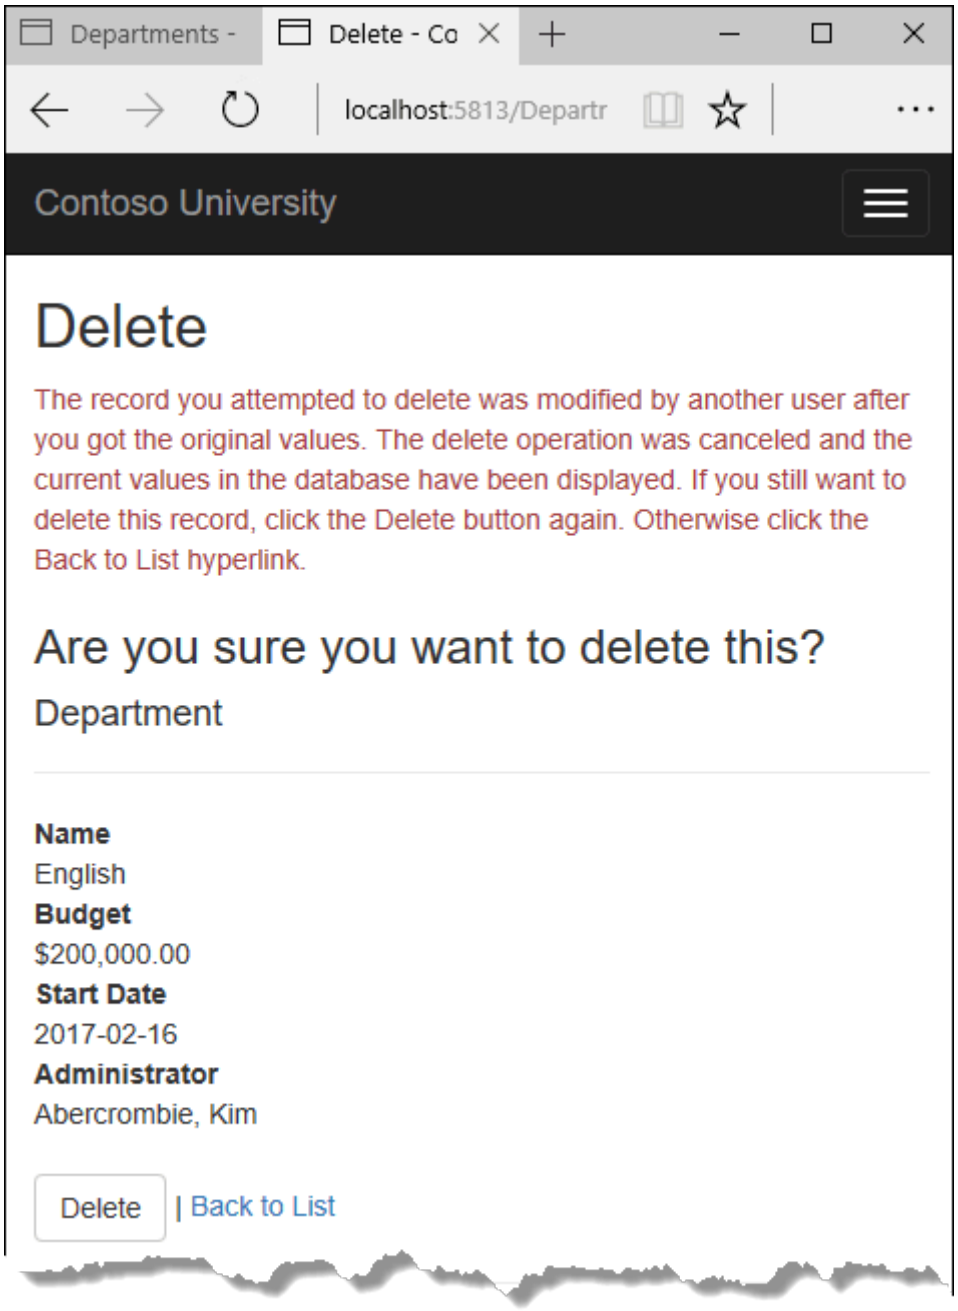
In this tutorial, you:

- ✓ Customized Courses pages
- ✓ Added Instructors Edit page
- ✓ Added courses to Edit page
- ✓ Updated Delete page
- ✓ Added office location and courses to Create page

Advance to the next tutorial to learn how to handle concurrency conflicts.



Handle concurrency conflicts



Tutorial: Handle concurrency - ASP.NET MVC with EF Core

Article • 07/09/2024

In earlier tutorials, you learned how to update data. This tutorial shows how to handle conflicts when multiple users update the same entity at the same time.

You'll create web pages that work with the `Department` entity and handle concurrency errors. The following illustrations show the Edit and Delete pages, including some messages that are displayed if a concurrency conflict occurs.

Departmen
Edit - Cont
localhost:5813/Departr
Contoso University
Edit
Department
The record you attempted to edit was modified by another user after you got the original value. The edit operation was canceled and the current values in the database have been displayed. If you still want to edit this record, click the Save button again. Otherwise click the Back to List hyperlink.
Name
English
Budget
200000.00
Current value: $50,000.00
Start Date
9/1/2007
InstructorID
Abercrombie, Kim
Save

In this tutorial, you:

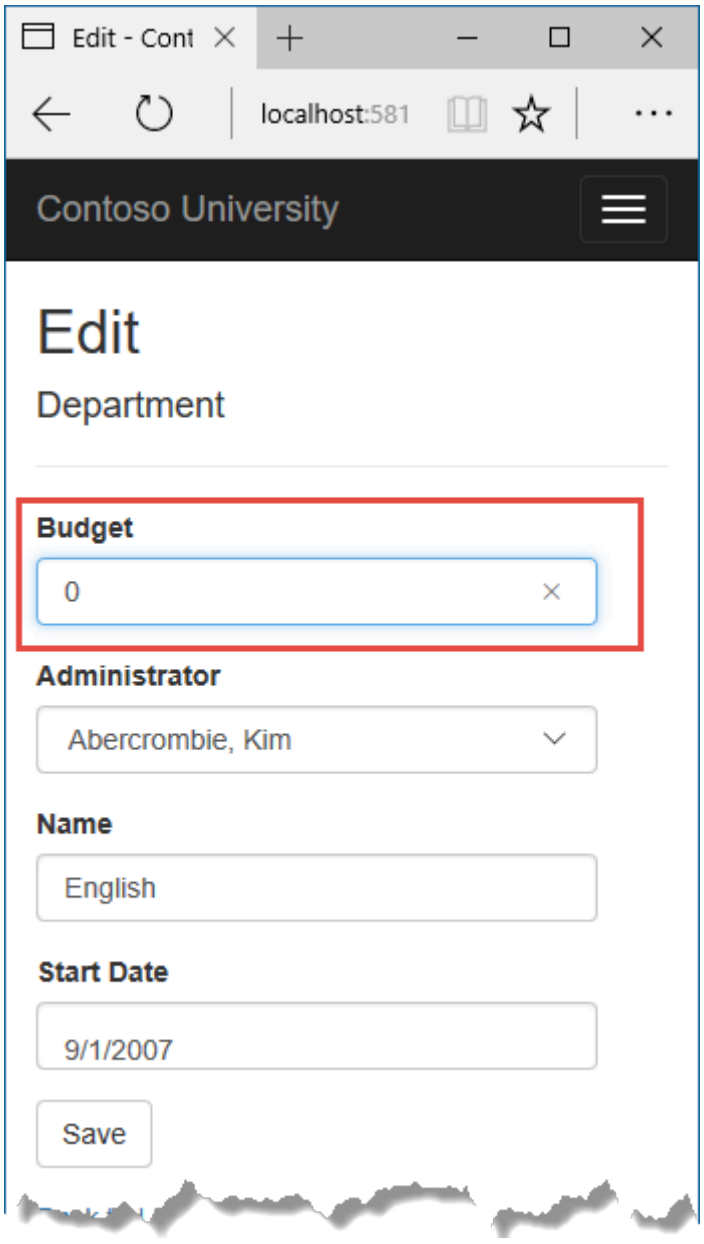
- ✓ Learn about concurrency conflicts
- ✓ Add a tracking property
- ✓ Create Departments controller and views
- ✓ Update Index view
- ✓ Update Edit methods
- ✓ Update Edit view
- ✓ Test concurrency conflicts
- ✓ Update the Delete page
- ✓ Update Details and Create views

Prerequisites

- Update related data

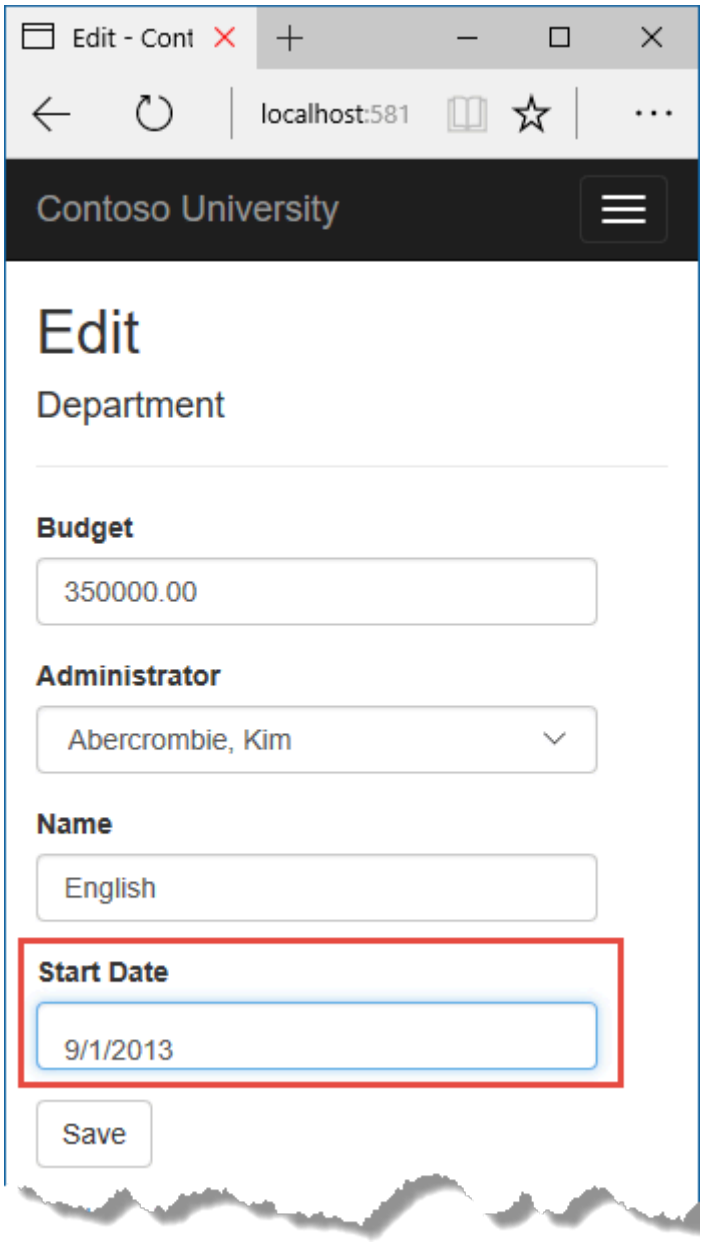
Concurrency conflicts

A concurrency conflict occurs when one user displays an entity's data in order to edit it, and then another user updates the same entity's data before the first user's change is written to the database. If you don't enable the detection of such conflicts, whoever updates the database last overwrites the other user's changes. In many applications, this risk is acceptable: if there are few users, or few updates, or if isn't really critical if some changes are overwritten, the cost of programming for concurrency might outweigh the benefit. In that case, you don't have to configure the application to handle concurrency conflicts.



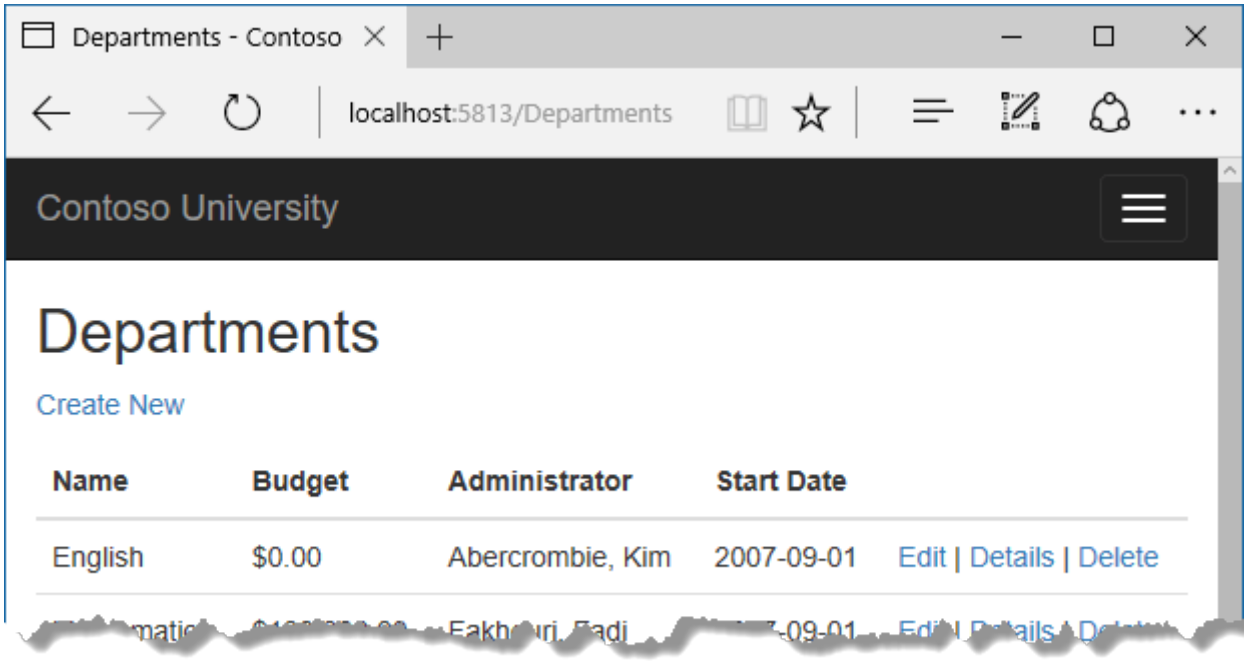
Pessimistic concurrency (locking)

If your application does need to prevent accidental data loss in concurrency scenarios, one way to do that is to use database locks. This is called pessimistic concurrency. For example, before you read a row from a database, you request a lock for read-only or for update access. If you lock a row for update access, no other users are allowed to lock the row either for read-only or update access, because they would get a copy of data that's in the process of being changed. If you lock a row for read-only access, others can also lock it for read-only access but not for update.



Managing locks has disadvantages. It can be complex to program. It requires significant database management resources, and it can cause performance problems as the number of users of an application increases. For these reasons, not all database management systems support pessimistic concurrency. Entity Framework Core provides no built-in support for it, and this tutorial doesn't show you how to implement it.

Optimistic Concurrency



The alternative to pessimistic concurrency is optimistic concurrency. Optimistic concurrency means allowing concurrency conflicts to happen, and then reacting appropriately if they do. For example, Jane visits the Department Edit page and changes the Budget amount for the English department from $350,000.00 to $0.00.

Before Jane clicks **Save**, John visits the same page and changes the Start Date field from 9/1/2007 to 9/1/2013.

Jane clicks **Save** first and sees her change when the browser returns to the Index page.

Then John clicks **Save** on an Edit page that still shows a budget of $350,000.00. What happens next is determined by how you handle concurrency conflicts.

Some of the options include the following:

- You can keep track of which property a user has modified and update only the corresponding columns in the database.

  In the example scenario, no data would be lost, because different properties were updated by the two users. The next time someone browses the English department, they will see both Jane's and John's changes -- a start date of 9/1/2013 and a budget of zero dollars. This method of updating can reduce the number of conflicts that could result in data loss, but it can't avoid data loss if competing changes are made to the same property of an entity. Whether the Entity Framework works this way depends on how you implement your update code. It's often not practical in a web application, because it can require that you maintain large amounts of state in order to keep track of all original property values for an entity as well as new values. Maintaining large amounts of state can affect application performance because it either requires server resources or must be included in the web page itself (for example, in hidden fields) or in a cookie.

- You can let John's change overwrite Jane's change.

  The next time someone browses the English department, they will see 9/1/2013 and the restored $350,000.00 value. This is called a *Client Wins* or *Last in Wins* scenario. (All values from the client take precedence over what's in the data store.) As noted in the introduction to this section, if you don't do any coding for concurrency handling, this will happen automatically.

- You can prevent John's change from being updated in the database.

  Typically, you would display an error message, show him the current state of the data, and allow him to reapply his changes if he still wants to make them. This is called a *Store Wins* scenario. (The data-store values take precedence over the values submitted by the client.) You'll implement the Store Wins scenario in this tutorial. This method ensures that no changes are overwritten without a user being alerted to what's happening.

Detecting concurrency conflicts

You can resolve conflicts by handling `DbConcurrencyException` exceptions that the Entity Framework throws. In order to know when to throw these exceptions, the Entity Framework must be able to detect conflicts. Therefore, you must configure the database

and the data model appropriately. Some options for enabling conflict detection include the following:

- In the database table, include a tracking column that can be used to determine when a row has been changed. You can then configure the Entity Framework to include that column in the Where clause of SQL Update or Delete commands.

  The data type of the tracking column is typically `rowversion`. The `rowversion` value is a sequential number that's incremented each time the row is updated. In an Update or Delete command, the Where clause includes the original value of the tracking column (the original row version) . If the row being updated has been changed by another user, the value in the `rowversion` column is different than the original value, so the Update or Delete statement can't find the row to update because of the Where clause. When the Entity Framework finds that no rows have been updated by the Update or Delete command (that is, when the number of affected rows is zero), it interprets that as a concurrency conflict.

- Configure the Entity Framework to include the original values of every column in the table in the Where clause of Update and Delete commands.

  As in the first option, if anything in the row has changed since the row was first read, the Where clause won't return a row to update, which the Entity Framework interprets as a concurrency conflict. For database tables that have many columns, this approach can result in very large Where clauses, and can require that you maintain large amounts of state. As noted earlier, maintaining large amounts of state can affect application performance. Therefore this approach is generally not recommended, and it isn't the method used in this tutorial.

  If you do want to implement this approach to concurrency, you have to mark all non-primary-key properties in the entity you want to track concurrency for by adding the `ConcurrencyCheck` attribute to them. That change enables the Entity Framework to include all columns in the SQL Where clause of Update and Delete statements.

In the remainder of this tutorial you'll add a `rowversion` tracking property to the Department entity, create a controller and views, and test to verify that everything works correctly.

Add a tracking property

In `Models/Department.cs`, add a tracking property named RowVersion:

```
```

C#

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Department
    {
        public int DepartmentID { get; set; }

        [StringLength(50, MinimumLength = 3)]
        public string Name { get; set; }

        [DataType(DataType.Currency)]
        [Column(TypeName = "money")]
        public decimal Budget { get; set; }

        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}",
ApplyFormatInEditMode = true)]
        [Display(Name = "Start Date")]
        public DateTime StartDate { get; set; }

        public int? InstructorID { get; set; }

        [Timestamp]
        public byte[] RowVersion { get; set; }

        public Instructor Administrator { get; set; }
        public ICollection<Course> Courses { get; set; }
    }
}
```

The `Timestamp` attribute specifies that this column will be included in the Where clause of Update and Delete commands sent to the database. The attribute is called `Timestamp` because previous versions of SQL Server used a SQL `timestamp` data type before the SQL `rowversion` replaced it. The .NET type for `rowversion` is a byte array.

If you prefer to use the fluent API, you can use the `IsRowVersion()` method (in `Data/SchoolContext.cs`) to specify the tracking property, as shown in the following example:

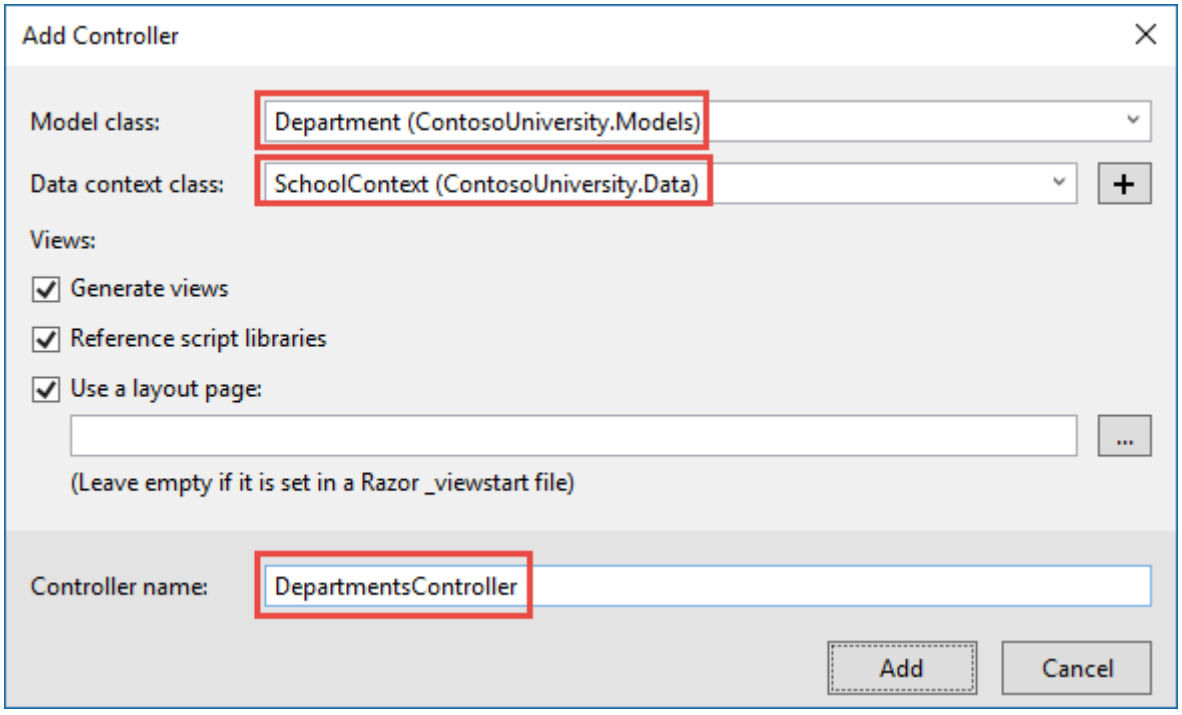
C#

```
modelBuilder.Entity<Department>()
    .Property(p => p.RowVersion).IsRowVersion();
```

By adding a property you changed the database model, so you need to do another migration.

Save your changes and build the project, and then enter the following commands in the command window:

.NET CLI



```
dotnet ef migrations add RowVersion
```

.NET CLI

```
dotnet ef database update
```

Create Departments controller and views

Scaffold a Departments controller and views as you did earlier for Students, Courses, and Instructors.

In the `DepartmentsController.cs` file, change all four occurrences of "FirstMidName" to "FullName" so that the department administrator drop-down lists will contain the full name of the instructor rather than just the last name.

C#

```
ViewData["InstructorID"] = new SelectList(_context.Instructors, "ID",
"FullName", department.InstructorID);
```

Update Index view

The scaffolding engine created a `RowVersion` column in the Index view, but that field shouldn't be displayed.

Replace the code in `Views/Departments/Index.cshtml` with the following code.

CSHTML

```
@model IEnumerable<ContosoUniversity.Models.Department>

@{
    ViewData["Title"] = "Departments";
}

<h2>Departments</h2>

<p>
    <a asp-action="Create">Create New</a>
</p>
<table class="table">
    <thead>
        <tr>
            <th>
                @Html.DisplayNameFor(model => model.Name)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Budget)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.StartDate)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Administrator)
            </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
        @foreach (var item in Model)
        {
            <tr>
                <td>
                    @Html.DisplayFor(modelItem => item.Name)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Budget)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.StartDate)
                </td>
                <td>
```

```
                    @Html.DisplayFor(modelItem =>
item.Administrator.FullName)
                </td>
                <td>
                    <a asp-action="Edit" asp-route-
id="@item.DepartmentID">Edit</a> |
                    <a asp-action="Details" asp-route-
id="@item.DepartmentID">Details</a> |
                    <a asp-action="Delete" asp-route-
id="@item.DepartmentID">Delete</a>
                </td>
            </tr>
        }
    </tbody>
</table>
```

This changes the heading to "Departments", deletes the `RowVersion` column, and shows full name instead of first name for the administrator.

Update Edit methods

In both the HttpGet `Edit` method and the `Details` method, add `AsNoTracking`. In the HttpGet `Edit` method, add eager loading for the Administrator.

C#

```
var department = await _context.Departments
    .Include(i => i.Administrator)
    .AsNoTracking()
    .FirstOrDefaultAsync(m => m.DepartmentID == id);
```

Replace the existing code for the HttpPost `Edit` method with the following code:

C#

```
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<IActionResult> Edit(int? id, byte[] rowVersion)
{
    if (id == null)
    {
        return NotFound();
    }

    var departmentToUpdate = await _context.Departments.Include(i =>
i.Administrator).FirstOrDefaultAsync(m => m.DepartmentID == id);

    if (departmentToUpdate == null)
    {
```

```
        Department deletedDepartment = new Department();
        await TryUpdateModelAsync(deletedDepartment);
        ModelState.AddModelError(string.Empty,
            "Unable to save changes. The department was deleted by another
user.");
        ViewData["InstructorID"] = new SelectList(_context.Instructors,
"ID", "FullName", deletedDepartment.InstructorID);
        return View(deletedDepartment);
    }

    _context.Entry(departmentToUpdate).Property("RowVersion").OriginalValue
= rowVersion;

    if (await TryUpdateModelAsync<Department>(
        departmentToUpdate,
        "",
        s => s.Name, s => s.StartDate, s => s.Budget, s => s.InstructorID))
    {
        try
        {
            await _context.SaveChangesAsync();
            return RedirectToAction(nameof(Index));
        }
        catch (DbUpdateConcurrencyException ex)
        {
            var exceptionEntry = ex.Entries.Single();
            var clientValues = (Department)exceptionEntry.Entity;
            var databaseEntry = exceptionEntry.GetDatabaseValues();
            if (databaseEntry == null)
            {
                ModelState.AddModelError(string.Empty,
                    "Unable to save changes. The department was deleted by
another user.");
            }
            else
            {
                var databaseValues = (Department)databaseEntry.ToObject();

                if (databaseValues.Name != clientValues.Name)
                {
                    ModelState.AddModelError("Name", $"Current value:
{databaseValues.Name}");
                }
                if (databaseValues.Budget != clientValues.Budget)
                {
                    ModelState.AddModelError("Budget", $"Current value:
{databaseValues.Budget:c}");
                }
                if (databaseValues.StartDate != clientValues.StartDate)
                {
                    ModelState.AddModelError("StartDate", $"Current value:
{databaseValues.StartDate:d}");
                }
                if (databaseValues.InstructorID !=
clientValues.InstructorID)
```

```
                {
                    Instructor databaseInstructor = await
_context.Instructors.FirstOrDefaultAsync(i => i.ID ==
databaseValues.InstructorID);
                    ModelState.AddModelError("InstructorID", $"Current
value: {databaseInstructor?.FullName}");
                }

                ModelState.AddModelError(string.Empty, "The record you
attempted to edit "
                        + "was modified by another user after you got the
original value. The "
                        + "edit operation was canceled and the current
values in the database "
                        + "have been displayed. If you still want to edit
this record, click "
                        + "the Save button again. Otherwise click the Back
to List hyperlink.");
                departmentToUpdate.RowVersion =
(byte[])databaseValues.RowVersion;
                ModelState.Remove("RowVersion");
            }
        }
    }
    ViewData["InstructorID"] = new SelectList(_context.Instructors, "ID",
"FullName", departmentToUpdate.InstructorID);
    return View(departmentToUpdate);
}
```

The code begins by trying to read the department to be updated. If the `FirstOrDefaultAsync` method returns null, the department was deleted by another user. In that case the code uses the posted form values to create a `Department` entity so that the Edit page can be redisplayed with an error message. As an alternative, you wouldn't have to re-create the `Department` entity if you display only an error message without redisplaying the department fields.

The view stores the original `RowVersion` value in a hidden field, and this method receives that value in the `rowVersion` parameter. Before you call `SaveChanges`, you have to put that original `RowVersion` property value in the `OriginalValues` collection for the entity.

C#

```
_context.Entry(departmentToUpdate).Property("RowVersion").OriginalValue =
rowVersion;
```

Then when the Entity Framework creates a SQL UPDATE command, that command will include a WHERE clause that looks for a row that has the original `RowVersion` value. If no

rows are affected by the UPDATE command (no rows have the original `RowVersion` value), the Entity Framework throws a `DbUpdateConcurrencyException` exception.

The code in the catch block for that exception gets the affected Department entity that has the updated values from the `Entries` property on the exception object.

C#

```
var exceptionEntry = ex.Entries.Single();
```

The `Entries` collection will have just one `EntityEntry` object. You can use that object to get the new values entered by the user and the current database values.

C#

```
var clientValues = (Department)exceptionEntry.Entity;
var databaseEntry = exceptionEntry.GetDatabaseValues();
```

The code adds a custom error message for each column that has database values different from what the user entered on the Edit page (only one field is shown here for brevity).

C#

```
var databaseValues = (Department)databaseEntry.ToObject();

if (databaseValues.Name != clientValues.Name)
{
    ModelState.AddModelError("Name", $"Current value:
{databaseValues.Name}");
```

Finally, the code sets the `RowVersion` value of the `departmentToUpdate` to the new value retrieved from the database. This new `RowVersion` value will be stored in the hidden field when the Edit page is redisplayed, and the next time the user clicks **Save**, only concurrency errors that happen since the redisplay of the Edit page will be caught.

C#

```
departmentToUpdate.RowVersion = (byte[])databaseValues.RowVersion;
ModelState.Remove("RowVersion");
```

The `ModelState.Remove` statement is required because `ModelState` has the old `RowVersion` value. In the view, the `ModelState` value for a field takes precedence over the model property values when both are present.

Update Edit view

In `Views/Departments/Edit.cshtml`, make the following changes:

- Add a hidden field to save the `RowVersion` property value, immediately following the hidden field for the `DepartmentID` property.
- Add a "Select Administrator" option to the drop-down list.

CSHTML

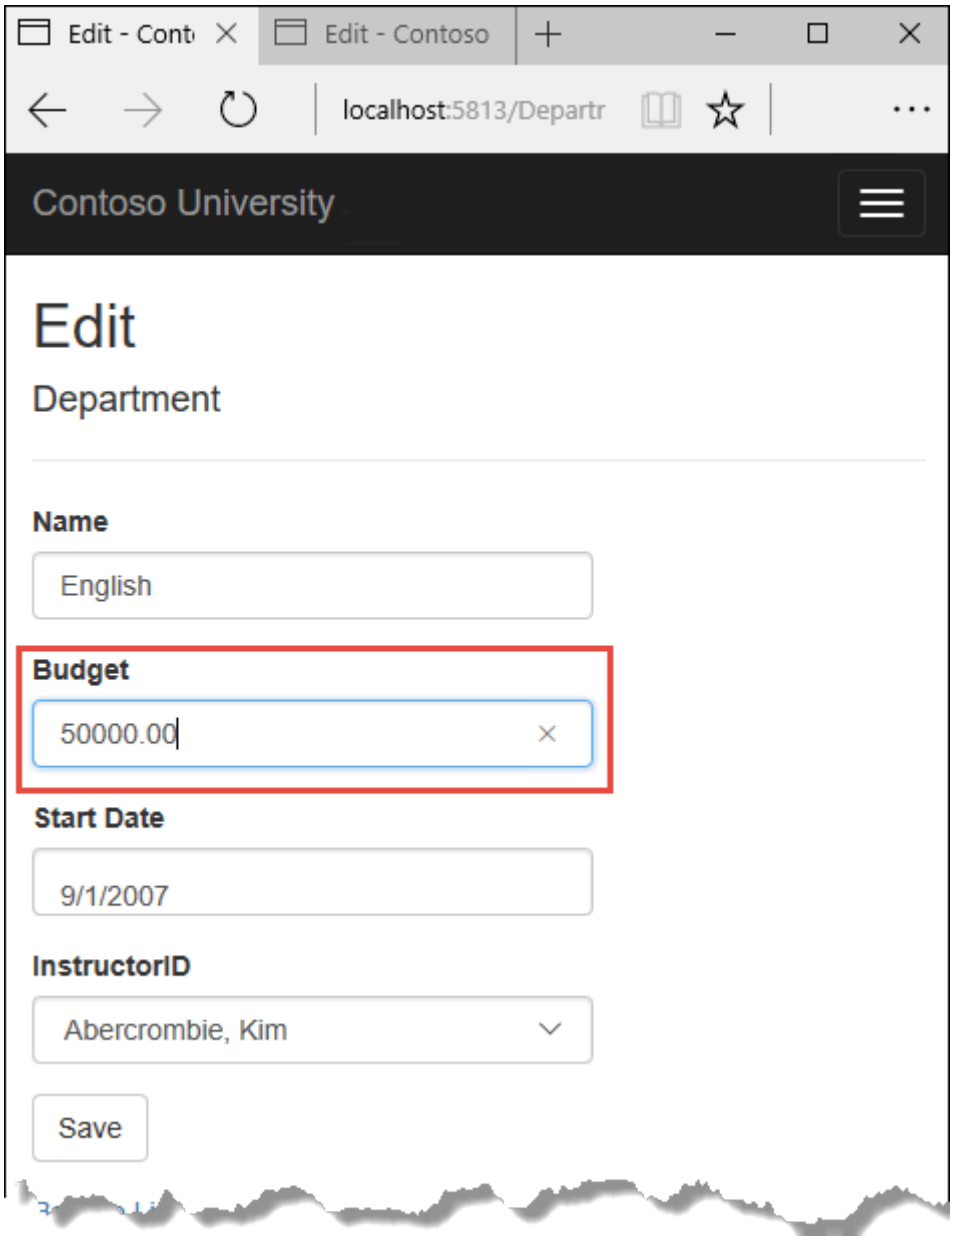
```
@model ContosoUniversity.Models.Department

@{
    ViewData["Title"] = "Edit";
}

<h2>Edit</h2>

<h4>Department</h4>
<hr />
<div class="row">
    <div class="col-md-4">
        <form asp-action="Edit">
            <div asp-validation-summary="ModelOnly" class="text-danger">
</div>
            <input type="hidden" asp-for="DepartmentID" />
            <input type="hidden" asp-for="RowVersion" />
            <div class="form-group">
                <label asp-for="Name" class="control-label"></label>
                <input asp-for="Name" class="form-control" />
                <span asp-validation-for="Name" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Budget" class="control-label"></label>
                <input asp-for="Budget" class="form-control" />
                <span asp-validation-for="Budget" class="text-danger">
</span>
            </div>
            <div class="form-group">
                <label asp-for="StartDate" class="control-label"></label>
                <input asp-for="StartDate" class="form-control" />
                <span asp-validation-for="StartDate" class="text-danger">
</span>
            </div>
            <div class="form-group">
                <label asp-for="InstructorID" class="control-label"></label>
                <select asp-for="InstructorID" class="form-control" asp-
items="ViewBag.InstructorID">
                    <option value="">-- Select Administrator --</option>
                </select>
                <span asp-validation-for="InstructorID" class="text-danger">
```

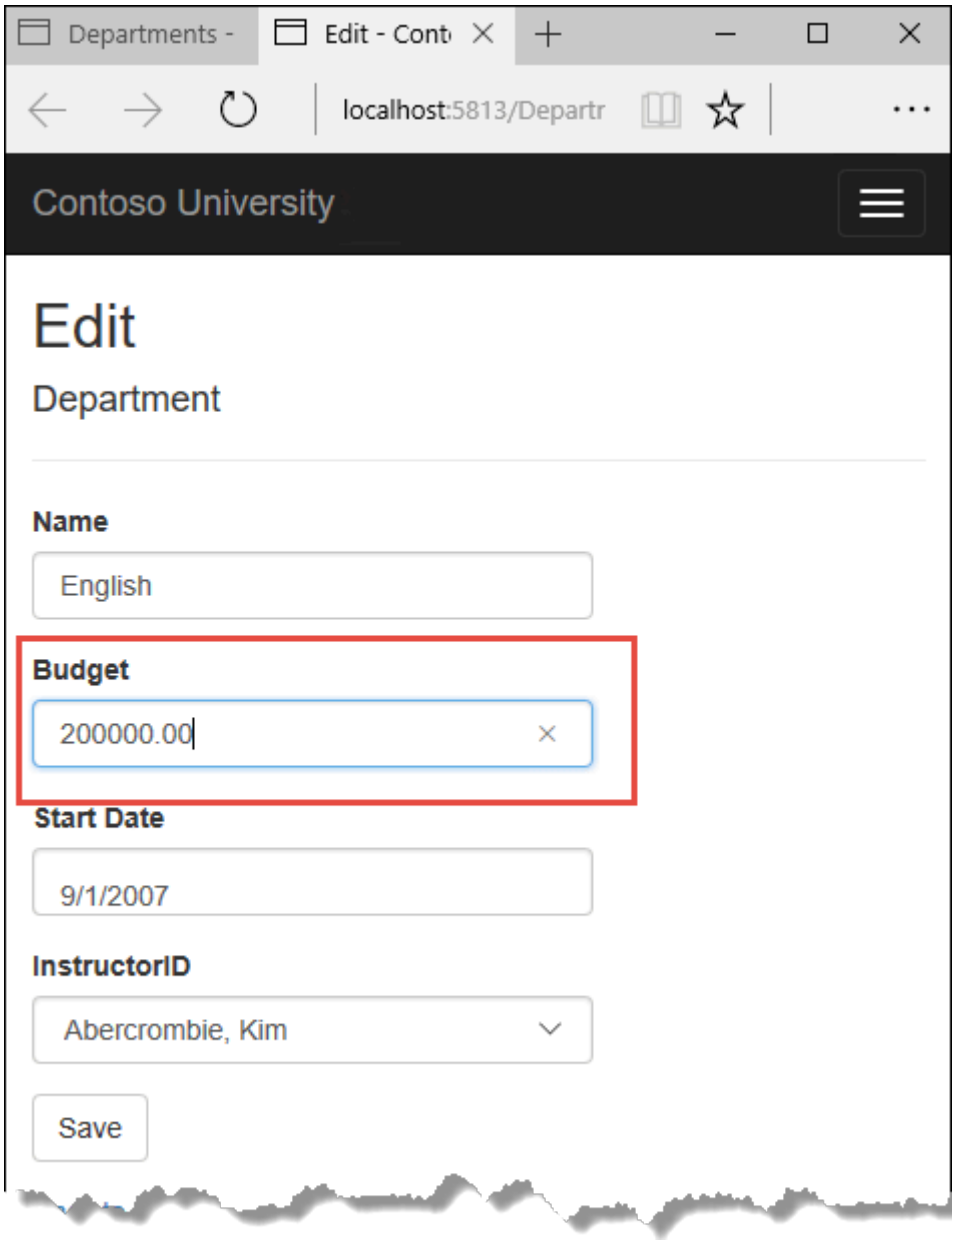
```
</span>
            </div>
            <div class="form-group">
                <input type="submit" value="Save" class="btn btn-default" />
            </div>
        </form>
    </div>
</div>



<div>
    <a asp-action="Index">Back to List</a>
</div>

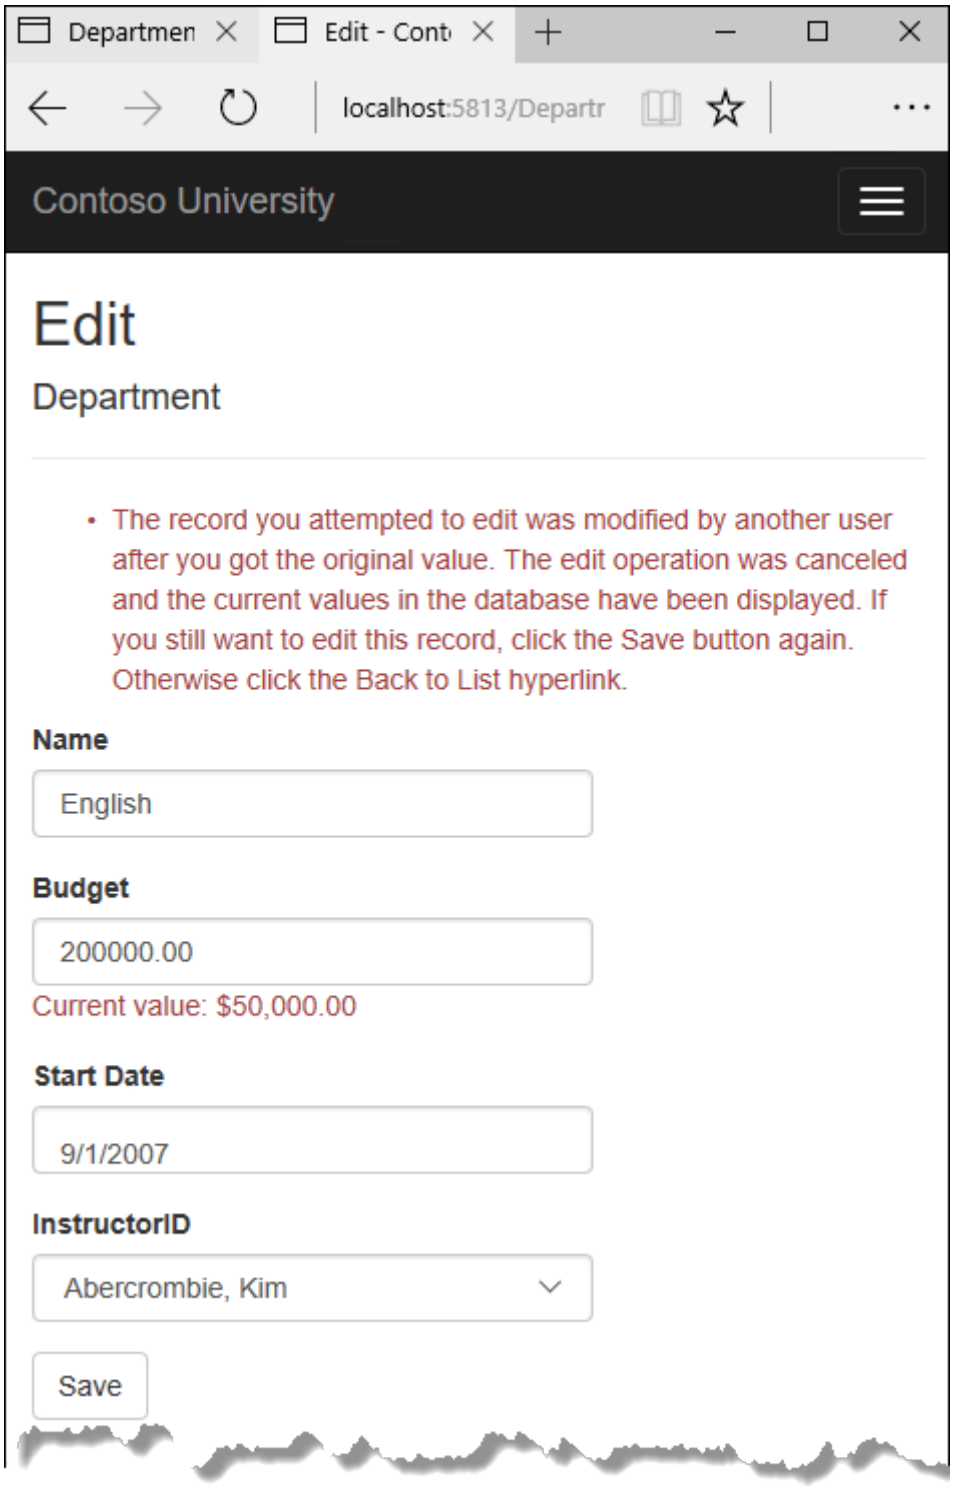
@section Scripts {
    @{await Html.RenderPartialAsync("_ValidationScriptsPartial");}
}
```

Test concurrency conflicts



Run the app and go to the Departments Index page. Right-click the **Edit** hyperlink for the English department and select **Open in new tab**, then click the **Edit** hyperlink for the English department. The two browser tabs now display the same information.

Change a field in the first browser tab and click **Save**.



The browser shows the Index page with the changed value.

Change a field in the second browser tab.

Click **Save**. You see an error message:

Click **Save** again. The value you entered in the second browser tab is saved. You see the saved values when the Index page appears.

Update the Delete page

For the Delete page, the Entity Framework detects concurrency conflicts caused by someone else editing the department in a similar manner. When the HttpGet `Delete` method displays the confirmation view, the view includes the original `RowVersion` value in a hidden field. That value is then available to the HttpPost `Delete` method that's called when the user confirms the deletion. When the Entity Framework creates the SQL

DELETE command, it includes a WHERE clause with the original `RowVersion` value. If the command results in zero rows affected (meaning the row was changed after the Delete confirmation page was displayed), a concurrency exception is thrown, and the HttpGet `Delete` method is called with an error flag set to true in order to redisplay the confirmation page with an error message. It's also possible that zero rows were affected because the row was deleted by another user, so in that case no error message is displayed.

Update the Delete methods in the Departments controller

In `DepartmentsController.cs`, replace the HttpGet `Delete` method with the following code:

C#

```
public async Task<IActionResult> Delete(int? id, bool? concurrencyError)
{
    if (id == null)
    {
        return NotFound();
    }

    var department = await _context.Departments
        .Include(d => d.Administrator)
        .AsNoTracking()
        .FirstOrDefaultAsync(m => m.DepartmentID == id);
    if (department == null)
    {
        if (concurrencyError.GetValueOrDefault())
        {
            return RedirectToAction(nameof(Index));
        }
        return NotFound();
    }

    if (concurrencyError.GetValueOrDefault())
    {
        ViewData["ConcurrencyErrorMessage"] = "The record you attempted to
delete "
            + "was modified by another user after you got the original
values. "
            + "The delete operation was canceled and the current values in
the "
            + "database have been displayed. If you still want to delete
this "
            + "record, click the Delete button again. Otherwise "
            + "click the Back to List hyperlink.";
    }
```

```
    return View(department);
}
```

The method accepts an optional parameter that indicates whether the page is being redisplayed after a concurrency error. If this flag is true and the department specified no longer exists, it was deleted by another user. In that case, the code redirects to the Index page. If this flag is true and the department does exist, it was changed by another user. In that case, the code sends an error message to the view using `ViewData`.

Replace the code in the HttpPost `Delete` method (named `DeleteConfirmed`) with the following code:

C#

```
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<IActionResult> Delete(Department department)
{
    try
    {
        if (await _context.Departments.AnyAsync(m => m.DepartmentID ==
department.DepartmentID))
        {
            _context.Departments.Remove(department);
            await _context.SaveChangesAsync();
        }
        return RedirectToAction(nameof(Index));
    }
    catch (DbUpdateConcurrencyException /* ex */)
    {
        //Log the error (uncomment ex variable name and write a log.)
        return RedirectToAction(nameof(Delete), new { concurrencyError =
true, id = department.DepartmentID });
    }
}
```

In the scaffolded code that you just replaced, this method accepted only a record ID:

C#

```
public async Task<IActionResult> DeleteConfirmed(int id)
```

You've changed this parameter to a `Department` entity instance created by the model binder. This gives EF access to the RowVers`ion property value in addition to the record key.

C#

```
public async Task<IActionResult> Delete(Department department)
```

You have also changed the action method name from `DeleteConfirmed` to `Delete`. The scaffolded code used the name `DeleteConfirmed` to give the HttpPost method a unique signature. (The CLR requires overloaded methods to have different method parameters.) Now that the signatures are unique, you can stick with the MVC convention and use the same name for the HttpPost and HttpGet delete methods.

If the department is already deleted, the `AnyAsync` method returns false and the application just goes back to the Index method.

If a concurrency error is caught, the code redisplays the Delete confirmation page and provides a flag that indicates it should display a concurrency error message.

Update the Delete view

In `Views/Departments/Delete.cshtml`, replace the scaffolded code with the following code that adds an error message field and hidden fields for the DepartmentID and RowVersion properties. The changes are highlighted.

CSHTML

```
@model ContosoUniversity.Models.Department

@{
    ViewData["Title"] = "Delete";
}

<h2>Delete</h2>

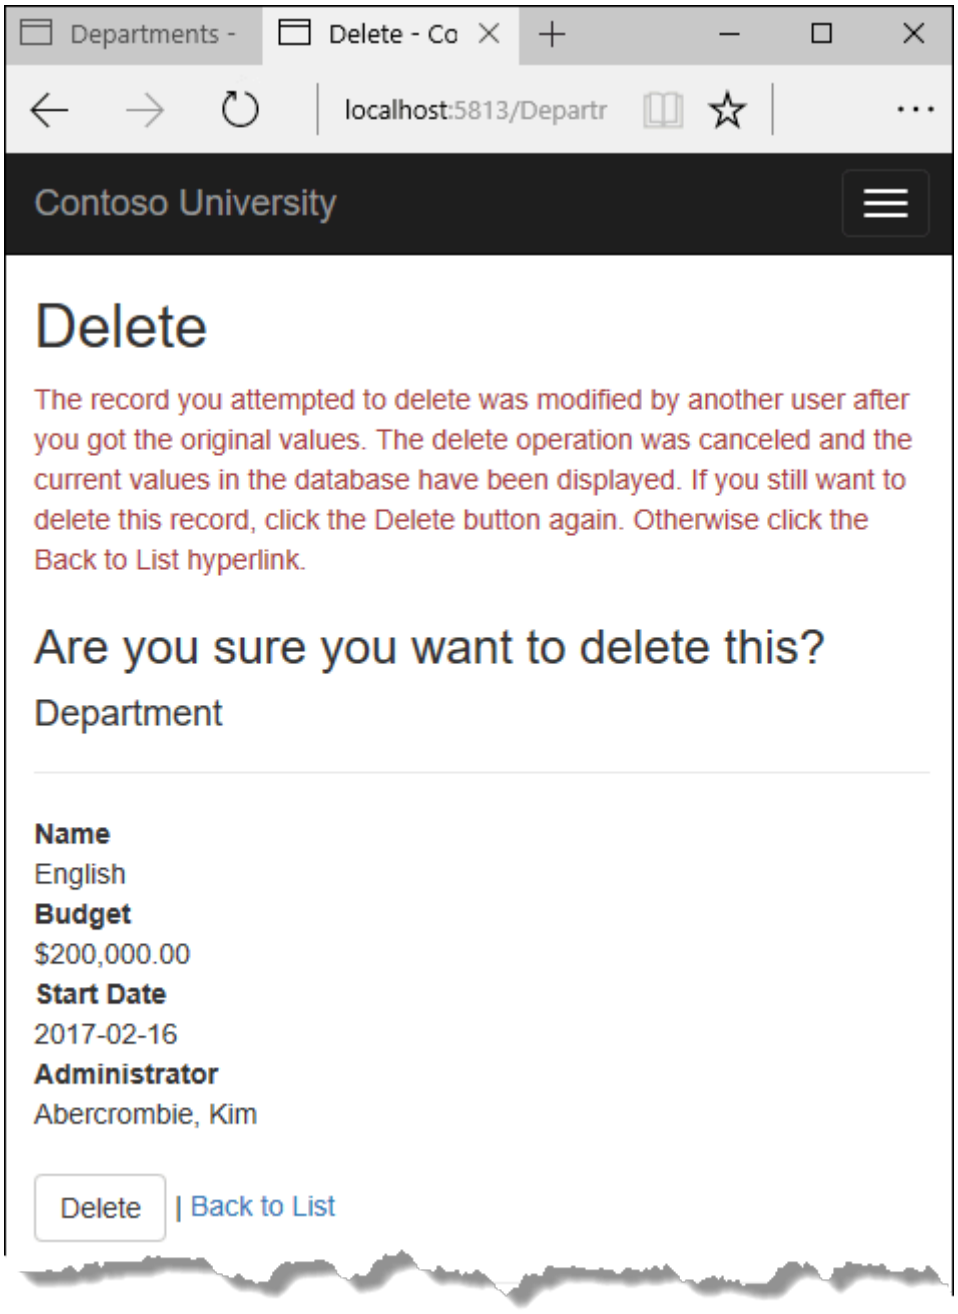
<p class="text-danger">@ViewData["ConcurrencyErrorMessage"]</p>

<h3>Are you sure you want to delete this?</h3>
<div>
    <h4>Department</h4>
    <hr />
    <dl class="row">
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Name)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Name)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Budget)
        </dt>
        <dd class="col-sm-10">
```

```
            @Html.DisplayFor(model => model.Budget)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.StartDate)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.StartDate)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Administrator)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Administrator.FullName)
        </dd>
    </dl>

    <form asp-action="Delete">
        <input type="hidden" asp-for="DepartmentID" />
        <input type="hidden" asp-for="RowVersion" />
        <div class="form-actions no-color">
            <input type="submit" value="Delete" class="btn btn-default" /> |
            <a asp-action="Index">Back to List</a>
        </div>
    </form>
</div>
```

This makes the following changes:



- Adds an error message between the `h2` and `h3` headings.
- Replaces FirstMidName with FullName in the **Administrator** field.
- Removes the RowVersion field.
- Adds a hidden field for the `RowVersion` property.

Run the app and go to the Departments Index page. Right-click the **Delete** hyperlink for the English department and select **Open in new tab**, then in the first tab click the **Edit** hyperlink for the English department.

In the first window, change one of the values, and click **Save**:

In the second tab, click **Delete**. You see the concurrency error message, and the Department values are refreshed with what's currently in the database.

If you click **Delete** again, you're redirected to the Index page, which shows that the department has been deleted.

Update Details and Create views

You can optionally clean up scaffolded code in the Details and Create views.

Replace the code in `Views/Departments/Details.cshtml` to delete the RowVersion column and show the full name of the Administrator.

CSHTML

```
@model ContosoUniversity.Models.Department

@{
    ViewData["Title"] = "Details";
```

```
}

<h2>Details</h2>

<div>
    <h4>Department</h4>
    <hr />
    <dl class="row">
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Name)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Name)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Budget)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Budget)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.StartDate)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.StartDate)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Administrator)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Administrator.FullName)
        </dd>
    </dl>
</div>
<div>
    <a asp-action="Edit" asp-route-id="@Model.DepartmentID">Edit</a> |
    <a asp-action="Index">Back to List</a>
</div>
```

Replace the code in `Views/Departments/Create.cshtml` to add a Select option to the drop-down list.

CSHTML

```
@model ContosoUniversity.Models.Department

@{
    ViewData["Title"] = "Create";
}

<h2>Create</h2>

<h4>Department</h4>
```

```
<hr />
<div class="row">
    <div class="col-md-4">
        <form asp-action="Create">
            <div asp-validation-summary="ModelOnly" class="text-danger">
</div>
            <div class="form-group">
                <label asp-for="Name" class="control-label"></label>
                <input asp-for="Name" class="form-control" />
                <span asp-validation-for="Name" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Budget" class="control-label"></label>
                <input asp-for="Budget" class="form-control" />
                <span asp-validation-for="Budget" class="text-danger">
</span>
            </div>
            <div class="form-group">
                <label asp-for="StartDate" class="control-label"></label>
                <input asp-for="StartDate" class="form-control" />
                <span asp-validation-for="StartDate" class="text-danger">
</span>
            </div>
            <div class="form-group">
                <label asp-for="InstructorID" class="control-label"></label>
                <select asp-for="InstructorID" class="form-control" asp-
items="ViewBag.InstructorID">
                    <option value="">-- Select Administrator --</option>
                </select>
            </div>
            <div class="form-group">
                <input type="submit" value="Create" class="btn btn-default"
/>
            </div>
        </form>
    </div>
</div>

<div>
    <a asp-action="Index">Back to List</a>
</div>

@section Scripts {
    @{await Html.RenderPartialAsync("_ValidationScriptsPartial");}
}
```

For more information about how to handle concurrency in EF Core, see Concurrency conflicts.

Next steps

In this tutorial, you:

- ✓ Learned about concurrency conflicts
- ✓ Added a tracking property
- ✓ Created Departments controller and views
- ✓ Updated Index view
- ✓ Updated Edit methods
- ✓ Updated Edit view
- ✓ Tested concurrency conflicts
- ✓ Updated the Delete page
- ✓ Updated Details and Create views

Advance to the next tutorial to learn how to implement table-per-hierarchy inheritance for the Instructor and Student entities.

Next: Implement table-per-hierarchy inheritance

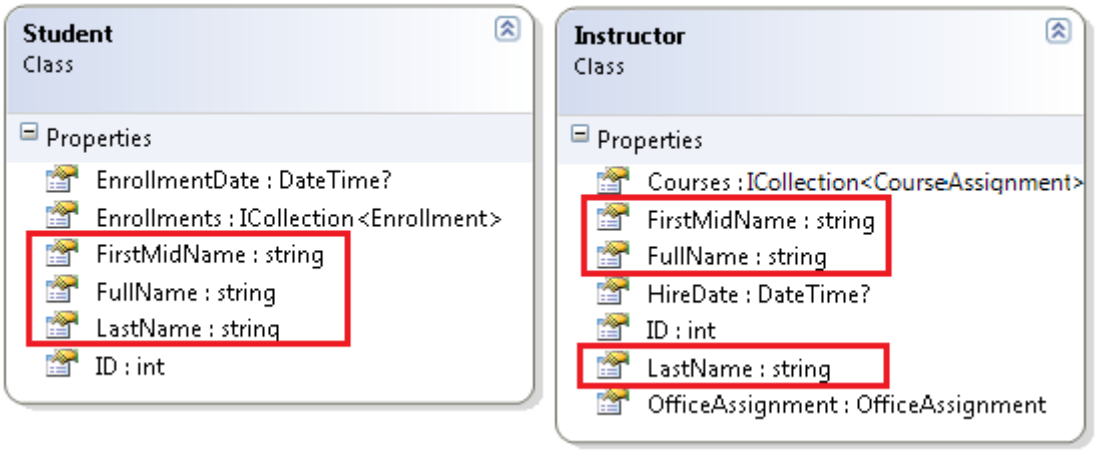
Tutorial: Implement inheritance - ASP.NET MVC with EF Core

Article • 04/10/2024

In the previous tutorial, you handled concurrency exceptions. This tutorial will show you how to implement inheritance in the data model.

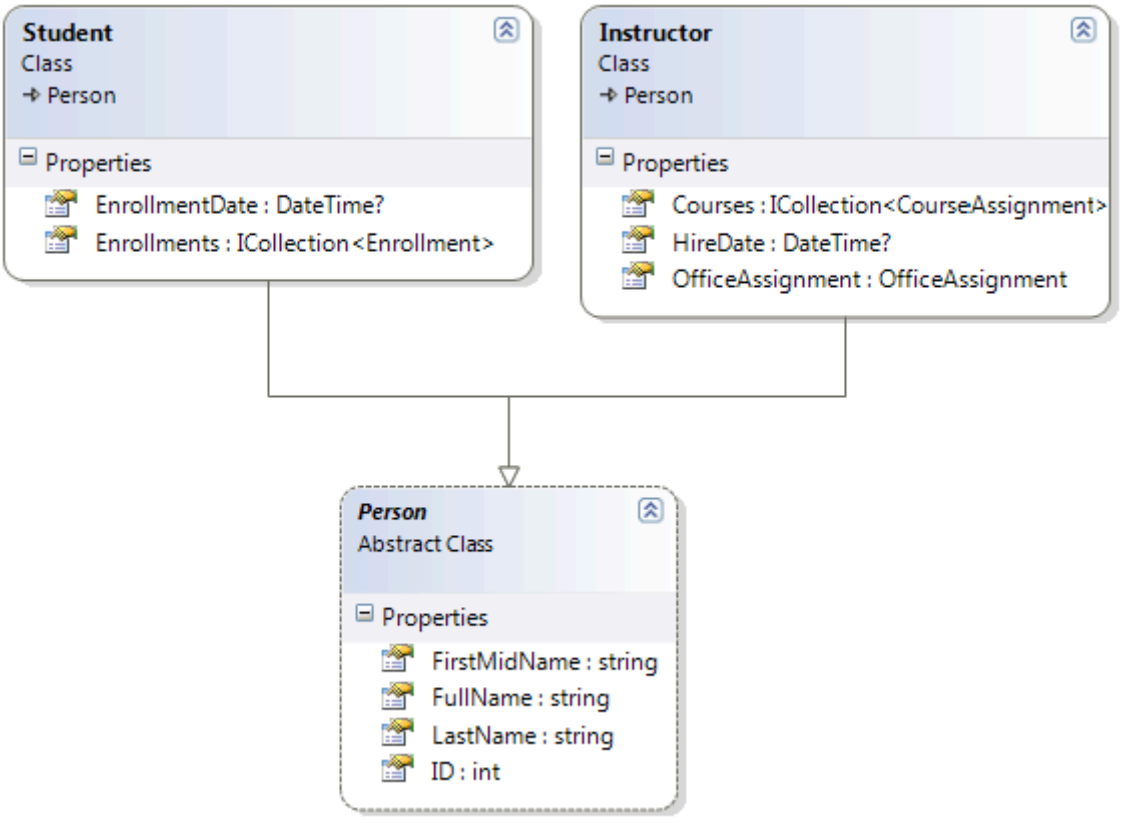
In object-oriented programming, you can use inheritance to facilitate code reuse. In this tutorial, you'll change the `Instructor` and `Student` classes so that they derive from a `Person` base class which contains properties such as `LastName` that are common to both instructors and students. You won't add or change any web pages, but you'll change some of the code and those changes will be automatically reflected in the database.

In this tutorial, you:



- ✓ Map inheritance to database
- ✓ Create the Person class
- ✓ Update Instructor and Student
- ✓ Add Person to the model
- ✓ Create and update migrations
- ✓ Test the implementation

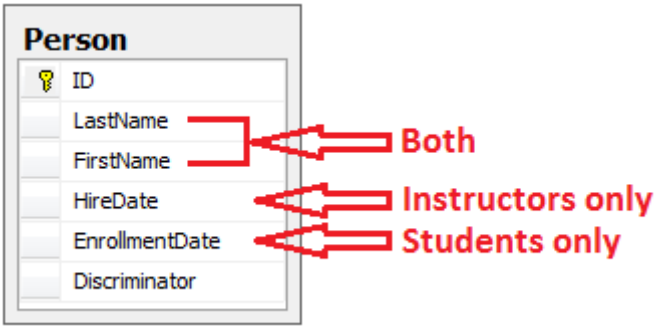
Prerequisites



- Handle Concurrency

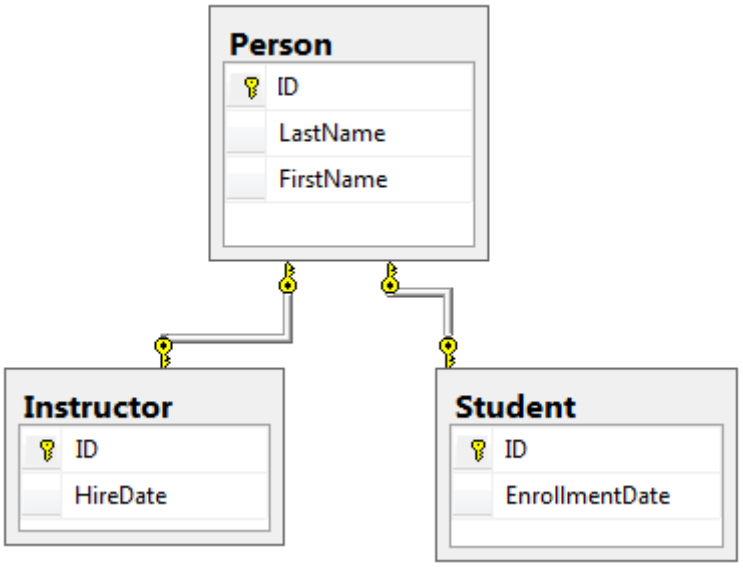
Map inheritance to database

The `Instructor` and `Student` classes in the School data model have several properties that are identical:



Suppose you want to eliminate the redundant code for the properties that are shared by the `Instructor` and `Student` entities. Or you want to write a service that can format names without caring whether the name came from an instructor or a student. You could create a `Person` base class that contains only those shared properties, then make the `Instructor` and `Student` classes inherit from that base class, as shown in the following illustration:

There are several ways this inheritance structure could be represented in the database. You could have a `Person` table that includes information about both students and instructors in a single table. Some of the columns could apply only to instructors (HireDate), some only to students (EnrollmentDate), some to both (LastName, FirstName). Typically, you'd have a discriminator column to indicate which type each row



represents. For example, the discriminator column might have "Instructor" for instructors and "Student" for students.

This pattern of generating an entity inheritance structure from a single database table is called *table-per-hierarchy (TPH)* inheritance.

An alternative is to make the database look more like the inheritance structure. For example, you could have only the name fields in the `Person` table and have separate `Instructor` and `Student` tables with the date fields.

> ⚠ **Warning**
>
> Table-Per-Type (TPT) is not supported by EF Core 3.x, however it is has been implemented in EF Core 5.0.

This pattern of making a database table for each entity class is called *table-per-type (TPT)* inheritance.

Yet another option is to map all non-abstract types to individual tables. All properties of a class, including inherited properties, map to columns of the corresponding table. This pattern is called *Table-per-Concrete Class (TPC)* inheritance. If you implemented TPC

inheritance for the `Person`, `Student`, and `Instructor` classes as shown earlier, the `Student` and `Instructor` tables would look no different after implementing inheritance than they did before.

TPC and TPH inheritance patterns generally deliver better performance than TPT inheritance patterns, because TPT patterns can result in complex join queries.

This tutorial demonstrates how to implement TPH inheritance. TPH is the only inheritance pattern that the Entity Framework Core supports. What you'll do is create a `Person` class, change the `Instructor` and `Student` classes to derive from `Person`, add the new class to the `DbContext`, and create a migration.

> **Tip**
>
> Consider saving a copy of the project before making the following changes. Then if you run into problems and need to start over, it will be easier to start from the saved project instead of reversing steps done for this tutorial or going back to the beginning of the whole series.

Create the Person class

In the Models folder, create Person.cs and replace the template code with the following code:

C#

```
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public abstract class Person
    {
        public int ID { get; set; }

        [Required]
        [StringLength(50)]
        [Display(Name = "Last Name")]
        public string LastName { get; set; }
        [Required]
        [StringLength(50, ErrorMessage = "First name cannot be longer than
50 characters.")]
        [Column("FirstName")]
        [Display(Name = "First Name")]
        public string FirstMidName { get; set; }
```

```
        [Display(Name = "Full Name")]
        public string FullName
        {
            get
            {
                return LastName + ", " + FirstMidName;
            }
        }
    }
}
```

Update Instructor and Student

In `Instructor.cs`, derive the Instructor class from the Person class and remove the key and name fields. The code will look like the following example:

C#

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Instructor : Person
    {
        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}",
ApplyFormatInEditMode = true)]
        [Display(Name = "Hire Date")]
        public DateTime HireDate { get; set; }

        public ICollection<CourseAssignment> CourseAssignments { get; set; }
        public OfficeAssignment OfficeAssignment { get; set; }
    }
}
```

Make the same changes in `Student.cs`.

C#

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
```

```
    public class Student : Person
    {
        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}",
ApplyFormatInEditMode = true)]
        [Display(Name = "Enrollment Date")]
        public DateTime EnrollmentDate { get; set; }

        public ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

Add Person to the model

Add the Person entity type to `SchoolContext.cs`. The new lines are highlighted.

C#

```
using ContosoUniversity.Models;
using Microsoft.EntityFrameworkCore;

namespace ContosoUniversity.Data
{
    public class SchoolContext : DbContext
    {
        public SchoolContext(DbContextOptions<SchoolContext> options) :
base(options)
        {
        }

        public DbSet<Course> Courses { get; set; }
        public DbSet<Enrollment> Enrollments { get; set; }
        public DbSet<Student> Students { get; set; }
        public DbSet<Department> Departments { get; set; }
        public DbSet<Instructor> Instructors { get; set; }
        public DbSet<OfficeAssignment> OfficeAssignments { get; set; }
        public DbSet<CourseAssignment> CourseAssignments { get; set; }
        public DbSet<Person> People { get; set; }

        protected override void OnModelCreating(ModelBuilder modelBuilder)
        {
            modelBuilder.Entity<Course>().ToTable("Course");
            modelBuilder.Entity<Enrollment>().ToTable("Enrollment");
            modelBuilder.Entity<Student>().ToTable("Student");
            modelBuilder.Entity<Department>().ToTable("Department");
            modelBuilder.Entity<Instructor>().ToTable("Instructor");
            modelBuilder.Entity<OfficeAssignment>
().ToTable("OfficeAssignment");
            modelBuilder.Entity<CourseAssignment>
().ToTable("CourseAssignment");
```

```
            modelBuilder.Entity<Person>().ToTable("Person");

            modelBuilder.Entity<CourseAssignment>()
                .HasKey(c => new { c.CourseID, c.InstructorID });
        }
    }
}
```

This is all that the Entity Framework needs in order to configure table-per-hierarchy inheritance. As you'll see, when the database is updated, it will have a Person table in place of the Student and Instructor tables.

Create and update migrations

Save your changes and build the project. Then open the command window in the project folder and enter the following command:

.NET CLI

```
dotnet ef migrations add Inheritance
```

Don't run the `database update` command yet. That command will result in lost data because it will drop the Instructor table and rename the Student table to Person. You need to provide custom code to preserve existing data.

Open `Migrations/<timestamp>_Inheritance.cs` and replace the `Up` method with the following code:

C#

```
protected override void Up(MigrationBuilder migrationBuilder)
{
    migrationBuilder.DropForeignKey(
        name: "FK_Enrollment_Student_StudentID",
        table: "Enrollment");

    migrationBuilder.DropIndex(name: "IX_Enrollment_StudentID", table:
"Enrollment");

    migrationBuilder.RenameTable(name: "Instructor", newName: "Person");
    migrationBuilder.AddColumn<DateTime>(name: "EnrollmentDate", table:
"Person", nullable: true);
    migrationBuilder.AddColumn<string>(name: "Discriminator", table:
"Person", nullable: false, maxLength: 128, defaultValue: "Instructor");
    migrationBuilder.AlterColumn<DateTime>(name: "HireDate", table:
"Person", nullable: true);
    migrationBuilder.AddColumn<int>(name: "OldId", table: "Person",
```

```
nullable: true);

    // Copy existing Student data into new Person table.
    migrationBuilder.Sql("INSERT INTO dbo.Person (LastName, FirstName,
HireDate, EnrollmentDate, Discriminator, OldId) SELECT LastName, FirstName,
null AS HireDate, EnrollmentDate, 'Student' AS Discriminator, ID AS OldId
FROM dbo.Student");
    // Fix up existing relationships to match new PK's.
    migrationBuilder.Sql("UPDATE dbo.Enrollment SET StudentId = (SELECT ID
FROM dbo.Person WHERE OldId = Enrollment.StudentId AND Discriminator =
'Student')");

    // Remove temporary key
    migrationBuilder.DropColumn(name: "OldID", table: "Person");

    migrationBuilder.DropTable(
        name: "Student");

    migrationBuilder.CreateIndex(
         name: "IX_Enrollment_StudentID",
         table: "Enrollment",
         column: "StudentID");

    migrationBuilder.AddForeignKey(
        name: "FK_Enrollment_Person_StudentID",
        table: "Enrollment",
        column: "StudentID",
        principalTable: "Person",
        principalColumn: "ID",
        onDelete: ReferentialAction.Cascade);
}
```

This code takes care of the following database update tasks:

- Removes foreign key constraints and indexes that point to the Student table.
- Renames the Instructor table as Person and makes changes needed for it to store Student data:
- Adds nullable EnrollmentDate for students.
- Adds Discriminator column to indicate whether a row is for a student or an instructor.
- Makes HireDate nullable since student rows won't have hire dates.
- Adds a temporary field that will be used to update foreign keys that point to students. When you copy students into the Person table they will get new primary key values.

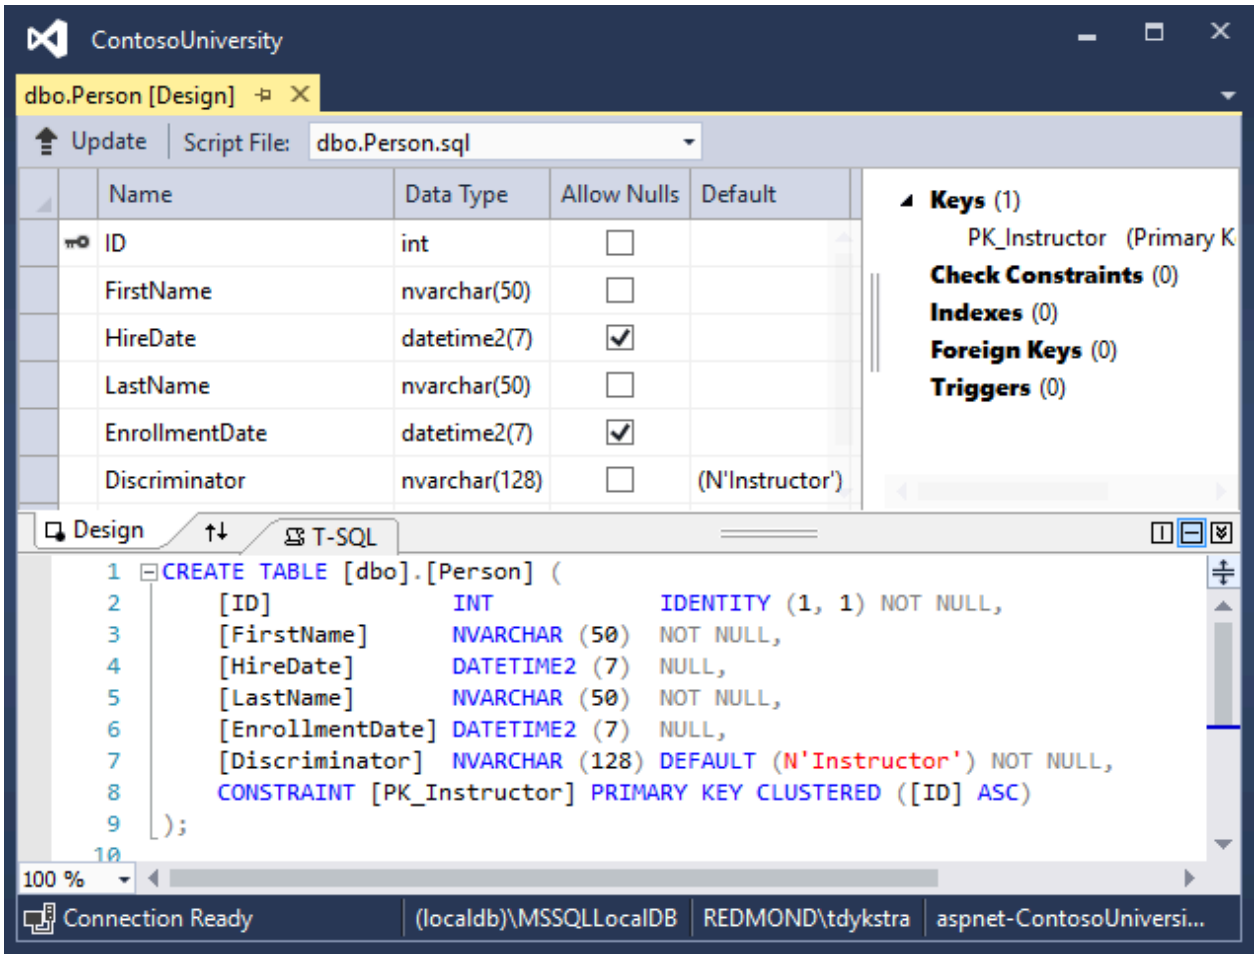
- Copies data from the Student table into the Person table. This causes students to get assigned new primary key values.
- Fixes foreign key values that point to students.
- Re-creates foreign key constraints and indexes, now pointing them to the Person table.

(If you had used GUID instead of integer as the primary key type, the student primary key values wouldn't have to change, and several of these steps could have been omitted.)

Run the `database update` command:

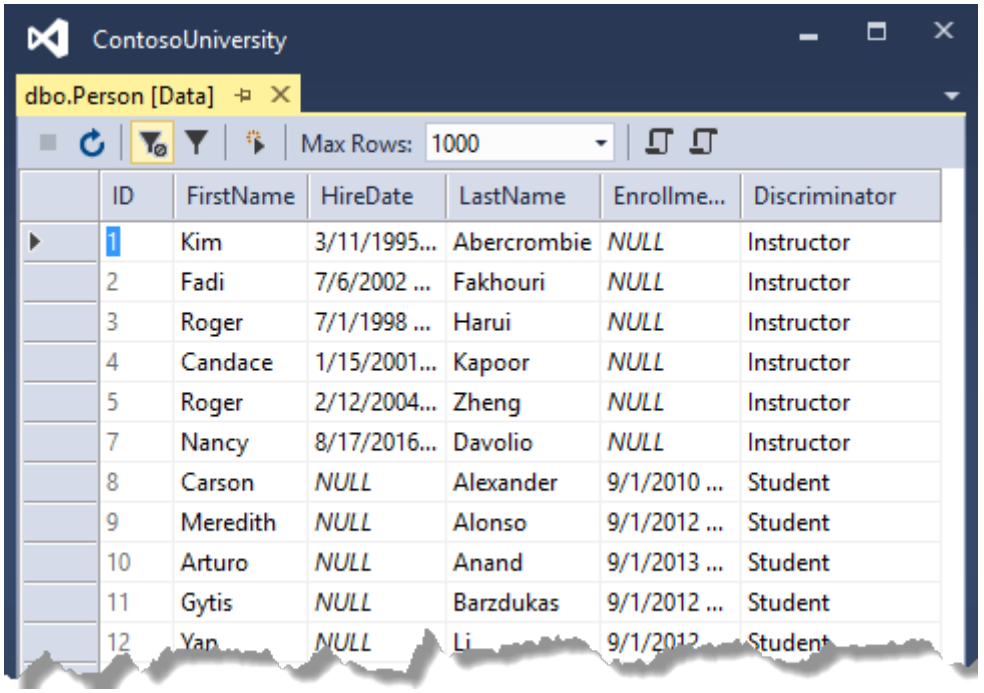
.NET CLI

```
dotnet ef database update
```



(In a production system you would make corresponding changes to the `Down` method in case you ever had to use that to go back to the previous database version. For this tutorial you won't be using the `Down` method.)

> **Note**
>
> It's possible to get other errors when making schema changes in a database that has existing data. If you get migration errors that you can't resolve, you can either change the database name in the connection string or delete the database. With a new database, there's no data to migrate, and the update-database command is more likely to complete without errors. To delete the database, use SSOX or run the `database drop` CLI command.



Test the implementation

Run the app and try various pages. Everything works the same as it did before.

In **SQL Server Object Explorer**, expand **Data Connections/SchoolContext** and then **Tables**, and you see that the Student and Instructor tables have been replaced by a Person table. Open the Person table designer and you see that it has all of the columns that used to be in the Student and Instructor tables.

Right-click the Person table, and then click **Show Table Data** to see the discriminator column.

Get the code

Download or view the completed application.

Additional resources

For more information about inheritance in Entity Framework Core, see Inheritance.

Next steps

In this tutorial, you:

- ✓ Mapped inheritance to database
- ✓ Created the Person class
- ✓ Updated Instructor and Student
- ✓ Added Person to the model
- ✓ Created and update migrations
- ✓ Tested the implementation

Advance to the next tutorial to learn how to handle a variety of relatively advanced Entity Framework scenarios.

Next: Advanced topics

Tutorial: Learn about advanced scenarios - ASP.NET MVC with EF Core

Article • 04/10/2024

In the previous tutorial, you implemented table-per-hierarchy inheritance. This tutorial introduces several topics that are useful to be aware of when you go beyond the basics of developing ASP.NET Core web applications that use Entity Framework Core.

In this tutorial, you:

- ✓ Perform raw SQL queries
- ✓ Call a query to return entities
- ✓ Call a query to return other types
- ✓ Call an update query
- ✓ Examine SQL queries
- ✓ Create an abstraction layer
- ✓ Learn about Automatic change detection
- ✓ Learn about EF Core source code and development plans
- ✓ Learn how to use dynamic LINQ to simplify code

Prerequisites

- Implement Inheritance

Perform raw SQL queries

One of the advantages of using the Entity Framework is that it avoids tying your code too closely to a particular method of storing data. It does this by generating SQL queries and commands for you, which also frees you from having to write them yourself. But there are exceptional scenarios when you need to run specific SQL queries that you have manually created. For these scenarios, the Entity Framework Code First API includes methods that enable you to pass SQL commands directly to the database. You have the following options in EF Core 1.0:

- Use the `DbSet.FromSql` method for queries that return entity types. The returned objects must be of the type expected by the `DbSet` object, and they're automatically tracked by the database context unless you turn tracking off.
- Use the `Database.ExecuteSqlCommand` for non-query commands.

If you need to run a query that returns types that aren't entities, you can use ADO.NET with the database connection provided by EF. The returned data isn't tracked by the database context, even if you use this method to retrieve entity types.

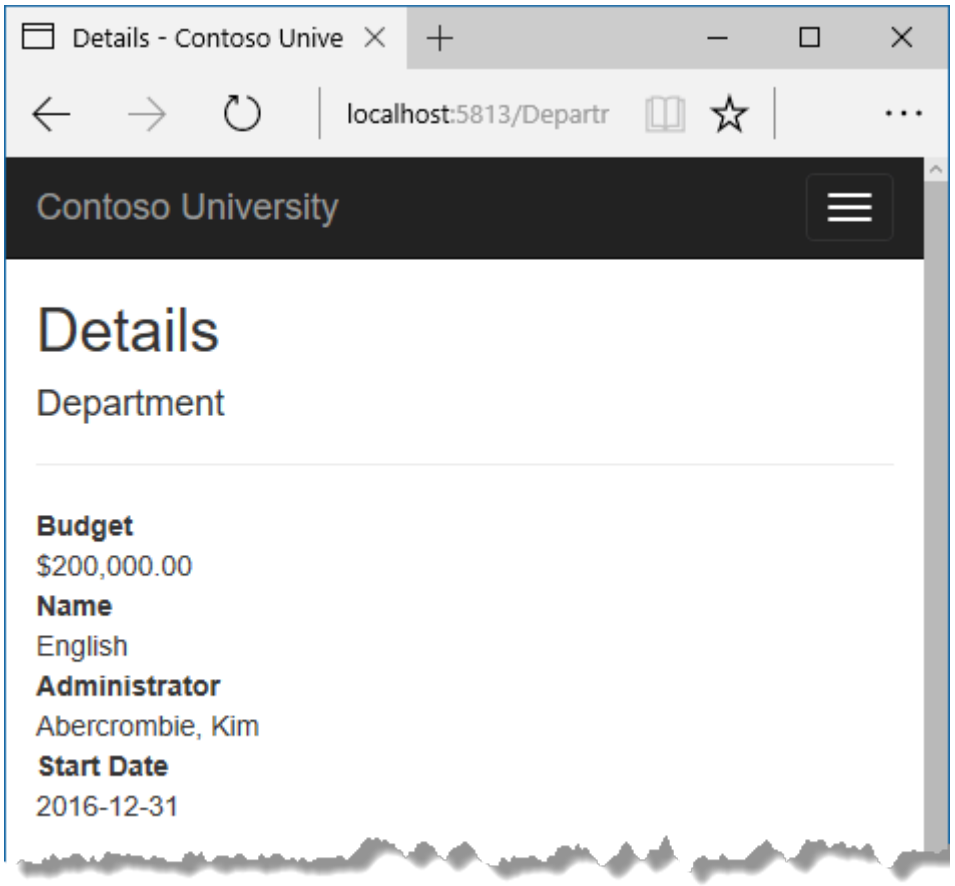
As is always true when you execute SQL commands in a web application, you must take precautions to protect your site against SQL injection attacks. One way to do that is to use parameterized queries to make sure that strings submitted by a web page can't be interpreted as SQL commands. In this tutorial you'll use parameterized queries when integrating user input into a query.

Call a query to return entities

The `DbSet<TEntity>` class provides a method that you can use to execute a query that returns an entity of type `TEntity`. To see how this works you'll change the code in the `Details` method of the Department controller.

In `DepartmentsController.cs`, in the `Details` method, replace the code that retrieves a department with a `FromSql` method call, as shown in the following highlighted code:

C#



```
public async Task<IActionResult> Details(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    string query = "SELECT * FROM Department WHERE DepartmentID = {0}";
    var department = await _context.Departments
        .FromSql(query, id)
        .Include(d => d.Administrator)
        .AsNoTracking()
        .FirstOrDefaultAsync();

    if (department == null)
    {
        return NotFound();
    }

    return View(department);
}
```

To verify that the new code works correctly, select the **Departments** tab and then **Details** for one of the departments.

Call a query to return other types

Earlier you created a student statistics grid for the About page that showed the number of students for each enrollment date. You got the data from the Students entity set (`_context.Students`) and used LINQ to project the results into a list of `EnrollmentDateGroup` view model objects. Suppose you want to write the SQL itself rather than using LINQ. To do that you need to run a SQL query that returns something other than entity objects. In EF Core 1.0, one way to do that is to write ADO.NET code and get the database connection from EF.

In `HomeController.cs`, replace the `About` method with the following code:

C#

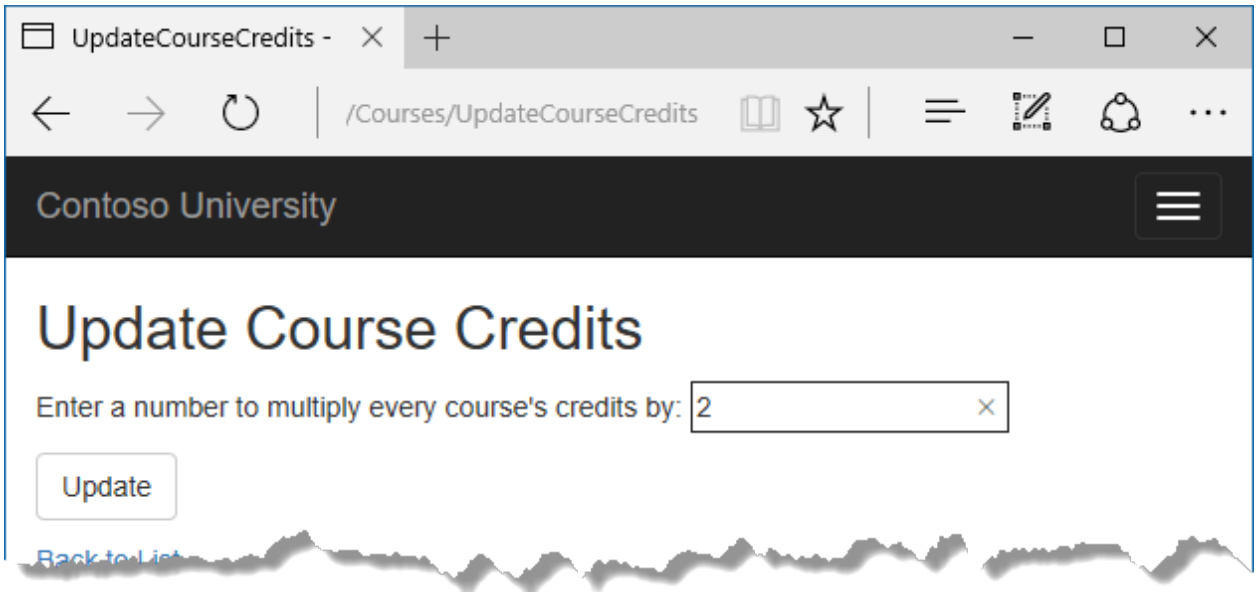
```
public async Task<ActionResult> About()
{
```

```
    List<EnrollmentDateGroup> groups = new List<EnrollmentDateGroup>();
    var conn = _context.Database.GetDbConnection();
    try
    {
        await conn.OpenAsync();
        using (var command = conn.CreateCommand())
        {
            string query = "SELECT EnrollmentDate, COUNT(*) AS StudentCount
"
                + "FROM Person "
                + "WHERE Discriminator = 'Student' "
                + "GROUP BY EnrollmentDate";
            command.CommandText = query;
            DbDataReader reader = await command.ExecuteReaderAsync();

            if (reader.HasRows)
            {
                while (await reader.ReadAsync())
                {
                    var row = new EnrollmentDateGroup { EnrollmentDate =
reader.GetDateTime(0), StudentCount = reader.GetInt32(1) };
                    groups.Add(row);
                }
            }
            reader.Dispose();
        }
    }
    finally
    {
        conn.Close();
    }
    return View(groups);
}
```

Add a using statement:

C#



```
using System.Data.Common;
```

Run the app and go to the About page. It displays the same data it did before.

Call an update query

Suppose Contoso University administrators want to perform global changes in the database, such as changing the number of credits for every course. If the university has a large number of courses, it would be inefficient to retrieve them all as entities and change them individually. In this section you'll implement a web page that enables the user to specify a factor by which to change the number of credits for all courses, and you'll make the change by executing a SQL UPDATE statement. The web page will look like the following illustration:

In `CoursesController.cs`, add UpdateCourseCredits methods for HttpGet and HttpPost:

C#

```
public IActionResult UpdateCourseCredits()
{
```

```
    return View();
}
```

C#

```
[HttpPost]
public async Task<IActionResult> UpdateCourseCredits(int? multiplier)
{
    if (multiplier != null)
    {
        ViewData["RowsAffected"] =
            await _context.Database.ExecuteSqlCommandAsync(
                "UPDATE Course SET Credits = Credits * {0}",
                parameters: multiplier);
    }
    return View();
}
```

When the controller processes an HttpGet request, nothing is returned in `ViewData["RowsAffected"]`, and the view displays an empty text box and a submit button, as shown in the preceding illustration.

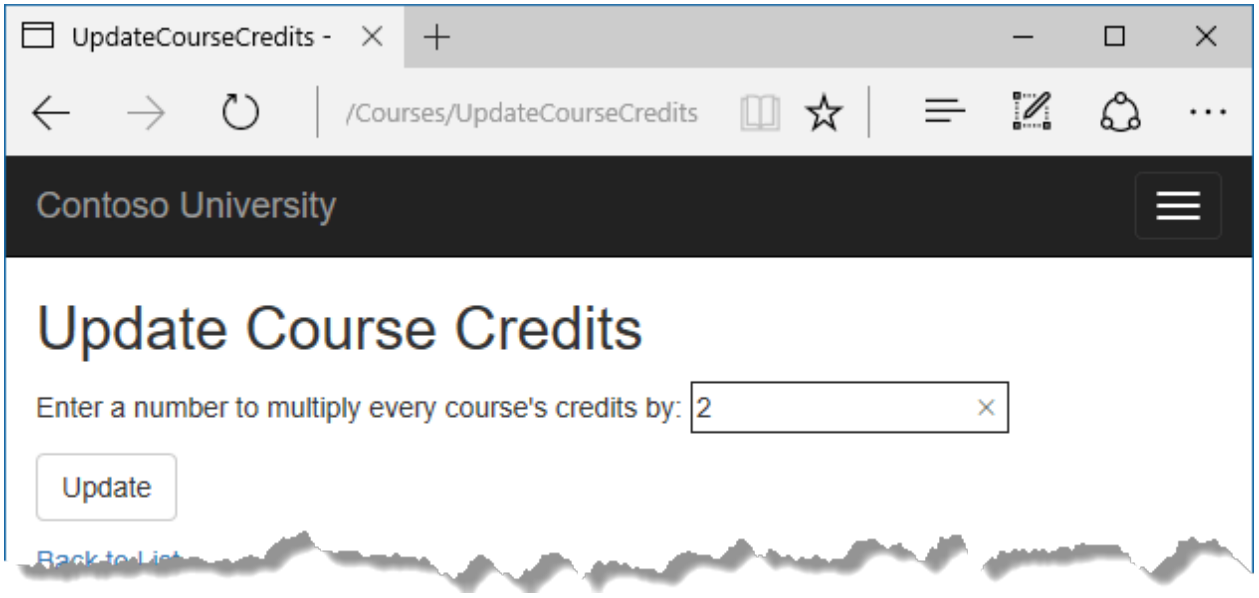
When the **Update** button is clicked, the HttpPost method is called, and multiplier has the value entered in the text box. The code then executes the SQL that updates courses and returns the number of affected rows to the view in `ViewData`. When the view gets a `RowsAffected` value, it displays the number of rows updated.

In **Solution Explorer**, right-click the *Views/Courses* folder, and then click **Add** > **New Item**.

In the **Add New Item** dialog, click **ASP.NET Core** under **Installed** in the left pane, click **Razor View**, and name the new view `UpdateCourseCredits.cshtml`.

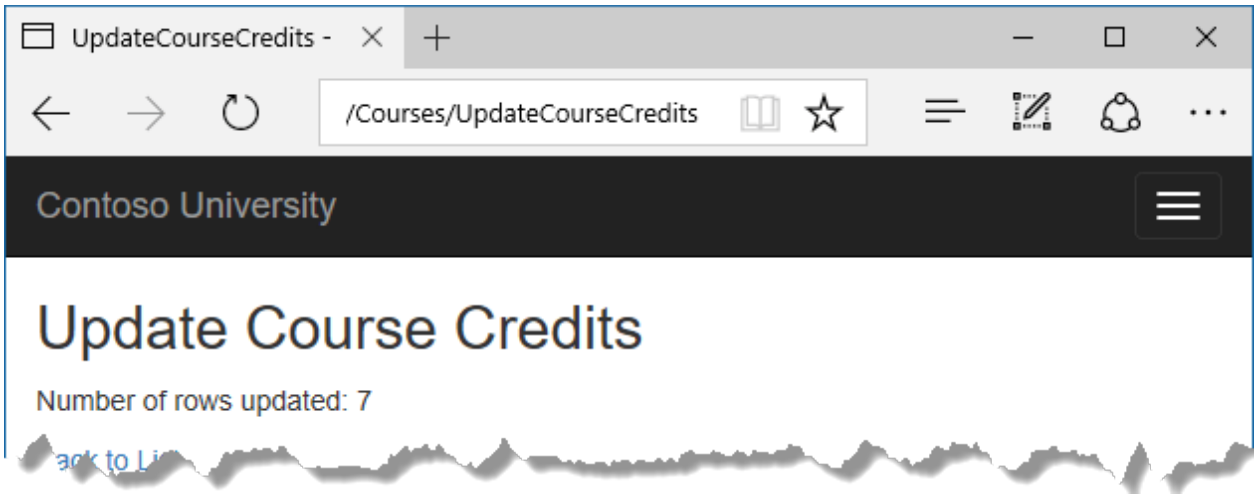
In `Views/Courses/UpdateCourseCredits.cshtml`, replace the template code with the following code:

CSHTML



```
@{
    ViewBag.Title = "UpdateCourseCredits";
}

<h2>Update Course Credits</h2>



@if (ViewData["RowsAffected"] == null)
{
    <form asp-action="UpdateCourseCredits">
        <div class="form-actions no-color">
```

```
            <p>
                Enter a number to multiply every course's credits by:
@Html.TextBox("multiplier")
            </p>
            <p>
                <input type="submit" value="Update" class="btn btn-default"
/>
            </p>
        </div>
    </form>
}
@if (ViewData["RowsAffected"] != null)
{
    <p>
        Number of rows updated: @ViewData["RowsAffected"]
    </p>
}
<div>
    @Html.ActionLink("Back to List", "Index")
</div>
```

Run the `UpdateCourseCredits` method by selecting the **Courses** tab, then adding "/UpdateCourseCredits" to the end of the URL in the browser's address bar (for example: `http://localhost:5813/Courses/UpdateCourseCredits`). Enter a number in the text box:

Click **Update**. You see the number of rows affected:

Click **Back to List** to see the list of courses with the revised number of credits.

Note that production code would ensure that updates always result in valid data. The simplified code shown here could multiply the number of credits enough to result in numbers greater than 5. (The `Credits` property has a `[Range(0, 5)]` attribute.) The update query would work but the invalid data could cause unexpected results in other parts of the system that assume the number of credits is 5 or less.

For more information about raw SQL queries, see Raw SQL Queries.

Examine SQL queries

Sometimes it's helpful to be able to see the actual SQL queries that are sent to the database. Built-in logging functionality for ASP.NET Core is automatically used by EF Core to write logs that contain the SQL for queries and updates. In this section you'll see some examples of SQL logging.

Open `StudentsController.cs` and in the `Details` method set a breakpoint on the `if (student == null)` statement.

Run the app in debug mode, and go to the Details page for a student.

Go to the **Output** window showing debug output, and you see the query:

```
Microsoft.EntityFrameworkCore.Database.Command:Information: Executed
DbCommand (56ms) [Parameters=[@__id_0='?'], CommandType='Text',
CommandTimeout='30']
SELECT TOP(2) [s].[ID], [s].[Discriminator], [s].[FirstName], [s].
[LastName], [s].[EnrollmentDate]
FROM [Person] AS [s]
WHERE ([s].[Discriminator] = N'Student') AND ([s].[ID] = @__id_0)
ORDER BY [s].[ID]
```

```
Microsoft.EntityFrameworkCore.Database.Command:Information: Executed
DbCommand (122ms) [Parameters=[@__id_0='?'], CommandType='Text',
CommandTimeout='30']
SELECT [s.Enrollments].[EnrollmentID], [s.Enrollments].[CourseID],
[s.Enrollments].[Grade], [s.Enrollments].[StudentID], [e.Course].[CourseID],
[e.Course].[Credits], [e.Course].[DepartmentID], [e.Course].[Title]
FROM [Enrollment] AS [s.Enrollments]
INNER JOIN [Course] AS [e.Course] ON [s.Enrollments].[CourseID] =
[e.Course].[CourseID]
INNER JOIN (
    SELECT TOP(1) [s0].[ID]
    FROM [Person] AS [s0]
    WHERE ([s0].[Discriminator] = N'Student') AND ([s0].[ID] = @__id_0)
    ORDER BY [s0].[ID]
) AS [t] ON [s.Enrollments].[StudentID] = [t].[ID]
ORDER BY [t].[ID]
```

You'll notice something here that might surprise you: the SQL selects up to 2 rows (`TOP(2)`) from the Person table. The `SingleOrDefaultAsync` method doesn't resolve to 1 row on the server. Here's why:

- If the query would return multiple rows, the method returns null.
- To determine whether the query would return multiple rows, EF has to check if it returns at least 2.

Note that you don't have to use debug mode and stop at a breakpoint to get logging output in the **Output** window. It's just a convenient way to stop the logging at the point you want to look at the output. If you don't do that, logging continues and you have to scroll back to find the parts you're interested in.

Create an abstraction layer

Many developers write code to implement the repository and unit of work patterns as a wrapper around code that works with the Entity Framework. These patterns are intended to create an abstraction layer between the data access layer and the business logic layer of an application. Implementing these patterns can help insulate your application from changes in the data store and can facilitate automated unit testing or test-driven development (TDD). However, writing additional code to implement these patterns isn't always the best choice for applications that use EF, for several reasons:

- The EF context class itself insulates your code from data-store-specific code.
- The EF context class can act as a unit-of-work class for database updates that you do using EF.
- EF includes features for implementing TDD without writing repository code.

For information about how to implement the repository and unit of work patterns, see the Entity Framework 5 version of this tutorial series.

Entity Framework Core implements an in-memory database provider that can be used for testing. For more information, see Test with InMemory.

Automatic change detection

The Entity Framework determines how an entity has changed (and therefore which updates need to be sent to the database) by comparing the current values of an entity with the original values. The original values are stored when the entity is queried or attached. Some of the methods that cause automatic change detection are the following:

- DbContext.SaveChanges
- DbContext.Entry
- ChangeTracker.Entries

If you're tracking a large number of entities and you call one of these methods many times in a loop, you might get significant performance improvements by temporarily turning off automatic change detection using the `ChangeTracker.AutoDetectChangesEnabled` property. For example:

```
C#

_context.ChangeTracker.AutoDetectChangesEnabled = false;
```

EF Core source code and development plans

The Entity Framework Core source is at https://github.com/dotnet/efcore. The EF Core repository contains nightly builds, issue tracking, feature specs, design meeting notes, and the roadmap for future development. You can file or find bugs, and contribute.

Although the source code is open, Entity Framework Core is fully supported as a Microsoft product. The Microsoft Entity Framework team keeps control over which contributions are accepted and tests all code changes to ensure the quality of each release.

Reverse engineer from existing database

To reverse engineer a data model including entity classes from an existing database, use the scaffold-dbcontext command. See the getting-started tutorial.

Use dynamic LINQ to simplify code

The third tutorial in this series shows how to write LINQ code by hard-coding column names in a `switch` statement. With two columns to choose from, this works fine, but if you have many columns the code could get verbose. To solve that problem, you can use the `EF.Property` method to specify the name of the property as a string. To try out this approach, replace the `Index` method in the `StudentsController` with the following code.

C#

```
 public async Task<IActionResult> Index(
     string sortOrder,
     string currentFilter,
     string searchString,
     int? pageNumber)
 {
     ViewData["CurrentSort"] = sortOrder;
     ViewData["NameSortParm"] =
         String.IsNullOrEmpty(sortOrder) ? "LastName_desc" : "";
     ViewData["DateSortParm"] =
         sortOrder == "EnrollmentDate" ? "EnrollmentDate_desc" :
"EnrollmentDate";

     if (searchString != null)
     {
         pageNumber = 1;
     }
     else
     {
         searchString = currentFilter;
     }

     ViewData["CurrentFilter"] = searchString;

     var students = from s in _context.Students
                    select s;

     if (!String.IsNullOrEmpty(searchString))
     {
         students = students.Where(s => s.LastName.Contains(searchString)
                                || s.FirstMidName.Contains(searchString));
     }

     if (string.IsNullOrEmpty(sortOrder))
     {
         sortOrder = "LastName";
     }
```

```
      bool descending = false;
      if (sortOrder.EndsWith("_desc"))
      {
          sortOrder = sortOrder.Substring(0, sortOrder.Length - 5);
          descending = true;
      }

      if (descending)
      {
          students = students.OrderByDescending(e => EF.Property<object>(e,
sortOrder));
      }
      else
      {
          students = students.OrderBy(e => EF.Property<object>(e,
sortOrder));
      }

      int pageSize = 3;
      return View(await
PaginatedList<Student>.CreateAsync(students.AsNoTracking(),
          pageNumber ?? 1, pageSize));
  }
```

Acknowledgments

Tom Dykstra and Rick Anderson (twitter @RickAndMSFT) wrote this tutorial. Rowan Miller, Diego Vega, and other members of the Entity Framework team assisted with code reviews and helped debug issues that arose while we were writing code for the tutorials. John Parente and Paul Goldman worked on updating the tutorial for ASP.NET Core 2.2.

Troubleshoot common errors

ContosoUniversity.dll used by another process

Error message:

> Cannot open '...bin\Debug\netcoreapp1.0\ContosoUniversity.dll' for writing -- 'The process cannot access the file '...\bin\Debug\netcoreapp1.0\ContosoUniversity.dll' because it is being used by another process.

Solution:

Stop the site in IIS Express. Go to the Windows System Tray, find IIS Express and right-click its icon, select the Contoso University site, and then click **Stop Site**.

Migration scaffolded with no code in Up and Down methods

Possible cause:

The EF CLI commands don't automatically close and save code files. If you have unsaved changes when you run the `migrations add` command, EF won't find your changes.

Solution:

Run the `migrations remove` command, save your code changes and rerun the `migrations add` command.

Errors while running database update

It's possible to get other errors when making schema changes in a database that has existing data. If you get migration errors you can't resolve, you can either change the database name in the connection string or delete the database. With a new database, there's no data to migrate, and the update-database command is much more likely to complete without errors.

The simplest approach is to rename the database in `appsettings.json`. The next time you run `database update`, a new database will be created.

To delete a database in SSOX, right-click the database, click **Delete**, and then in the **Delete Database** dialog box select **Close existing connections** and click **OK**.

To delete a database by using the CLI, run the `database drop` CLI command:

.NET CLI

```
dotnet ef database drop
```

Error locating SQL Server instance

Error Message:

> A network-related or instance-specific error occurred while establishing a connection to SQL Server. The server was not found or was not accessible. Verify

> that the instance name is correct and that SQL Server is configured to allow remote connections. (provider: SQL Network Interfaces, error: 26 - Error Locating Server/Instance Specified)

Solution:

Check the connection string. If you have manually deleted the database file, change the name of the database in the construction string to start over with a new database.

Get the code

Download or view the completed application.

Additional resources

For more information about EF Core, see the Entity Framework Core documentation. A book is also available: Entity Framework Core in Action.

For information on how to deploy a web app, see Host and deploy ASP.NET Core.

For information about other topics related to ASP.NET Core MVC, such as authentication and authorization, see Overview of ASP.NET Core.

Next steps

In this tutorial, you:

- ✓ Performed raw SQL queries
- ✓ Called a query to return entities
- ✓ Called a query to return other types
- ✓ Called an update query
- ✓ Examined SQL queries
- ✓ Created an abstraction layer
- ✓ Learned about Automatic change detection
- ✓ Learned about EF Core source code and development plans
- ✓ Learned how to use dynamic LINQ to simplify code

This completes this series of tutorials on using the Entity Framework Core in an ASP.NET Core MVC application. This series worked with a new database; an alternative is to reverse engineer a model from an existing database.

Tutorial: EF Core with MVC, existing database

ASP.NET Core fundamentals overview

Article • 09/18/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

This article provides an overview of the fundamentals for building ASP.NET Core apps, including dependency injection (DI), configuration, middleware, and more.

For Blazor fundamentals guidance, which adds to or supersedes the guidance in this node, see ASP.NET Core Blazor fundamentals.

Program.cs

ASP.NET Core apps created with the web templates contain the application startup code in the `Program.cs` file. The `Program.cs` file is where:

- Services required by the app are configured.
- The app's request handling pipeline is defined as a series of middleware components.

The following app startup code supports:

- Razor Pages
- MVC controllers with views
- Web API with controllers
- Minimal web APIs

C#

```
var builder = WebApplication.CreateBuilder(args);

// Add services to the container.
builder.Services.AddRazorPages();
builder.Services.AddControllersWithViews();

var app = builder.Build();
```

```
// Configure the HTTP request pipeline.
if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseAuthorization();

app.MapGet("/hi", () => "Hello!");

app.MapDefaultControllerRoute();
app.MapRazorPages();

app.Run();
```

Dependency injection (services)

ASP.NET Core includes dependency injection (DI) that makes configured services available throughout an app. Services are added to the DI container with WebApplicationBuilder.Services, `builder.Services` in the preceding code. When the WebApplicationBuilder is instantiated, many framework-provided services are added. `builder` is a `WebApplicationBuilder` in the following code:

C#

```
var builder = WebApplication.CreateBuilder(args);

// Add services to the container.
builder.Services.AddRazorPages();
builder.Services.AddControllersWithViews();

var app = builder.Build();
```

In the preceding highlighted code, `builder` has configuration, logging, and many other services added to the DI container.

The following code adds Razor Pages, MVC controllers with views, and a custom DbContext to the DI container:

C#

```
using Microsoft.EntityFrameworkCore;
using RazorPagesMovie.Data;
```

```
var builder = WebApplication.CreateBuilder(args);

// Add services to the container.
builder.Services.AddRazorPages();
builder.Services.AddControllersWithViews();

builder.Services.AddDbContext<RazorPagesMovieContext>(options =>

options.UseSqlServer(builder.Configuration.GetConnectionString("RPMovieConte
xt")));

var app = builder.Build();
```

Services are typically resolved from DI using constructor injection. The DI framework provides an instance of this service at runtime.

The following code uses constructor injection to resolve the database context and logger from DI:

C#

```
public class IndexModel : PageModel
{
    private readonly RazorPagesMovieContext _context;
    private readonly ILogger<IndexModel> _logger;

    public IndexModel(RazorPagesMovieContext context, ILogger<IndexModel>
logger)
    {
        _context = context;
        _logger = logger;
    }

    public IList<Movie> Movie { get;set; }

    public async Task OnGetAsync()
    {
        _logger.LogInformation("IndexModel OnGetAsync.");
        Movie = await _context.Movie.ToListAsync();
    }
}
```

Middleware

The request handling pipeline is composed as a series of middleware components. Each component performs operations on an HttpContext and either invokes the next middleware in the pipeline or terminates the request.

By convention, a middleware component is added to the pipeline by invoking a `Use{Feature}` extension method. Middleware added to the app is highlighted in the following code:

C#

```
var builder = WebApplication.CreateBuilder(args);

// Add services to the container.
builder.Services.AddRazorPages();
builder.Services.AddControllersWithViews();

var app = builder.Build();

// Configure the HTTP request pipeline.
if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseAuthorization();

app.MapGet("/hi", () => "Hello!");

app.MapDefaultControllerRoute();
app.MapRazorPages();

app.Run();
```

For more information, see ASP.NET Core Middleware.

Host

On startup, an ASP.NET Core app builds a *host*. The host encapsulates all of the app's resources, such as:

- An HTTP server implementation
- Middleware components
- Logging
- Dependency injection (DI) services
- Configuration

There are three different hosts capable of running an ASP.NET Core app:

- ASP.NET Core WebApplication, also known as the Minimal Host
- .NET Generic Host combined with ASP.NET Core's ConfigureWebHostDefaults
- ASP.NET Core WebHost

The ASP.NET Core WebApplication and WebApplicationBuilder types are recommended and used in all the ASP.NET Core templates. `WebApplication` behaves similarly to the .NET Generic Host and exposes many of the same interfaces but requires less callbacks to configure. The ASP.NET Core WebHost is available only for backward compatibility.

The following example instantiates a `WebApplication`:

C#

```
var builder = WebApplication.CreateBuilder(args);

// Add services to the container.
builder.Services.AddRazorPages();
builder.Services.AddControllersWithViews();

var app = builder.Build();
```

The WebApplicationBuilder.Build method configures a host with a set of default options, such as:

- Use Kestrel as the web server and enable IIS integration.
- Load configuration from `appsettings.json`, environment variables, command line arguments, and other configuration sources.
- Send logging output to the console and debug providers.

Non-web scenarios

The Generic Host allows other types of apps to use cross-cutting framework extensions, such as logging, dependency injection (DI), configuration, and app lifetime management. For more information, see .NET Generic Host in ASP.NET Core and Background tasks with hosted services in ASP.NET Core.

Servers

An ASP.NET Core app uses an HTTP server implementation to listen for HTTP requests. The server surfaces requests to the app as a set of request features composed into an `HttpContext`.

Windows

ASP.NET Core provides the following server implementations:

- *Kestrel* is a cross-platform web server. Kestrel is often run in a reverse proxy configuration using IIS. In ASP.NET Core 2.0 or later, Kestrel can be run as a public-facing edge server exposed directly to the Internet.
- *IIS HTTP Server* is a server for Windows that uses IIS. With this server, the ASP.NET Core app and IIS run in the same process.
- *HTTP.sys* is a server for Windows that isn't used with IIS.

For more information, see Web server implementations in ASP.NET Core.

Configuration

ASP.NET Core provides a configuration framework that gets settings as name-value pairs from an ordered set of configuration providers. Built-in configuration providers are available for a variety of sources, such as `.json` files, `.xml` files, environment variables, and command-line arguments. Write custom configuration providers to support other sources.

By default, ASP.NET Core apps are configured to read from `appsettings.json`, environment variables, the command line, and more. When the app's configuration is loaded, values from environment variables override values from `appsettings.json`.

For managing confidential configuration data such as passwords, .NET Core provides the Secret Manager. For production secrets, we recommend Azure Key Vault.

For more information, see Configuration in ASP.NET Core.

Environments

Execution environments, such as `Development`, `Staging`, and `Production`, are available in ASP.NET Core. Specify the environment an app is running in by setting the `ASPNETCORE_ENVIRONMENT` environment variable. ASP.NET Core reads that environment variable at app startup and stores the value in an `IWebHostEnvironment` implementation. This implementation is available anywhere in an app via dependency injection (DI).

The following example configures the exception handler and HTTP Strict Transport Security Protocol (HSTS) middleware when ***not*** running in the `Development` environment:

```
C#
```

```
var builder = WebApplication.CreateBuilder(args);

// Add services to the container.
builder.Services.AddRazorPages();
builder.Services.AddControllersWithViews();

var app = builder.Build();

// Configure the HTTP request pipeline.
if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseAuthorization();

app.MapGet("/hi", () => "Hello!");

app.MapDefaultControllerRoute();
app.MapRazorPages();

app.Run();
```

For more information, see Use multiple environments in ASP.NET Core.

Logging

ASP.NET Core supports a logging API that works with a variety of built-in and third-party logging providers. Available providers include:

- Console
- Debug
- Event Tracing on Windows
- Windows Event Log
- TraceSource
- Azure App Service
- Azure Application Insights

To create logs, resolve an ILogger<TCategoryName> service from dependency injection (DI) and call logging methods such as LogInformation. For example:

```
C#
```

```
public class IndexModel : PageModel
{
    private readonly RazorPagesMovieContext _context;
    private readonly ILogger<IndexModel> _logger;

    public IndexModel(RazorPagesMovieContext context, ILogger<IndexModel>
logger)
    {
        _context = context;
        _logger = logger;
    }

    public IList<Movie> Movie { get;set; }

    public async Task OnGetAsync()
    {
        _logger.LogInformation("IndexModel OnGetAsync.");
        Movie = await _context.Movie.ToListAsync();
    }
}
```

For more information, see Logging in .NET Core and ASP.NET Core.

Routing

A *route* is a URL pattern that is mapped to a handler. The handler is typically a Razor page, an action method in an MVC controller, or a middleware. ASP.NET Core routing gives you control over the URLs used by your app.

The following code, generated by the ASP.NET Core web application template, calls UseRouting:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();

var app = builder.Build();

// Configure the HTTP request pipeline.
if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();
```

```
app.UseRouting();

app.UseAuthorization();

app.MapRazorPages();

app.Run();
```

For more information, see Routing in ASP.NET Core.

Error handling

ASP.NET Core has built-in features for handling errors, such as:

- A developer exception page
- Custom error pages
- Static status code pages
- Startup exception handling

For more information, see Handle errors in ASP.NET Core.

Make HTTP requests

An implementation of `IHttpClientFactory` is available for creating `HttpClient` instances. The factory:

- Provides a central location for naming and configuring logical `HttpClient` instances. For example, register and configure a *github* client for accessing GitHub. Register and configure a default client for other purposes.
- Supports registration and chaining of multiple delegating handlers to build an outgoing request middleware pipeline. This pattern is similar to ASP.NET Core's inbound middleware pipeline. The pattern provides a mechanism to manage cross-cutting concerns for HTTP requests, including caching, error handling, serialization, and logging.
- Integrates with *Polly*, a popular third-party library for transient fault handling.
- Manages the pooling and lifetime of underlying `HttpClientHandler` instances to avoid common DNS problems that occur when managing `HttpClient` lifetimes manually.
- Adds a configurable logging experience via ILogger for all requests sent through clients created by the factory.

For more information, see Make HTTP requests using IHttpClientFactory in ASP.NET Core.

Content root

The content root is the base path for:

- The executable hosting the app (*.exe*).
- Compiled assemblies that make up the app (*.dll*).
- Content files used by the app, such as:
  - Razor files (`.cshtml`, `.razor`)
  - Configuration files (`.json`, `.xml`)
  - Data files (`.db`)
- The Web root, typically the *wwwroot* folder.

During development, the content root defaults to the project's root directory. This directory is also the base path for both the app's content files and the Web root. Specify a different content root by setting its path when building the host. For more information, see Content root.

Web root

The web root is the base path for public, static resource files, such as:

- Stylesheets (`.css`)
- JavaScript (`.js`)
- Images (`.png`, `.jpg`)

By default, static files are served only from the web root directory and its sub-directories. The web root path defaults to *{content root}/wwwroot*. Specify a different web root by setting its path when building the host. For more information, see Web root.

Prevent publishing files in *wwwroot* with the <Content> project item in the project file. The following example prevents publishing content in *wwwroot/local* and its sub-directories:

XML

```
<ItemGroup>
  <Content Update="wwwroot\local\**\*.*" CopyToPublishDirectory="Never" />
</ItemGroup>
```

In Razor `.cshtml` files, `~/` points to the web root. A path beginning with `~/` is referred to as a *virtual path*.

For more information, see Static files in ASP.NET Core.

By Rick Anderson

ASP.NET Core apps created with the web templates contain the application startup code in the `Program.cs` file.

For Blazor startup guidance, which adds to or supersedes the guidance in this article, see ASP.NET Core Blazor startup.

The following app startup code supports:

- Razor Pages
- MVC controllers with views
- Web API with controllers
- Minimal APIs

C#

```
var builder = WebApplication.CreateBuilder(args);

// Add services to the container.
builder.Services.AddRazorPages();
builder.Services.AddControllersWithViews();

var app = builder.Build();

// Configure the HTTP request pipeline.
if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();
```

```
app.UseAuthorization();

app.MapGet("/hi", () => "Hello!");

app.MapDefaultControllerRoute();
app.MapRazorPages();

app.Run();
```

Apps using EventSource can measure the startup time to understand and optimize startup performance. The ServerReady event in Microsoft.AspNetCore.Hosting represents the point where the server is ready to respond to requests.

For more information on application startup, see ASP.NET Core fundamentals overview.

Extend Startup with startup filters

Use IStartupFilter:

- To configure middleware at the beginning or end of an app's middleware pipeline without an explicit call to `Use{Middleware}`. Use `IStartupFilter` to add defaults to the beginning of the pipeline without explicitly registering the default middleware. `IStartupFilter` allows a different component to call `Use{Middleware}` on behalf of the app author.
- To create a pipeline of `Configure` methods. IStartupFilter.Configure can set a middleware to run before or after middleware added by libraries.

`IStartupFilter` implements Configure, which receives and returns an `Action<IApplicationBuilder>`. An IApplicationBuilder defines a class to configure an app's request pipeline. For more information, see Create a middleware pipeline with IApplicationBuilder.

Each `IStartupFilter` can add one or more middlewares in the request pipeline. The filters are invoked in the order they were added to the service container. Filters may add middleware before or after passing control to the next filter, thus they append to the beginning or end of the app pipeline.

The following example demonstrates how to register a middleware with `IStartupFilter`. The `RequestSetOptionsMiddleware` middleware sets an options value from a query string parameter:

```
C#
```

```
public class RequestSetOptionsMiddleware
{
    private readonly RequestDelegate _next;

    public RequestSetOptionsMiddleware(RequestDelegate next)
    {
        _next = next;
    }

    // Test with https://localhost:5001/Privacy/?option=Hello
    public async Task Invoke(HttpContext httpContext)
    {
        var option = httpContext.Request.Query["option"];

        if (!string.IsNullOrWhiteSpace(option))
        {
            httpContext.Items["option"] = WebUtility.HtmlEncode(option);
        }

        await _next(httpContext);
    }
}
```

The `RequestSetOptionsMiddleware` is configured in the `RequestSetOptionsStartupFilter` class:

C#

```
namespace WebStartup.Middleware;
// <snippet1>
public class RequestSetOptionsStartupFilter : IStartupFilter
{
    public Action<IApplicationBuilder> Configure(Action<IApplicationBuilder>
next)
    {
        return builder =>
        {
            builder.UseMiddleware<RequestSetOptionsMiddleware>();
            next(builder);
        };
    }
}
// </snippet1>
```

The `IStartupFilter` is registered in `Program.cs`:

C#

```
using WebStartup.Middleware;
```

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();
builder.Services.AddTransient<IStartupFilter,
                        RequestSetOptionsStartupFilter>();

var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseRouting();

app.UseAuthorization();

app.MapRazorPages();

app.Run();
```

When a query string parameter for `option` is provided, the middleware processes the value assignment before the ASP.NET Core middleware renders the response:

CSHTML

```
@page
@model PrivacyModel
@{
    ViewData["Title"] = "Privacy Policy";
}
<h1>@ViewData["Title"]</h1>

<p> Append query string ?option=hello</p>
Option String: @HttpContext.Items["option"];
```

Middleware execution order is set by the order of `IStartupFilter` registrations:

- Multiple `IStartupFilter` implementations may interact with the same objects. If ordering is important, order their `IStartupFilter` service registrations to match the order that their middlewares should run.
- Libraries may add middleware with one or more `IStartupFilter` implementations that run before or after other app middleware registered with `IStartupFilter`. To

invoke an `IStartupFilter` middleware before a middleware added by a library's `IStartupFilter`:

- Position the service registration before the library is added to the service container.
- To invoke afterward, position the service registration after the library is added.

Note: You can't extend the ASP.NET Core app when you override `Configure`. For more informaton, see this GitHub issue.

Add configuration at startup from an external assembly

An IHostingStartup implementation allows adding enhancements to an app at startup from an external assembly outside of the app's `Program.cs` file. For more information, see Use hosting startup assemblies in ASP.NET Core.

Startup, ConfigureServices, and Configure

For information on using the ConfigureServices and Configure methods with the minimal hosting model, see:

- Use Startup with the minimal hosting model

  - The ConfigureServices method
  - The Configure method

Dependency injection in ASP.NET Core

Article • 09/18/2024

> **Important**

>
> For the current release, see the **.NET 8 version of this article**.

By Kirk Larkin, Steve Smith, and Brandon Dahler

ASP.NET Core supports the dependency injection (DI) software design pattern, which is a technique for achieving Inversion of Control (IoC) between classes and their dependencies.

For more information specific to dependency injection within MVC controllers, see Dependency injection into controllers in ASP.NET Core.

For information on using dependency injection in applications other than web apps, see Dependency injection in .NET.

For more information on dependency injection of options, see Options pattern in ASP.NET Core.

This topic provides information on dependency injection in ASP.NET Core. The primary documentation on using dependency injection is contained in Dependency injection in .NET.

For Blazor DI guidance, which adds to or supersedes the guidance in this article, see ASP.NET Core Blazor dependency injection.

View or download sample code (how to download)

Overview of dependency injection

A *dependency* is an object that another object depends on. Examine the following `MyDependency` class with a `WriteMessage` method that other classes depend on:

```
C#
```

```
public class MyDependency
{
    public void WriteMessage(string message)
    {
        Console.WriteLine($"MyDependency.WriteMessage called. Message:
{message}");
    }
}
```

A class can create an instance of the `MyDependency` class to make use of its `WriteMessage` method. In the following example, the `MyDependency` class is a dependency of the `IndexModel` class:

C#

```
public class IndexModel : PageModel
{
    private readonly MyDependency _dependency = new MyDependency();

    public void OnGet()
    {
        _dependency.WriteMessage("IndexModel.OnGet");
    }
}
```

The class creates and directly depends on the `MyDependency` class. Code dependencies, such as in the previous example, are problematic and should be avoided for the following reasons:

- To replace `MyDependency` with a different implementation, the `IndexModel` class must be modified.
- If `MyDependency` has dependencies, they must also be configured by the `IndexModel` class. In a large project with multiple classes depending on `MyDependency`, the configuration code becomes scattered across the app.
- This implementation is difficult to unit test.

Dependency injection addresses these problems through:

- The use of an interface or base class to abstract the dependency implementation.
- Registration of the dependency in a service container. ASP.NET Core provides a built-in service container, IServiceProvider. Services are typically registered in the app's `Program.cs` file.
- *Injection* of the service into the constructor of the class where it's used. The framework takes on the responsibility of creating an instance of the dependency

and disposing of it when it's no longer needed.

In the sample app, the `IMyDependency` interface defines the `WriteMessage` method:

```
C#

public interface IMyDependency
{
    void WriteMessage(string message);
}
```

This interface is implemented by a concrete type, `MyDependency`:

```
C#

public class MyDependency : IMyDependency
{
    public void WriteMessage(string message)
    {
        Console.WriteLine($"MyDependency.WriteMessage Message: {message}");
    }
}
```

The sample app registers the `IMyDependency` service with the concrete type `MyDependency`. The AddScoped method registers the service with a scoped lifetime, the lifetime of a single request. Service lifetimes are described later in this topic.

```
C#

using DependencyInjectionSample.Interfaces;
using DependencyInjectionSample.Services;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();

builder.Services.AddScoped<IMyDependency, MyDependency>();

var app = builder.Build();
```

In the sample app, the `IMyDependency` service is requested and used to call the `WriteMessage` method:

```
C#

public class Index2Model : PageModel
{
```

```
    private readonly IMyDependency _myDependency;

    public Index2Model(IMyDependency myDependency)
    {
        _myDependency = myDependency;
    }

    public void OnGet()
    {
        _myDependency.WriteMessage("Index2Model.OnGet");
    }
}
```

By using the DI pattern, the controller or Razor Page:

- Doesn't use the concrete type `MyDependency`, only the `IMyDependency` interface it implements. That makes it easy to change the implementation without modifying the controller or Razor Page.
- Doesn't create an instance of `MyDependency`, it's created by the DI container.

The implementation of the `IMyDependency` interface can be improved by using the built-in logging API:

C#

```
public class MyDependency2 : IMyDependency
{
    private readonly ILogger<MyDependency2> _logger;

    public MyDependency2(ILogger<MyDependency2> logger)
    {
        _logger = logger;
    }

    public void WriteMessage(string message)
    {
        _logger.LogInformation( $"MyDependency2.WriteMessage Message:
{message}");
    }
}
```

The updated `Program.cs` registers the new `IMyDependency` implementation:

C#

```
using DependencyInjectionSample.Interfaces;
using DependencyInjectionSample.Services;

var builder = WebApplication.CreateBuilder(args);
```

```
builder.Services.AddRazorPages();

builder.Services.AddScoped<IMyDependency, MyDependency2>();

var app = builder.Build();
```

`MyDependency2` depends on ILogger<TCategoryName>, which it requests in the constructor. `ILogger<TCategoryName>` is a framework-provided service.

It's not unusual to use dependency injection in a chained fashion. Each requested dependency in turn requests its own dependencies. The container resolves the dependencies in the graph and returns the fully resolved service. The collective set of dependencies that must be resolved is typically referred to as a *dependency tree*, *dependency graph*, or *object graph*.

The container resolves `ILogger<TCategoryName>` by taking advantage of (generic) open types, eliminating the need to register every (generic) constructed type.

In dependency injection terminology, a service:

- Is typically an object that provides a service to other objects, such as the `IMyDependency` service.
- Is not related to a web service, although the service may use a web service.

The framework provides a robust logging system. The `IMyDependency` implementations shown in the preceding examples were written to demonstrate basic DI, not to implement logging. Most apps shouldn't need to write loggers. The following code demonstrates using the default logging, which doesn't require any services to be registered:

C#

```
public class AboutModel : PageModel
{
    private readonly ILogger _logger;

    public AboutModel(ILogger<AboutModel> logger)
    {
        _logger = logger;
    }

    public string Message { get; set; } = string.Empty;

    public void OnGet()
    {
        Message = $"About page visited at
{DateTime.UtcNow.ToLongTimeString()}";
```

```
        _logger.LogInformation(Message);
    }
}
```

Using the preceding code, there is no need to update `Program.cs`, because logging is provided by the framework.

Register groups of services with extension methods

The ASP.NET Core framework uses a convention for registering a group of related services. The convention is to use a single `Add{GROUP_NAME}` extension method to register all of the services required by a framework feature. For example, the AddControllers extension method registers the services required for MVC controllers.

The following code is generated by the Razor Pages template using individual user accounts and shows how to add additional services to the container using the extension methods AddDbContext and AddDefaultIdentity:

C#

```
using DependencyInjectionSample.Data;
using Microsoft.AspNetCore.Identity;
using Microsoft.EntityFrameworkCore;

var builder = WebApplication.CreateBuilder(args);

var connectionString =
builder.Configuration.GetConnectionString("DefaultConnection");
builder.Services.AddDbContext<ApplicationDbContext>(options =>
    options.UseSqlServer(connectionString));
builder.Services.AddDatabaseDeveloperPageExceptionFilter();

builder.Services.AddDefaultIdentity<IdentityUser>(options =>
options.SignIn.RequireConfirmedAccount = true)
    .AddEntityFrameworkStores<ApplicationDbContext>();
builder.Services.AddRazorPages();

var app = builder.Build();
```

Consider the following which registers services and configures options:

C#

```
using ConfigSample.Options;
using Microsoft.Extensions.DependencyInjection.ConfigSample.Options;
```

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();

builder.Services.Configure<PositionOptions>(
    builder.Configuration.GetSection(PositionOptions.Position));
builder.Services.Configure<ColorOptions>(
    builder.Configuration.GetSection(ColorOptions.Color));

builder.Services.AddScoped<IMyDependency, MyDependency>();
builder.Services.AddScoped<IMyDependency2, MyDependency2>();

var app = builder.Build();
```

Related groups of registrations can be moved to an extension method to register services. For example, the configuration services are added to the following class:

C#

```
using ConfigSample.Options;
using Microsoft.Extensions.Configuration;

namespace Microsoft.Extensions.DependencyInjection
{
    public static class MyConfigServiceCollectionExtensions
    {
        public static IServiceCollection AddConfig(
             this IServiceCollection services, IConfiguration config)
        {
            services.Configure<PositionOptions>(
                config.GetSection(PositionOptions.Position));
            services.Configure<ColorOptions>(
                config.GetSection(ColorOptions.Color));

            return services;
        }

        public static IServiceCollection AddMyDependencyGroup(
             this IServiceCollection services)
        {
            services.AddScoped<IMyDependency, MyDependency>();
            services.AddScoped<IMyDependency2, MyDependency2>();

            return services;
        }
    }
}
```

The remaining services are registered in a similar class. The following code uses the new extension methods to register the services:

```
C#
```

```
using Microsoft.Extensions.DependencyInjection.ConfigSample.Options;

var builder = WebApplication.CreateBuilder(args);

builder.Services
    .AddConfig(builder.Configuration)
    .AddMyDependencyGroup();

builder.Services.AddRazorPages();

var app = builder.Build();
```

Note: Each `services.Add{GROUP_NAME}` extension method adds and potentially configures services. For example, AddControllersWithViews adds the services MVC controllers with views require, and AddRazorPages adds the services Razor Pages requires.

Service lifetimes

See Service lifetimes in Dependency injection in .NET

To use scoped services in middleware, use one of the following approaches:

- Inject the service into the middleware's `Invoke` or `InvokeAsync` method. Using constructor injection throws a runtime exception because it forces the scoped service to behave like a singleton. The sample in the Lifetime and registration options section demonstrates the `InvokeAsync` approach.
- Use Factory-based middleware. Middleware registered using this approach is activated per client request (connection), which allows scoped services to be injected into the middleware's constructor.

For more information, see Write custom ASP.NET Core middleware.

Service registration methods

See Service registration methods in Dependency injection in .NET

It's common to use multiple implementations when mocking types for testing.

Registering a service with only an implementation type is equivalent to registering that service with the same implementation and service type. This is why multiple implementations of a service cannot be registered using the methods that don't take an explicit service type. These methods can register multiple *instances* of a service, but they will all have the same *implementation* type.

Any of the above service registration methods can be used to register multiple service instances of the same service type. In the following example, `AddSingleton` is called twice with `IMyDependency` as the service type. The second call to `AddSingleton` overrides the previous one when resolved as `IMyDependency` and adds to the previous one when multiple services are resolved via `IEnumerable<IMyDependency>`. Services appear in the order they were registered when resolved via `IEnumerable<{SERVICE}>`.

C#

```
services.AddSingleton<IMyDependency, MyDependency>();
services.AddSingleton<IMyDependency, DifferentDependency>();

public class MyService
{
    public MyService(IMyDependency myDependency,
       IEnumerable<IMyDependency> myDependencies)
    {
        Trace.Assert(myDependency is DifferentDependency);

        var dependencyArray = myDependencies.ToArray();
        Trace.Assert(dependencyArray[0] is MyDependency);
        Trace.Assert(dependencyArray[1] is DifferentDependency);
    }
}
```

Keyed services

Keyed services refers to a mechanism for registering and retrieving Dependency Injection (DI) services using keys. A service is associated with a key by calling AddKeyedSingleton (or `AddKeyedScoped` or `AddKeyedTransient`) to register it. Access a registered service by specifying the key with the [FromKeyedServices] attribute. The following code shows how to use keyed services:

C#

```
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.SignalR;

var builder = WebApplication.CreateBuilder(args);
```

```
builder.Services.AddKeyedSingleton<ICache, BigCache>("big");
builder.Services.AddKeyedSingleton<ICache, SmallCache>("small");
builder.Services.AddControllers();

var app = builder.Build();

app.MapGet("/big", ([FromKeyedServices("big")] ICache bigCache) =>
bigCache.Get("date"));
app.MapGet("/small", ([FromKeyedServices("small")] ICache smallCache) =>

smallCache.Get("date"));

app.MapControllers();

app.Run();

public interface ICache
{
    object Get(string key);
}
public class BigCache : ICache
{
    public object Get(string key) => $"Resolving {key} from big cache.";
}

public class SmallCache : ICache
{
    public object Get(string key) => $"Resolving {key} from small cache.";
}

[ApiController]
[Route("/cache")]
public class CustomServicesApiController : Controller
{
    [HttpGet("big-cache")]
    public ActionResult<object> GetOk([FromKeyedServices("big")] ICache
cache)
    {
        return cache.Get("data-mvc");
    }
}

public class MyHub : Hub
{
    public void Method([FromKeyedServices("small")] ICache cache)
    {
        Console.WriteLine(cache.Get("signalr"));
    }
}
```

Keyed services in Middleware

Middleware supports Keyed services in both the constructor and the `Invoke`/`InvokeAsync` method:

C#

```
var builder = WebApplication.CreateBuilder(args);
builder.Services.AddKeyedSingleton<MySingletonClass>("test");
builder.Services.AddKeyedScoped<MyScopedClass>("test2");

var app = builder.Build();
app.UseMiddleware<MyMiddleware>();
app.Run();

internal class MyMiddleware
{
    private readonly RequestDelegate _next;

    public MyMiddleware(RequestDelegate next,
        [FromKeyedServices("test")] MySingletonClass service)
    {
        _next = next;
    }

    public Task Invoke(HttpContext context,
        [FromKeyedServices("test2")]
            MyScopedClass scopedService) => _next(context);
}
```

For more information on creating Middleware, see Write custom ASP.NET Core middleware

Constructor injection behavior

See Constructor injection behavior in Dependency injection in .NET

Entity Framework contexts

By default, Entity Framework contexts are added to the service container using the scoped lifetime because web app database operations are normally scoped to the client request. To use a different lifetime, specify the lifetime by using an AddDbContext overload. Services of a given lifetime shouldn't use a database context with a lifetime that's shorter than the service's lifetime.

Lifetime and registration options

To demonstrate the difference between service lifetimes and their registration options, consider the following interfaces that represent a task as an operation with an identifier, `OperationId`. Depending on how the lifetime of an operation's service is configured for the following interfaces, the container provides either the same or different instances of the service when requested by a class:

C#

```
public interface IOperation
{
    string OperationId { get; }
}

public interface IOperationTransient : IOperation { }
public interface IOperationScoped : IOperation { }
public interface IOperationSingleton : IOperation { }
```

The following `Operation` class implements all of the preceding interfaces. The `Operation` constructor generates a GUID and stores the last 4 characters in the `OperationId` property:

C#

```
public class Operation : IOperationTransient, IOperationScoped,
IOperationSingleton
{
    public Operation()
    {
        OperationId = Guid.NewGuid().ToString()[^4..];
    }

    public string OperationId { get; }
}
```

The following code creates multiple registrations of the `Operation` class according to the named lifetimes:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();

builder.Services.AddTransient<IOperationTransient, Operation>();
builder.Services.AddScoped<IOperationScoped, Operation>();
builder.Services.AddSingleton<IOperationSingleton, Operation>();

var app = builder.Build();
```

```
if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseMyMiddleware();
app.UseRouting();

app.UseAuthorization();

app.MapRazorPages();

app.Run();
```

The sample app demonstrates object lifetimes both within and between requests. The `IndexModel` and the middleware request each kind of `IOperation` type and log the `OperationId` for each:

C#

```
public class IndexModel : PageModel
{
    private readonly ILogger _logger;
    private readonly IOperationTransient _transientOperation;
    private readonly IOperationSingleton _singletonOperation;
    private readonly IOperationScoped _scopedOperation;

    public IndexModel(ILogger<IndexModel> logger,
                      IOperationTransient transientOperation,
                      IOperationScoped scopedOperation,
                      IOperationSingleton singletonOperation)
    {
        _logger = logger;
        _transientOperation = transientOperation;
        _scopedOperation    = scopedOperation;
        _singletonOperation = singletonOperation;
    }

    public void  OnGet()
    {
        _logger.LogInformation("Transient: " +
_transientOperation.OperationId);
        _logger.LogInformation("Scoped: "    +
_scopedOperation.OperationId);
        _logger.LogInformation("Singleton: " +
_singletonOperation.OperationId);
```

```
    }
}
```

Similar to the `IndexModel`, the middleware resolves the same services:

C#

```
public class MyMiddleware
{
    private readonly RequestDelegate _next;
    private readonly ILogger _logger;

    private readonly IOperationSingleton _singletonOperation;

    public MyMiddleware(RequestDelegate next, ILogger<MyMiddleware> logger,
        IOperationSingleton singletonOperation)
    {
        _logger = logger;
        _singletonOperation = singletonOperation;
        _next = next;
    }

    public async Task InvokeAsync(HttpContext context,
        IOperationTransient transientOperation, IOperationScoped
scopedOperation)
    {
        _logger.LogInformation("Transient: " +
transientOperation.OperationId);
        _logger.LogInformation("Scoped: " + scopedOperation.OperationId);
        _logger.LogInformation("Singleton: " +
_singletonOperation.OperationId);

        await _next(context);
    }
}

public static class MyMiddlewareExtensions
{
    public static IApplicationBuilder UseMyMiddleware(this
IApplicationBuilder builder)
    {
        return builder.UseMiddleware<MyMiddleware>();
    }
}
```

Scoped and transient services must be resolved in the `InvokeAsync` method:

C#

```
public async Task InvokeAsync(HttpContext context,
    IOperationTransient transientOperation, IOperationScoped
scopedOperation)
{
    _logger.LogInformation("Transient: " + transientOperation.OperationId);
    _logger.LogInformation("Scoped: " + scopedOperation.OperationId);
    _logger.LogInformation("Singleton: " + _singletonOperation.OperationId);

    await _next(context);
}
```

The logger output shows:

- *Transient* objects are always different. The transient `OperationId` value is different in the `IndexModel` and in the middleware.
- *Scoped* objects are the same for a given request but differ across each new request.
- *Singleton* objects are the same for every request.

To reduce the logging output, set "Logging:LogLevel:Microsoft:Error" in the `appsettings.Development.json` file:

JSON

```
{
  "MyKey": "MyKey from appsettings.Developement.json",
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "System": "Debug",
      "Microsoft": "Error"
    }
  }
}
```

Resolve a service at app start up

The following code shows how to resolve a scoped service for a limited duration when the app starts:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddScoped<IMyDependency, MyDependency>();

var app = builder.Build();
```

```
using (var serviceScope = app.Services.CreateScope())
{
    var services = serviceScope.ServiceProvider;

    var myDependency = services.GetRequiredService<IMyDependency>();
    myDependency.WriteMessage("Call services from main");
}

app.MapGet("/", () => "Hello World!");

app.Run();
```

Scope validation

See Constructor injection behavior in Dependency injection in .NET

For more information, see Scope validation.

Request Services

Services and their dependencies within an ASP.NET Core request are exposed through HttpContext.RequestServices.

The framework creates a scope per request, and `RequestServices` exposes the scoped service provider. All scoped services are valid for as long as the request is active.

> **Note**
>
> Prefer requesting dependencies as constructor parameters over resolving services from `RequestServices`. Requesting dependencies as constructor parameters yields classes that are easier to test.

Design services for dependency injection

When designing services for dependency injection:

- Avoid stateful, static classes and members. Avoid creating global state by designing apps to use singleton services instead.
- Avoid direct instantiation of dependent classes within services. Direct instantiation couples the code to a particular implementation.
- Make services small, well-factored, and easily tested.

If a class has a lot of injected dependencies, it might be a sign that the class has too many responsibilities and violates the Single Responsibility Principle (SRP). Attempt to refactor the class by moving some of its responsibilities into new classes. Keep in mind that Razor Pages page model classes and MVC controller classes should focus on UI concerns.

Disposal of services

The container calls Dispose for the IDisposable types it creates. Services resolved from the container should never be disposed by the developer. If a type or factory is registered as a singleton, the container disposes the singleton automatically.

In the following example, the services are created by the service container and disposed automatically: dependency-injection\samples\6.x\DIsample2\DIsample2\Services\Service1.cs

C#

```
public class Service1 : IDisposable
{
    private bool _disposed;

    public void Write(string message)
    {
        Console.WriteLine($"Service1: {message}");
    }

    public void Dispose()
    {
        if (_disposed)
            return;

        Console.WriteLine("Service1.Dispose");
        _disposed = true;
    }
}

public class Service2 : IDisposable
{
    private bool _disposed;

    public void Write(string message)
    {
        Console.WriteLine($"Service2: {message}");
    }

    public void Dispose()
    {
        if (_disposed)
            return;
```

```
        Console.WriteLine("Service2.Dispose");
        _disposed = true;
    }
}

public interface IService3
{
    public void Write(string message);
}

public class Service3 : IService3, IDisposable
{
    private bool _disposed;

    public Service3(string myKey)
    {
        MyKey = myKey;
    }

    public string MyKey { get; }

    public void Write(string message)
    {
        Console.WriteLine($"Service3: {message}, MyKey = {MyKey}");
    }

    public void Dispose()
    {
        if (_disposed)
            return;

        Console.WriteLine("Service3.Dispose");
        _disposed = true;
    }
}
```

C#

```
using DIsample2.Services;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();

builder.Services.AddScoped<Service1>();
builder.Services.AddSingleton<Service2>();

var myKey = builder.Configuration["MyKey"];
builder.Services.AddSingleton<IService3>(sp => new Service3(myKey));

var app = builder.Build();
```

C#

```
public class IndexModel : PageModel
{
    private readonly Service1 _service1;
    private readonly Service2 _service2;
    private readonly IService3 _service3;

    public IndexModel(Service1 service1, Service2 service2, IService3
service3)
    {
        _service1 = service1;
        _service2 = service2;
        _service3 = service3;
    }

    public void OnGet()
    {
        _service1.Write("IndexModel.OnGet");
        _service2.Write("IndexModel.OnGet");
        _service3.Write("IndexModel.OnGet");
    }
}
```

The debug console shows the following output after each refresh of the Index page:

Console

```
Service1: IndexModel.OnGet
Service2: IndexModel.OnGet
Service3: IndexModel.OnGet, MyKey = MyKey from appsettings.Developement.json
Service1.Dispose
```

Services not created by the service container

Consider the following code:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();

builder.Services.AddSingleton(new Service1());
builder.Services.AddSingleton(new Service2());
```

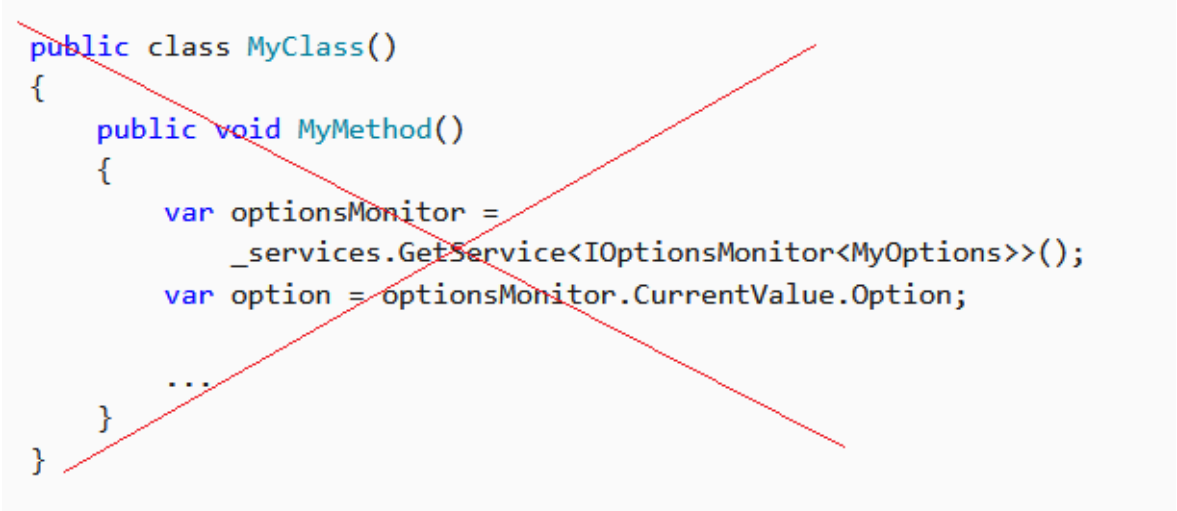
In the preceding code:

- The service instances aren't created by the service container.
- The framework doesn't dispose of the services automatically.
- The developer is responsible for disposing the services.

IDisposable guidance for Transient and shared instances

See IDisposable guidance for Transient and shared instance in Dependency injection in .NET

Default service container replacement



See Default service container replacement in Dependency injection in .NET

Recommendations

See Recommendations in Dependency injection in .NET

- Avoid using the *service locator pattern*. For example, don't invoke GetService to obtain a service instance when you can use DI instead:

  Incorrect:

  Correct:

```C#
public class MyClass
{
    private readonly IOptionsMonitor<MyOptions> _optionsMonitor;

    public MyClass(IOptionsMonitor<MyOptions> optionsMonitor)
    {
```

```
            _optionsMonitor = optionsMonitor;
        }

        public void MyMethod()
        {
            var option = _optionsMonitor.CurrentValue.Option;

            ...
        }
    }
```

- Another service locator variation to avoid is injecting a factory that resolves dependencies at runtime. Both of these practices mix Inversion of Control strategies.
- Avoid static access to `HttpContext` (for example, IHttpContextAccessor.HttpContext).

DI is an *alternative* to static/global object access patterns. You may not be able to realize the benefits of DI if you mix it with static object access.

Recommended patterns for multi-tenancy in DI

Orchard Core is an application framework for building modular, multi-tenant applications on ASP.NET Core. For more information, see the Orchard Core Documentation.

See the Orchard Core samples for examples of how to build modular and multi-tenant apps using just the Orchard Core Framework without any of its CMS-specific features.

Framework-provided services

`Program.cs` registers services that the app uses, including platform features, such as Entity Framework Core and ASP.NET Core MVC. Initially, the `IServiceCollection` provided to `Program.cs` has services defined by the framework depending on how the host was configured. For apps based on the ASP.NET Core templates, the framework registers more than 250 services.

The following table lists a small sample of these framework-registered services:

Expand table

Service Type	Lifetime
Microsoft.AspNetCore.Hosting.Builder.IApplicationBuilderFactory	Transient
IHostApplicationLifetime	Singleton
IWebHostEnvironment	Singleton
Microsoft.AspNetCore.Hosting.IStartup	Singleton
Microsoft.AspNetCore.Hosting.IStartupFilter	Transient
Microsoft.AspNetCore.Hosting.Server.IServer	Singleton
Microsoft.AspNetCore.Http.IHttpContextFactory	Transient
Microsoft.Extensions.Logging.ILogger<TCategoryName>	Singleton
Microsoft.Extensions.Logging.ILoggerFactory	Singleton
Microsoft.Extensions.ObjectPool.ObjectPoolProvider	Singleton
Microsoft.Extensions.Options.IConfigureOptions<TOptions>	Transient
Microsoft.Extensions.Options.IOptions<TOptions>	Singleton
System.Diagnostics.DiagnosticSource	Singleton
System.Diagnostics.DiagnosticListener	Singleton

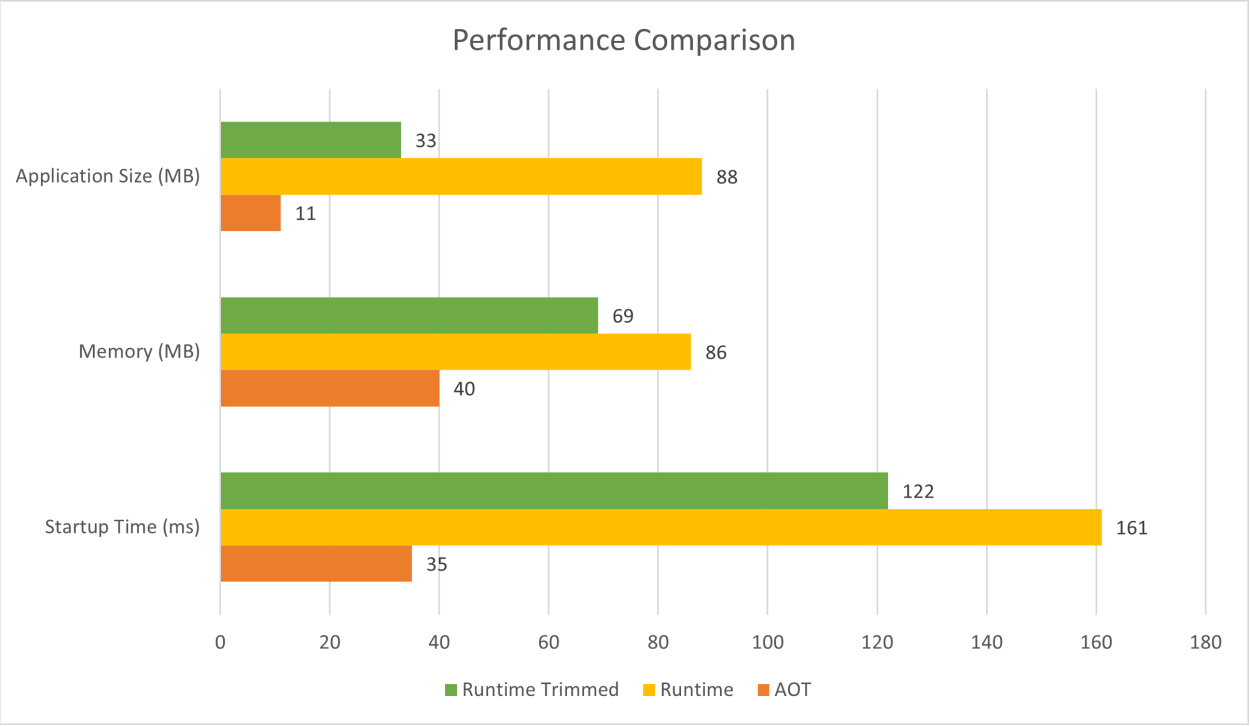
ASP.NET Core support for Native AOT

Article • 09/18/2024

By Mitch Denny

ASP.NET Core 8.0 introduces support for .NET native ahead-of-time (AOT).



For Blazor WebAssembly Native AOT guidance, which adds to or supersedes the guidance in this article, see ASP.NET Core Blazor WebAssembly build tools and ahead-of-time (AOT) compilation.

Why use Native AOT with ASP.NET Core

Publishing and deploying a Native AOT app provides the following benefits:

- **Minimized disk footprint**: When publishing using Native AOT, a single executable is produced containing just the code from external dependencies that is needed to support the program. Reduced executable size can lead to:
  - Smaller container images, for example in containerized deployment scenarios.
  - Reduced deployment time from smaller images.
- **Reduced startup time**: Native AOT applications can show reduced start-up times, which means
  - The app is ready to service requests quicker.
  - Improved deployment where container orchestrators need to manage transition from one version of the app to another.
- **Reduced memory demand**: Native AOT apps can have reduced memory demands, depending on the work done by the app. Reduced memory consumption can lead to greater deployment density and improved scalability.

The template app was run in our benchmarking lab to compare performance of an AOT published app, a trimmed runtime app, and an untrimmed runtime app. The following chart shows the results of the benchmarking:

The preceding chart shows that Native AOT has lower app size, memory usage, and startup time.

ASP.NET Core and Native AOT compatibility

Not all features in ASP.NET Core are currently compatible with Native AOT. The following table summarizes ASP.NET Core feature compatibility with Native AOT:

Expand table

Feature	Fully Supported	Partially Supported	Not Supported
gRPC	✔		
Minimal APIs		✔	
MVC			✘
Blazor Server			✘
SignalR		✔	
JWT Authentication	✔		
Other Authentication			✘
CORS	✔		
HealthChecks	✔		

Feature	Fully Supported	Partially Supported	Not Supported
HttpLogging	✔		
Localization	✔		
OutputCaching	✔		
RateLimiting	✔		
RequestDecompression	✔		
ResponseCaching	✔		
ResponseCompression	✔		
Rewrite	✔		
Session			✘
Spa			✘
StaticFiles	✔		
WebSockets	✔		

For more information on limitations, see:

- Limitations of Native AOT deployment
- Introduction to AOT warnings
- Known trimming incompatibilities
- Introduction to trim warnings
- GitHub issue dotnet/core #8288

It's important to test an app thoroughly when moving to a Native AOT deployment model. The AOT deployed app should be tested to verify functionality hasn't changed from the untrimmed and JIT-compiled app. When building the app, review and correct AOT warnings. An app that issues AOT warnings during publishing may not work correctly. If no AOT warnings are issued at publish time, the published AOT app should work the same as the untrimmed and JIT-compiled app.

Native AOT publishing

Native AOT is enabled with the `PublishAot` MSBuild property. The following example shows how to enable Native AOT in a project file:

```
XML
```

```
<PropertyGroup>
  <PublishAot>true</PublishAot>
</PropertyGroup>
```

This setting enables Native AOT compilation during publish and enables dynamic code usage analysis during build and editing. A project that uses Native AOT publishing uses JIT compilation when running locally. An AOT app has the following differences from a JIT-compiled app:

- Features that aren't compatible with Native AOT are disabled and throw exceptions at run time.
- A source analyzer is enabled to highlight code that isn't compatible with Native AOT. At publish time, the entire app, including NuGet packages, are analyzed for compatibility again.

Native AOT analysis includes all of the app's code and the libraries the app depends on. Review Native AOT warnings and take corrective steps. It's a good idea to publish apps frequently to discover issues early in the development lifecycle.

In .NET 8, Native AOT is supported by the following ASP.NET Core app types:

- minimal APIs - For more information, see the The Web API (Native AOT) template section later in this article.
- gRPC - For more information, see gRPC and Native AOT.
- Worker services - For more information, see AOT in Worker Service templates.

The Web API (Native AOT) template

The **ASP.NET Core Web API (Native AOT)** template (short name `webapiaot`) creates a project with AOT enabled. The template differs from the **Web API** project template in the following ways:

- Uses minimal APIs only, as MVC isn't yet compatible with Native AOT.
- Uses the CreateSlimBuilder() API to ensure only the essential features are enabled by default, minimizing the app's deployed size.
- Is configured to listen on HTTP only, as HTTPS traffic is commonly handled by an ingress service in cloud-native deployments.
- Doesn't include a launch profile for running under IIS or IIS Express.
- Creates an .http file configured with sample HTTP requests that can be sent to the app's endpoints.
- Includes a sample `Todo` API instead of the weather forecast sample.
- Adds `PublishAot` to the project file, as shown earlier in this article.

- Enables the JSON serializer source generators. The source generator is used to generate serialization code at build time, which is required for Native AOT compilation.

Changes to support source generation

The following example shows the code added to the `Program.cs` file to support JSON serialization source generation:

diff

```
using MyFirstAotWebApi;
+using System.Text.Json.Serialization;

-var builder = WebApplication.CreateBuilder();
+var builder = WebApplication.CreateSlimBuilder(args);

+builder.Services.ConfigureHttpJsonOptions(options =>
+{
+  options.SerializerOptions.TypeInfoResolverChain.Insert(0,
AppJsonSerializerContext.Default);
+});

var app = builder.Build();

var sampleTodos = TodoGenerator.GenerateTodos().ToArray();

var todosApi = app.MapGroup("/todos");
todosApi.MapGet("/", () => sampleTodos);
todosApi.MapGet("/{id}", (int id) =>
    sampleTodos.FirstOrDefault(a => a.Id == id) is { } todo
        ? Results.Ok(todo)
        : Results.NotFound());

app.Run();

+[JsonSerializable(typeof(Todo[]))]
+internal partial class AppJsonSerializerContext : JsonSerializerContext
+{
+
+}
```

Without this added code, `System.Text.Json` uses reflection to serialize and deserialize JSON. Reflection isn't supported in Native AOT.

For more information, see:

- Combine source generators
- TypeInfoResolverChain

Changes to `launchSettings.json`

The `launchSettings.json` file created by the **Web API (Native AOT)** template has the `iisSettings` section and `IIS Express` profile removed:

diff

```
{
  "$schema": "http://json.schemastore.org/launchsettings.json",
-  "iisSettings": {
-    "windowsAuthentication": false,
-    "anonymousAuthentication": true,
-    "iisExpress": {
-      "applicationUrl": "http://localhost:11152",
-      "sslPort": 0
-    }
-  },
  "profiles": {
    "http": {
      "commandName": "Project",
      "dotnetRunMessages": true,
      "launchBrowser": true,
      "launchUrl": "todos",
      "applicationUrl": "http://localhost:5102",
        "environmentVariables": {
          "ASPNETCORE_ENVIRONMENT": "Development"
        }
      },
-     "IIS Express": {
-       "commandName": "IISExpress",
-       "launchBrowser": true,
-       "launchUrl": "todos",
-      "environmentVariables": {
-       "ASPNETCORE_ENVIRONMENT": "Development"
-      }
-    }
  }
}
```

The `CreateSlimBuilder` method

The template uses the CreateSlimBuilder() method instead of the CreateBuilder() method.

C#

```
using System.Text.Json.Serialization;
using MyFirstAotWebApi;

var builder = WebApplication.CreateSlimBuilder(args);
```

```
builder.Logging.AddConsole();

builder.Services.ConfigureHttpJsonOptions(options =>
{
    options.SerializerOptions.TypeInfoResolverChain.Insert(0,
AppJsonSerializerContext.Default);
});

var app = builder.Build();

var sampleTodos = TodoGenerator.GenerateTodos().ToArray();

var todosApi = app.MapGroup("/todos");
todosApi.MapGet("/", () => sampleTodos);
todosApi.MapGet("/{id}", (int id) =>
    sampleTodos.FirstOrDefault(a => a.Id == id) is { } todo
        ? Results.Ok(todo)
        : Results.NotFound());

app.Run();

[JsonSerializable(typeof(Todo[]))]
internal partial class AppJsonSerializerContext : JsonSerializerContext
{

}
```

The `CreateSlimBuilder` method initializes the WebApplicationBuilder with the minimum ASP.NET Core features necessary to run an app.

As noted earlier, the `CreateSlimBuilder` method doesn't include support for HTTPS or HTTP/3. These protocols typically aren't required for apps that run behind a TLS termination proxy. For example, see TLS termination and end to end TLS with Application Gateway. HTTPS can be enabled by calling builder.WebHost.UseKestrelHttpsConfiguration HTTP/3 can be enabled by calling builder.WebHost.UseQuic.

`CreateSlimBuilder` vs `CreateBuilder`

The `CreateSlimBuilder` method doesn't support the following features that are supported by the `CreateBuilder` method:

- Hosting startup assemblies
- UseStartup
- The following logging providers:
  - Windows EventLog
  - Debug

    - Event Source
- Web hosting features:
    - UseStaticWebAssets
    - IIS Integration
- Kestrel configuration
    - HTTPS endpoints in Kestrel
    - Quic (HTTP/3)
- Regex and alpha constraints used in routing

The `CreateSlimBuilder` method includes the following features needed for an efficient development experience:

- JSON file configuration for `appsettings.json` and `appsettings.{EnvironmentName}.json`.
- User secrets configuration.
- Console logging.
- Logging configuration.

For a builder that omits the preceding features, see The CreateEmptyBuilder method.

Including minimal features has benefits for trimming as well as AOT. For more information, see Trim self-contained deployments and executables.

For more detailed information, see Comparing WebApplication.CreateBuilder to CreateSlimBuilder

Source generators

Because unused code is trimmed during publishing for Native AOT, the app can't use unbounded reflection at runtime. Source generators are used to produce code that avoids the need for reflection. In some cases, source generators produce code optimized for AOT even when a generator isn't required.

To view the source code that is generated, add the EmitCompilerGeneratedFiles property to an app's `.csproj` file, as shown in the following example:

XML

```xml
<Project Sdk="Microsoft.NET.Sdk.Web">

  <PropertyGroup>
    <!-- Other properties omitted for brevity -->
    <EmitCompilerGeneratedFiles>true</EmitCompilerGeneratedFiles>
  </PropertyGroup>
```

```
</Project>
```

Run the `dotnet build` command to see the generated code. The output includes an `obj/Debug/net8.0/generated/` directory that contains all the generated files for the project.

The `dotnet publish` command also compiles the source files and generates files that are compiled. In addition, `dotnet publish` passes the generated assemblies to a native IL compiler. The IL compiler produces the native executable. The native executable contains the native machine code.

Libraries and Native AOT

Many of the popular libraries used in ASP.NET Core projects currently have some compatibility issues when used in a project targeting Native AOT, such as:

- Use of reflection to inspect and discover types.
- Conditionally loading libraries at runtime.
- Generating code on the fly to implement functionality.

Libraries using these dynamic features need to be updated in order to work with Native AOT. They can be updated using tools like Roslyn source generators.

Library authors hoping to support Native AOT are encouraged to:

- Read about Native AOT compatibility requirements.
- Prepare the library for trimming.

Minimal APIs and JSON payloads

The Minimal API framework is optimized for receiving and returning JSON payloads using System.Text.Json. `System.Text.Json`:

- Imposes compatibility requirements for JSON and Native AOT.
- Requires the use of the System.Text.Json source generator.

All types that are transmitted as part of the HTTP body or returned from request delegates in Minimal APIs apps must be configured on a JsonSerializerContext that is registered via ASP.NET Core's dependency injection:

```
C#
```

```
using System.Text.Json.Serialization;
using MyFirstAotWebApi;

var builder = WebApplication.CreateSlimBuilder(args);
builder.Logging.AddConsole();

builder.Services.ConfigureHttpJsonOptions(options =>
{
    options.SerializerOptions.TypeInfoResolverChain.Insert(0,
AppJsonSerializerContext.Default);
});

var app = builder.Build();

var sampleTodos = TodoGenerator.GenerateTodos().ToArray();

var todosApi = app.MapGroup("/todos");
todosApi.MapGet("/", () => sampleTodos);
todosApi.MapGet("/{id}", (int id) =>
    sampleTodos.FirstOrDefault(a => a.Id == id) is { } todo
        ? Results.Ok(todo)
        : Results.NotFound());

app.Run();

[JsonSerializable(typeof(Todo[]))]
internal partial class AppJsonSerializerContext : JsonSerializerContext
{

}
```

In the preceding highlighted code:

- The JSON serializer context is registered with the DI container. For more information, see:
  - Combine source generators
  - TypeInfoResolverChain
- The custom `JsonSerializerContext` is annotated with the [JsonSerializable] attribute to enable source generated JSON serializer code for the `ToDo` type.

A parameter on the delegate that isn't bound to the body and does ***not*** need to be serializable. For example, a query string parameter that is a rich object type and implements `IParsable<T>`.

C#

```
public class Todo
{
    public int Id { get; set; }
```

```
    public string? Title { get; set; }
    public DateOnly? DueBy { get; set; }
    public bool IsComplete { get; set; }
}

static class TodoGenerator
{
    private static readonly (string[] Prefixes, string[] Suffixes)[] _parts
= new[]
        {
            (new[] { "Walk the", "Feed the" }, new[] { "dog", "cat", "goat"
}),
            (new[] { "Do the", "Put away the" }, new[] { "groceries",
"dishes", "laundry" }),
            (new[] { "Clean the" }, new[] { "bathroom", "pool", "blinds",
"car" })
        };
    // Remaining code omitted for brevity.
```

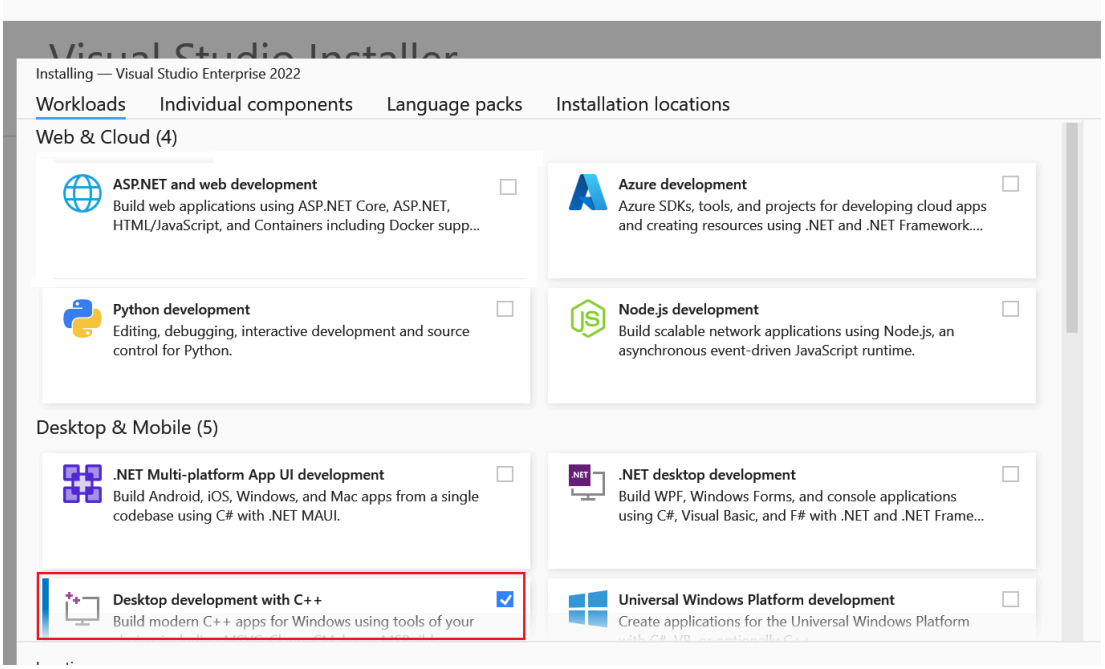
Tutorial: Publish an ASP.NET Core app using Native AOT

Article • 07/26/2024



ASP.NET Core 8.0 introduces support for .NET native ahead-of-time (AOT).

> **Note**
>
> - The Native AOT feature is currently in preview.
> - In .NET 8, not all ASP.NET Core features are compatible with Native AOT.
> - Tabs are provided for the .NET CLI and Visual Studio instructions:
>   - Visual Studio is a prerequisite even if the CLI tab is selected.
>   - The CLI must be used to publish even if the Visual Studio tab is selected.

Prerequisites

.NET CLI

- .NET 8.0 SDK
- On Linux, see Prerequisites for Native AOT deployment.
- Visual Studio 2022 Preview with the **Desktop development with C++** workload installed.

> **Note**
>
> Visual Studio 2022 Preview is required because Native AOT requires link.exe and the Visual C++ static runtime libraries. There are no plans to support Native AOT ***without*** Visual Studio.

Create a web app with Native AOT

Create an ASP.NET Core API app that is configured to work with Native AOT:

.NET CLI

Run the following commands:

.NET CLI

```
dotnet new webapiaot -o MyFirstAotWebApi && cd MyFirstAotWebApi
```

Output similar to the following example is displayed:

Output

```
The template "ASP.NET Core Web API (Native AOT)" was created
successfully.

Publish the Native AOT app

Verify the app can be published using Native AOT:

.NET CLI

.NET CLI

```
dotnet publish
```

The `dotnet publish` command:

- Compiles the source files.
- Generates source code files that are compiled.
- Passes generated assemblies to a native IL compiler. The IL compiler produces the native executable. The native executable contains the native machine code.

Output similar to the following example is displayed:

Output

```
MSBuild version 17.<version> for .NET
  Determining projects to restore...
  Restored C:\Code\Demos\MyFirstAotWebApi\MyFirstAotWebApi.csproj (in 241
ms).
C:\Code\dotnet\aspnetcore\.dotnet\sdk\8.0.
<version>\Sdks\Microsoft.NET.Sdk\targets\Microsoft.NET.RuntimeIde
ntifierInference.targets(287,5): message NETSDK1057: You are using a preview
version of .NET. See: https://aka.ms/dotne
t-support-policy [C:\Code\Demos\MyFirstAotWebApi\MyFirstAotWebApi.csproj]
  MyFirstAotWebApi -> C:\Code\Demos\MyFirstAotWebApi\bin\Release\net8.0\win-
x64\MyFirstAotWebApi.dll
  Generating native code
  MyFirstAotWebApi -> C:\Code\Demos\MyFirstAotWebApi\bin\Release\net8.0\win-
x64\publish\
```

The output may differ from the preceding example depending on the version of .NET 8 used, directory used, and other factors.

Review the contents of the output directory:

```
dir bin\Release\net8.0\win-x64\publish
```

Output similar to the following example is displayed:

Output

```
    Directory: C:\Code\Demos\MyFirstAotWebApi\bin\Release\net8.0\win-
x64\publish

Mode                 LastWriteTime         Length Name
----                 -------------         ------ ----
-a---          30/03/2023  1:41 PM        9480704 MyFirstAotWebApi.exe
-a---          30/03/2023  1:41 PM       43044864 MyFirstAotWebApi.pdb
```

The executable is self-contained and doesn't require a .NET runtime to run. When launched, it behaves the same as the app run in the development environment. Run the AOT app:

```
.\bin\Release\net8.0\win-x64\publish\MyFirstAotWebApi.exe
```

Output similar to the following example is displayed:

Output

```
info: Microsoft.Hosting.Lifetime[14]
      Now listening on: http://localhost:5000
info: Microsoft.Hosting.Lifetime[0]
      Application started. Press Ctrl+C to shut down.
info: Microsoft.Hosting.Lifetime[0]
      Hosting environment: Production
info: Microsoft.Hosting.Lifetime[0]
      Content root path: C:\Code\Demos\MyFirstAotWebApi
```

Libraries and Native AOT

Many of the popular libraries used in ASP.NET Core projects currently have some compatibility issues when used in a project targeting Native AOT, such as:

- Use of reflection to inspect and discover types.

- Conditionally loading libraries at runtime.
- Generating code on the fly to implement functionality.

Libraries using these dynamic features need to be updated in order to work with Native AOT. They can be updated using tools like Roslyn source generators.

Library authors hoping to support Native AOT are encouraged to:

- Read about Native AOT compatibility requirements.
- Prepare the library for trimming.

Turn Map methods into request delegates with the ASP.NET Core Request Delegate Generator

Article • 07/26/2024

The ASP.NET Core Request Delegate Generator (RDG) is a compile-time source generator that compiles route handlers provided to a minimal API to request delegates that can be processed by ASP.NET Core's routing infrastructure. The RDG is implicitly enabled when applications are published with AoT enabled or when trimming is enabled. The RDG generates trim and native AoT-friendly code.

> **Note**
>
> - The Native AOT feature is currently in preview.
> - In .NET 8, not all ASP.NET Core features are compatible with Native AOT.

The RDG:

- Is a source generator.
- Turns each `Map` method into a RequestDelegate associated with the specific route. `Map` methods include the methods in the EndpointRouteBuilderExtensions, such as MapGet, MapPost, MapPatch, MapPut, and MapDelete.

When publishing and Native AOT is ***not*** enabled:

- `Map` methods associated with a specific route are compiled in memory into a request delegate when the app starts, not when the app is built.
- The request delegates are generated at runtime.

When publishing with Native AOT enabled:

- `Map` methods associated with a specific route are compiled when the app is built. The RDG creates the request delegate for the route and the request delegate is compiled into the app's native image.
- Eliminates the need to generate the request delegate at runtime.
- Ensures:
  - The types used in the app's APIs are rooted in the app code in a way that is statically analyzable by the Native AOT tool-chain.
  - The required code isn't trimmed away.

The RDG:

- Is enabled automatically in projects when publishing with Native AOT is enabled or when trimming is enabled.
- Can be manually enabled even when not using Native AOT by setting `<EnableRequestDelegateGenerator>true</EnableRequestDelegateGenerator>` in the project file:

XML

```xml
<Project Sdk="Microsoft.NET.Sdk.Web">

  <PropertyGroup>
    <TargetFramework>net8.0</TargetFramework>
    <Nullable>enable</Nullable>
    <ImplicitUsings>enable</ImplicitUsings>
    <EnableRequestDelegateGenerator>true</EnableRequestDelegateGenerator>
  </PropertyGroup>

</Project>
```

Manually enabling RDG can be useful for:

- Evaluating a project's compatibility with Native AOT.
- Reducing the app's startup time by pregenerating the request delegates.

Minimal APIs are optimized for using System.Text.Json, which requires using the System.Text.Json source generator. All types accepted as parameters to or returned from request delegates in Minimal APIs must be configured on a JsonSerializerContext that's registered via ASP.NET Core's dependency injection:

C#

```csharp
using System.Text.Json.Serialization;

var builder = WebApplication.CreateSlimBuilder(args);

builder.Services.ConfigureHttpJsonOptions(options =>
{
    options.SerializerOptions.TypeInfoResolverChain.Insert(
                        0, AppJsonSerializerContext.Default);
});

var app = builder.Build();

var sampleTodos = new Todo[] {
    new(1, "Walk the dog"),
    new(2, "Do the dishes", DateOnly.FromDateTime(DateTime.Now)),
    new(3, "Do the laundry",
```

```
DateOnly.FromDateTime(DateTime.Now.AddDays(1))),
    new(4, "Clean the bathroom"),
    new(5, "Clean the car", DateOnly.FromDateTime(DateTime.Now.AddDays(2)))
};

var todosApi = app.MapGroup("/todos");
todosApi.MapGet("/", () => sampleTodos);
todosApi.MapGet("/{id}", (int id) =>
    sampleTodos.FirstOrDefault(a => a.Id == id) is { } todo
        ? Results.Ok(todo)
        : Results.NotFound());

app.Run();

public record Todo(int Id, string? Title, DateOnly? DueBy = null, bool
IsComplete = false);

[JsonSerializable(typeof(Todo[]))]
internal partial class AppJsonSerializerContext : JsonSerializerContext
{

}
```

Diagnostics for unsupported RDG scenarios

When the app is built, the RDG emits diagnostics for scenarios that aren't supported by Native AOT. The diagnostics are emitted as warnings and don't prevent the app from building. For the list of diagnostics, see ASP.NET Core Request Delegate Generator diagnostics.

ASP.NET Core Request Delegate Generator (RDG) diagnostics

Article • 07/26/2024

The ASP.NET Core Request Delegate Generator (RDG) is a tool that generates request delegates for ASP.NET Core apps. The RDG is used by the native ahead-of-time (AOT) compiler to generate request delegates for the app's `Map` methods.

> **Note**
>
> - The Native AOT feature is currently in preview.
> - In .NET 8, not all ASP.NET Core features are compatible with Native AOT.

The following list contains the RDG diagnostics for ASP.NET Core:

- RDG002: Unable to resolve endpoint handler
- RDG004: Unable to resolve anonymous type
- RDG005: Invalid abstract type
- RDG006: Invalid constructor parameters
- RDG007: No valid constructor found
- RDG008: Multiple public constructors
- RDG009: Invalid nested AsParameters
- RDG010: InvalidAsParameters Nullable
- RDG011: Type parameters not supported
- RDG012: Unable to resolve inaccessible type
- RDG013: Invalid source attributes

ⓘ **Note:** The author created this article with assistance from AI. Learn more

RDG002: Unable to resolve endpoint handler

Article • 07/26/2024

Expand table

	Value
Rule ID	RDG002
Fix is breaking or non-breaking	Non-breaking

Cause

This diagnostic is emitted by the Request Delegate Generator when an endpoint contains a route handler that can't be statically analyzed.

Rule description

The Request Delegate Generator runs at compile-time and needs to be able to statically analyze route handlers in an app. The current implementation only supports route handlers that are provided as a lambda expression, method group references, or references to read-only fields or variables.

The following code generates the RDG002 warning because the route handler is provided as a reference to a method:

C#

```
using System.Text.Json.Serialization;

var builder = WebApplication.CreateSlimBuilder(args);

builder.Services.ConfigureHttpJsonOptions(options =>
{
    options.SerializerOptions.TypeInfoResolverChain.Insert(0,
                                        AppJsonSerializerContext.Default);
});

var app = builder.Build();

var del = Wrapper.GetTodos;
app.MapGet("/v1/todos", del);
```

```
app.Run();

record Todo(int Id, string Task);
[JsonSerializable(typeof(Todo[]))]
internal partial class AppJsonSerializerContext : JsonSerializerContext
{

}

class Wrapper
{
    public static Func<IResult> GetTodos = () =>
        Results.Ok(new Todo(1, "Write test fix"));
}
```

How to fix violations

Declare the route handler using supported syntax, such as an inline lambda:

C#

```
using System.Text.Json.Serialization;

var builder = WebApplication.CreateSlimBuilder(args);

builder.Services.ConfigureHttpJsonOptions(options =>
{
    options.SerializerOptions.TypeInfoResolverChain.Insert(0,
                                   AppJsonSerializerContext.Default);
});

var app = builder.Build();

app.MapGet("/v1/todos", () => Results.Ok(new Todo(1, "Write tests")));

app.Run();

record Todo(int Id, string Task);
[JsonSerializable(typeof(Todo[]))]
internal partial class AppJsonSerializerContext : JsonSerializerContext
{

}
```

When to suppress warnings

This warning can be safely suppressed. When suppressed, the framework falls back to generating the request delegate at runtime.

RDG004: Unable to resolve anonymous type

Article • 07/26/2024

Expand table

	Value
Rule ID	RDG004
Fix is breaking or non-breaking	Non-breaking

Cause

This diagnostic is emitted by the Request Delegate Generator when an endpoint contains a route handler with an anonymous return type.

Rule description

The Request Delegate Generator runs at compile-time and needs to be able to statically analyze route handlers in an app. Anonymous types are generated with a type name only known to the complier and aren't statically analyzable. The following endpoint produces the diagnostic.

C#

```
using System.Text.Json.Serialization;

var builder = WebApplication.CreateSlimBuilder(args);

builder.Services.ConfigureHttpJsonOptions(options =>
{
    options.SerializerOptions.TypeInfoResolverChain.Insert(0,
                                        AppJsonSerializerContext.Default);
});

var app = builder.Build();

app.MapGet("/v1/todos", () => new { Id = 1, Task = "Write tests" });

app.Run();

record Todo(int Id, string Task);
[JsonSerializable(typeof(Todo[]))]
```

```
internal partial class AppJsonSerializerContext : JsonSerializerContext
{

}
```

How to fix violations

Declare the route handler with a concrete type as the return type.

C#

```
using System.Text.Json.Serialization;

var builder = WebApplication.CreateSlimBuilder(args);

builder.Services.ConfigureHttpJsonOptions(options =>
{
    options.SerializerOptions.TypeInfoResolverChain.Insert(0,
                                AppJsonSerializerContext.Default);
});

var app = builder.Build();

app.MapGet("/v1/todos", () => new Todo(1, "Write tests fix"));

app.Run();

record Todo(int Id, string Task);
[JsonSerializable(typeof(Todo[]))]
internal partial class AppJsonSerializerContext : JsonSerializerContext
{

}
```

When to suppress warnings

This warning can be safely suppressed. When suppressed, the framework falls back to generating the request delegate at runtime.

ⓘ **Note:** The author created this article with assistance from AI. Learn more

RDG005: Invalid abstract type

Article • 07/26/2024

Expand table

	Value
Rule ID	RDG005
Fix is breaking or non-breaking	Non-breaking

Cause

This diagnostic is emitted by the Request Delegate Generator when an endpoint contains a route handler with a parameter annotated with the [AsParameters] attribute that is an abstract type.

Rule description

The implementation of surrogate binding via the [AsParameters] attribute in minimal APIs only supports types with concrete implementations. Using a parameter with an abstract type as in the following sample produces the diagnostic.

C#

```
using System.Text.Json.Serialization;

var builder = WebApplication.CreateSlimBuilder(args);

builder.Services.ConfigureHttpJsonOptions(options =>
{
    options.SerializerOptions.TypeInfoResolverChain.Insert(0,
                                        AppJsonSerializerContext.Default);
});

var app = builder.Build();
app.MapPut("/v1/todos/{id}",
    ([AsParameters] TodoRequest todoRequest) =>
Results.Ok(todoRequest.Todo));

app.Run();
```

```
abstract class TodoRequest
{
    public int Id { get; set; }
    public Todo? Todo { get; set; }
}

record Todo(int Id, string Task);

[JsonSerializable(typeof(Todo[]))]
internal partial class AppJsonSerializerContext : JsonSerializerContext
{

}
```

How to fix violations

Use a concrete type for the surrogate:

C#

```
using System.Text.Json.Serialization;

var builder = WebApplication.CreateSlimBuilder(args);

builder.Services.ConfigureHttpJsonOptions(options =>
{
    options.SerializerOptions.TypeInfoResolverChain.Insert(0,
                                  AppJsonSerializerContext.Default);
});

var app = builder.Build();

app.MapPut("/v1/todos/{id}",
           ([AsParameters] TodoRequest todoRequest) =>
Results.Ok(todoRequest.Todo));

app.Run();

class TodoRequest
{
    public int Id { get; set; }
    public Todo? Todo { get; set; }
}

record Todo(int Id, string Task);

[JsonSerializable(typeof(Todo[]))]
internal partial class AppJsonSerializerContext : JsonSerializerContext
{

}
```

When to suppress warnings

This warning should not be suppressed. Suppressing the warning will lead to a runtime exception assocaited with the same warning.

ⓘ **Note:** The author created this article with assistance from AI. Learn more

RDG006: Invalid constructor parameters

Article • 07/26/2024

Expand table

	Value
Rule ID	RDG006
Fix is breaking or non-breaking	Non-breaking

Cause

This diagnostic is emitted by the Request Delegate Generator when an endpoint contains a route handler with a parameter annotated with the [AsParameters] attribute that contains an invalid constructor.

Rule description

Types that are used for surrogate binding via the [AsParameters] attribute must contain a public parameterized constructor where all parameters to the constructor match the public properties declared on the type. The `TodoRequest` type produces this diagnostic because there is no matching constructor parameter for the `Todo` property.

C#

```
using System.Text.Json.Serialization;

var builder = WebApplication.CreateSlimBuilder(args);

builder.Services.ConfigureHttpJsonOptions(options =>
{
    options.SerializerOptions.TypeInfoResolverChain.Insert(0,
                                       AppJsonSerializerContext.Default);
});

var app = builder.Build();

app.MapPut("/v1/todos/{id}",
           ([AsParameters] TodoRequest todoRequest) =>
Results.Ok(todoRequest.Todo));

app.Run();
```

```
class TodoRequest(int id, string name)
{
    public int Id { get; set; } = id;
    public Todo? Todo { get; set; }
}

record Todo(int Id, string Task);

[JsonSerializable(typeof(Todo[]))]
internal partial class AppJsonSerializerContext : JsonSerializerContext
{

}
```

How to fix violations

Ensure that all properties on the type have a matching parameter on the constructor.

C#

```
using System.Text.Json.Serialization;

var builder = WebApplication.CreateSlimBuilder(args);

builder.Services.ConfigureHttpJsonOptions(options =>
{
    options.SerializerOptions.TypeInfoResolverChain.Insert(0,
                                    AppJsonSerializerContext.Default);
});

var app = builder.Build();

app.MapPut("/v1/todos/{id}",
           ([AsParameters] TodoRequest todoRequest) =>
Results.Ok(todoRequest.Todo));

app.Run();

class TodoRequest(int id, Todo? todo)
{
    public int Id { get; set; } = id;
    public Todo? Todo { get; set; } = todo;
}

record Todo(int Id, string Task);

[JsonSerializable(typeof(Todo[]))]
internal partial class AppJsonSerializerContext : JsonSerializerContext
{

}
```

When to suppress warnings

This warning should ***not*** be suppressed. Suppressing the warning leads to a runtime exception associated with the same warning.

RDG007: No valid constructor found

Article • 07/26/2024

Expand table

	Value
Rule ID	RDG007
Fix is breaking or non-breaking	Non-breaking

Cause

This diagnostic is emitted by the Request Delegate Generator when an endpoint contains a route handler with a parameter annotated with the [AsParameters] attribute with no valid constructor.

Rule description

Types that are used for surrogate binding via the `AsParameters` attribute must contain a public constructor. The `TodoRequest` type produces this diagnostic because there is no public constructor.

C#

```
using System.Text.Json.Serialization;

var builder = WebApplication.CreateSlimBuilder(args);

builder.Services.ConfigureHttpJsonOptions(options =>
{
    options.SerializerOptions.TypeInfoResolverChain.Insert(0,
                                AppJsonSerializerContext.Default);
});

var app = builder.Build();

app.MapPut("/v1/todos/{id}", ([AsParameters] TodoRequest request)
    => Results.Ok(request.Todo));

app.Run();

public class TodoRequest
{
    public int Id { get; set; }
    public Todo Todo { get; set; }
```

```
    private TodoRequest()
    {
    }
}

public record Todo(int Id, string Task);

[JsonSerializable(typeof(Todo[]))]
internal partial class AppJsonSerializerContext : JsonSerializerContext
{

}
```

How to fix violations

Remove the non-public constructor, or add a new public constructor.

C#

```
using System.Text.Json.Serialization;

var builder = WebApplication.CreateSlimBuilder(args);

builder.Services.ConfigureHttpJsonOptions(options =>
{
    options.SerializerOptions.TypeInfoResolverChain.Insert(0,
                                AppJsonSerializerContext.Default);
});

var app = builder.Build();

app.MapPut("/v1/todos/{id}", ([AsParameters] TodoRequest request)
    => Results.Ok(request.Todo));
app.Run();

public class TodoRequest(int Id, Todo todo)
{
    public int Id { get; set; } = Id;
    public Todo Todo { get; set; } = todo;
}

public record Todo(int Id, string Task);

[JsonSerializable(typeof(Todo[]))]
internal partial class AppJsonSerializerContext : JsonSerializerContext
{

}
```

When to suppress warnings

This warning can't be safely suppressed. When suppressed, results in the `InvalidOperationException` runtime exception.

RDG008: Multiple public constructors

Article • 07/26/2024

Expand table

	Value
Rule ID	RDG008
Fix is breaking or non-breaking	Non-breaking

Cause

This diagnostic is emitted by the Request Delegate Generator when an endpoint contains a route handler with a parameter annotated with the [AsParameters] attribute with multiple public constructors.

Rule description

Types that are used for surrogate binding via the `AsParameters` attribute must contain a single public constructor. The `TodoRequest` type produces this diagnostic because there are multiple public constructors.

C#

```
using System.Text.Json.Serialization;

var builder = WebApplication.CreateSlimBuilder();
var todos = new[]
{
    new Todo(1, "Write tests", DateTime.UtcNow.AddDays(2)),
    new Todo(2, "Fix tests",DateTime.UtcNow.AddDays(1))
};
builder.Services.AddSingleton(todos);
builder.Services.ConfigureHttpJsonOptions(options =>
{
    options.SerializerOptions.TypeInfoResolverChain.Insert(0,
AppJsonSerializerContext.Default);
});

var app = builder.Build();

app.MapGet("/v1/todos/{id}", ([AsParameters] TodoItemRequest request) =>
{
    return request.Todos.ToList().Find(todoItem => todoItem.Id ==
request.Id)
```

```
is Todo todo
    ? Results.Ok(todo)
    : Results.NotFound();
});

app.Run();

public class TodoItemRequest
{
    public int Id { get; set; }
    public Todo[] Todos { get; set; }

    public TodoItemRequest(int id, Todo[] todos)
    {
        Id = id;
        Todos = todos;
    }

    // Additional Constructor
    public TodoItemRequest()
    {
        Id = 1;
        Todos = [new Todo(1, "Write tests", DateTime.UtcNow.AddDays(2))];
    }

}

public class Todo
{
    public DateTime DueDate { get; }
    public int Id { get; private set; }
    public string Task { get; private set; }

    public Todo(int id, string task, DateTime dueDate)

    {
        Id = id;
        Task = task;
        DueDate = dueDate;
    }
}

[JsonSerializable(typeof(Todo[]))]
internal partial class AppJsonSerializerContext : JsonSerializerContext
{
}
```

How to fix violations

Provide a single public constructor.

```
C#
```

```
using System.Text.Json.Serialization;

var builder = WebApplication.CreateSlimBuilder();
var todos = new[]
{
    new Todo(1, "Write tests", DateTime.UtcNow.AddDays(2)),
    new Todo(2, "Fix tests",DateTime.UtcNow.AddDays(1))
};
builder.Services.AddSingleton(todos);
builder.Services.ConfigureHttpJsonOptions(options =>
{
    options.SerializerOptions.TypeInfoResolverChain.Insert(0,
AppJsonSerializerContext.Default);
});

var app = builder.Build();

app.MapGet("/v1/todos/{id}", ([AsParameters] TodoItemRequest request) =>
{
    return request.Todos.ToList().Find(todoItem => todoItem.Id ==
request.Id)
is Todo todo
    ? Results.Ok(todo)
    : Results.NotFound();
});

app.Run();

public class TodoItemRequest
{
    public int Id { get; set; }
    public Todo[] Todos { get; set; }

    public TodoItemRequest(int id, Todo[] todos)
    {
        Id = id;
        Todos = todos;
    }
}

public class Todo
{
    public DateTime DueDate { get; }
    public int Id { get; private set; }
    public string Task { get; private set; }

    public Todo(int id, string task, DateTime dueDate)
    {
        Id = id;
        Task = task;
        DueDate = dueDate;
    }
}
```

```
[JsonSerializable(typeof(Todo[]))]
internal partial class AppJsonSerializerContext : JsonSerializerContext
{
}
```

When to suppress warnings

This warning can be safely suppressed.

RDG009: Invalid nested AsParameters

Article • 07/26/2024

Expand table

	Value
Rule ID	RDG009
Fix is breaking or non-breaking	Non-breaking

Cause

This diagnostic is emitted by the Request Delegate Generator when an endpoint contains invalid nested [AsParameters].

Rule description

Types that are used for surrogate binding via the [AsParameters] attribute must not contain nested types that are also annotated with the [AsParameters] attribute:

C#

```
using System.Text.Json.Serialization;

var builder = WebApplication.CreateSlimBuilder();

var todos = new[]
{
    new Todo(1, "Write tests", DateTime.UtcNow.AddDays(2)),
    new Todo(2, "Fix tests",DateTime.UtcNow.AddDays(1))
};

builder.Services.AddSingleton(todos);
builder.Services.ConfigureHttpJsonOptions(options =>
{
    options.SerializerOptions.TypeInfoResolverChain.Insert(0,
AppJsonSerializerContext.Default);
});

var app = builder.Build();

app.MapGet("/v1/todos/{id}", ([AsParameters] TodoItemRequest request) =>
{
     return request.Todos.ToList().Find(todoItem => todoItem.Id ==
request.Id) is Todo todo
```

```
    ? Results.Ok(todo)
    : Results.NotFound();
});

app.Run();

struct TodoItemRequest
{
    public int Id { get; set; }
    [AsParameters]
    public Todo[] Todos { get; set; }
}

internal record Todo(int Id, string Task, DateTime DueDate);

[JsonSerializable(typeof(Todo[]))]
internal partial class AppJsonSerializerContext : JsonSerializerContext
{
}
```

How to fix violations

Remove the nested `AsParameters` attribute:

C#

```
using System.Text.Json.Serialization;

var builder = WebApplication.CreateSlimBuilder();
var todos = new[]
{
    new Todo(1, "Write tests", DateTime.UtcNow.AddDays(2)),
    new Todo(2, "Fix tests",DateTime.UtcNow.AddDays(1))
};
builder.Services.AddSingleton(todos);
builder.Services.ConfigureHttpJsonOptions(options =>
{
    options.SerializerOptions.TypeInfoResolverChain.Insert(0,
AppJsonSerializerContext.Default);
});

var app = builder.Build();

app.MapGet("/v1/todos/{id}", ([AsParameters] TodoItemRequest request) =>
{
    return request.Todos.ToList().Find(todoItem => todoItem.Id ==
request.Id) is Todo todo
    ? Results.Ok(todo)
    : Results.NotFound();
});
```

```
app.Run();

struct TodoItemRequest
{
    public int Id { get; set; }
    //[AsParameters]
    public Todo[] Todos { get; set; }
}

internal record Todo(int Id, string Task, DateTime DueDate);

[JsonSerializable(typeof(Todo[]))]
internal partial class AppJsonSerializerContext : JsonSerializerContext
{
}
```

When to suppress warnings

This warning can ***not*** be suppressed.

RDG010: InvalidAsParameters Nullable

Article • 07/26/2024

Expand table

	Value
Rule ID	RDG010
Fix is breaking or non-breaking	Non-breaking

Cause

This diagnostic is emitted by the Request Delegate Generator when an endpoint contains a route handler with a parameter annotated with the [AsParameters] attribute that is marked as nullable.

Rule description

The implementation of surrogate binding via the [AsParameters] attribute in minimal APIs only supports types that are not nullable.

C#

```
using System.Text.Json.Serialization;
using Microsoft.AspNetCore.Mvc;

var builder = WebApplication.CreateSlimBuilder(args);
builder.Services.ConfigureHttpJsonOptions(options =>
{
    options.SerializerOptions.TypeInfoResolverChain.Insert(0,
                                AppJsonSerializerContext.Default);
});

var app = builder.Build();

app.MapGet("/todos/{id}", ([AsParameters] TodoRequest? request)
    => Results.Ok(new Todo(request!.Id)));

app.Run();

public record TodoRequest(HttpContext HttpContext, [FromRoute] int Id);
public record Todo(int Id);
[JsonSerializable(typeof(Todo[]))]
internal partial class AppJsonSerializerContext : JsonSerializerContext
{
```

```
}
```

How to fix violations

Declare the parameter as non-nullable.

C#

```
using System.Text.Json.Serialization;
using Microsoft.AspNetCore.Mvc;

var builder = WebApplication.CreateSlimBuilder(args);
builder.Services.ConfigureHttpJsonOptions(options =>
{
    options.SerializerOptions.TypeInfoResolverChain.Insert(0,
                                AppJsonSerializerContext.Default);
});

var app = builder.Build();

app.MapGet("/todos/{id}", ([AsParameters] TodoRequest request)
    => Results.Ok(new Todo(request.Id)));

app.Run();

public record TodoRequest(HttpContext HttpContext, [FromRoute] int Id);
public record Todo(int Id);
[JsonSerializable(typeof(Todo[]))]
internal partial class AppJsonSerializerContext : JsonSerializerContext
{

}
```

When to suppress warnings

This warning should ***not*** be suppressed. Suppressing the warning leads to a runtime exception associated with the same warning.

RDG011: Type parameters not supported

Article • 07/26/2024

Expand table

	Value
Rule ID	RDG011
Fix is breaking or non-breaking	Non-breaking

Cause

This diagnostic is emitted by the Request Delegate Generator when an endpoint contains a route handler that captures a generic type.

Rule description

Endpoints that use generic type parameters are not supported. The endpoints within `MapEndpoints` produce this diagnostic because of the generic `<T>` parameter.

C#

```
using System.Text.Json.Serialization;

var builder = WebApplication.CreateSlimBuilder(args);
builder.Services.ConfigureHttpJsonOptions(options =>
{
    options.SerializerOptions.TypeInfoResolverChain.Insert(0,
                                AppJsonSerializerContext.Default);
});

var app = builder.Build();
app.MapEndpoints<Todo>();
app.Run();

public static class RouteBuilderExtensions
{
    public static IEndpointRouteBuilder MapEndpoints<T>(this
IEndpointRouteBuilder app) where T : class, new()
    {
        app.MapPost("/input", (T value) => value);
        app.MapGet("/result", () => new T());
        app.MapPost("/input-with-wrapper", (Wrapper<T> value) => value);
        app.MapGet("/async", async () =>
        {
```

```
            await Task.CompletedTask;
            return new T();
        });
        return app;
    }
}

record Wrapper<T>(T Value);
class Todo
{
    public int Id { get; set; }
    public string Task { get; set; }
}
[JsonSerializable(typeof(Wrapper<Todo>[]))]
internal partial class AppJsonSerializerContext : JsonSerializerContext
{

}
```

How to fix violations

Remove the generic type from endpoints.

C#

```
using System.Text.Json.Serialization;

var builder = WebApplication.CreateSlimBuilder(args);
builder.Services.ConfigureHttpJsonOptions(options =>
{
    options.SerializerOptions.TypeInfoResolverChain.Insert(0,
                                    AppJsonSerializerContext.Default);
});

var app = builder.Build();
app.MapTodoEndpoints();
app.Run();

public static class TodoRouteBuilderExtensions
{
    public static IEndpointRouteBuilder MapTodoEndpoints(this
IEndpointRouteBuilder app)
    {
        app.MapPost("/input", (Todo value) => value);
        app.MapGet("/result", () => new Todo(1, "Walk the dog"));
        app.MapPost("/input-with-wrapper", (Wrapper<Todo> value) => value);
        app.MapGet("/async", async () =>
        {
            await Task.CompletedTask;
            return new Todo(1, "Walk the dog");
        });
        return app;
```

```
    }
}

record Wrapper<T>(T Value);
record Todo(int Id, string Task);
[JsonSerializable(typeof(Wrapper<Todo>[]))]
internal partial class AppJsonSerializerContext : JsonSerializerContext
{

}
```

When to suppress warnings

This warning can be safely suppressed. When suppressed, the framework will fallback to generating the request delegate at runtime.

RDG012: Unable to resolve inaccessible type

Article • 07/26/2024

Expand table

	Value
Rule ID	RDG012
Fix is breaking or non-breaking	Non-breaking

Cause

This diagnostic is emitted by the Request Delegate Generator when an endpoint contains a route handler with a parameter without the appropriate accessibility modifiers.

Rule description

Endpoints that use an inaccessible type (`private` or `protected`) are not supported. The endpoints within `MapEndpoints` produce this diagnostic because of the `Todo` type has the `private` accessibility modifiers.

C#

```
using System.Text.Json.Serialization;

var builder = WebApplication.CreateSlimBuilder(args);
builder.Services.ConfigureHttpJsonOptions(options =>
{
    options.SerializerOptions.TypeInfoResolverChain.Insert(0,
                                AppJsonSerializerContext.Default);
});

var app = builder.Build();
app.MapEndpoints();
app.Run();

public static class TodoRouteBuilderExtensions
{
```

```
    public static IEndpointRouteBuilder MapEndpoints(this
IEndpointRouteBuilder app)
    {
        app.MapPost("/input", (Todo value) => value);
        app.MapGet("/result", () => new Todo(1, "Walk the dog"));
        app.MapPost("/input-with-wrapper", (Wrapper<Todo> value) => value);
        app.MapGet("/async", async () =>
        {
            await Task.CompletedTask;
            return new Todo(1, "Walk the dog");
        });
        return app;
    }

    private record Todo(int Id, string Task);
}

record Wrapper<T>(T Value);
[JsonSerializable(typeof(Wrapper<TodoRouteBuilderExtensions.Todo>[]))]
internal partial class AppJsonSerializerContext : JsonSerializerContext
{

}
```

How to fix violations

When applicable, set the target parameter type with a friendly accessibility.

C#

```
using System.Text.Json.Serialization;

var builder = WebApplication.CreateSlimBuilder(args);
builder.Services.ConfigureHttpJsonOptions(options =>
{
    options.SerializerOptions.TypeInfoResolverChain.Insert(0,
                                AppJsonSerializerContext.Default);
});

var app = builder.Build();
app.MapEndpoints();
app.Run();

public static class TodoRouteBuilderExtensions
{
```

```
    public static IEndpointRouteBuilder MapEndpoints(this
IEndpointRouteBuilder app)
    {
        app.MapPost("/input", (Todo value) => value);
        app.MapGet("/result", () => new Todo(1, "Walk the dog"));
        app.MapPost("/input-with-wrapper", (Wrapper<Todo> value) => value);
        app.MapGet("/async", async () =>
        {
            await Task.CompletedTask;
            return new Todo(1, "Walk the dog");
        });
        return app;
    }

    public record Todo(int Id, string Task);
}

record Wrapper<T>(T Value);
[JsonSerializable(typeof(Wrapper<TodoRouteBuilderExtensions.Todo>[]))]
internal partial class AppJsonSerializerContext : JsonSerializerContext
{

}
```

When to suppress warnings

This warning can be safely suppressed. When suppressed, the framework will fallback to generating the request delegate at runtime.

RDG013: Invalid source attributes

Article • 07/26/2024

Expand table

	Value
Rule ID	RDG013
Fix is breaking or non-breaking	Non-breaking

Cause

This diagnostic is emitted by the Request Delegate Generator when an endpoint contains a route handler with a parameter that contains an invalid combination of service source attributes.

Rule description

ASP.NET Core supports resolving keyed and non-keyed services via dependency injection. It's ***not*** feasible to resolve a service as both keyed and non-keyed. The following code produces the diagnostic and throws a run time error with the same message:

C#

```
using System.Text.Json.Serialization;
using Microsoft.AspNetCore.Mvc;

var builder = WebApplication.CreateSlimBuilder(args);
builder.Services.ConfigureHttpJsonOptions(options =>
{
    options.SerializerOptions.TypeInfoResolverChain.Insert(0,
                                   AppJsonSerializerContext.Default);
});
builder.Services.AddKeyedSingleton<IService, FizzService>("fizz");

var app = builder.Build();

app.MapGet("/fizz", ([FromKeyedServices("fizz")][FromServices] IService
service) =>
{
    return Results.Ok(service.Echo());
});
```

```
app.Run();
```

How to fix violations

Resolve the target parameter as either a keyed or non-keyed service.

C#

```
using System.Text.Json.Serialization;
using Microsoft.AspNetCore.Mvc;

var builder = WebApplication.CreateSlimBuilder(args);
builder.Services.ConfigureHttpJsonOptions(options =>
{
    options.SerializerOptions.TypeInfoResolverChain.Insert(0,
                                AppJsonSerializerContext.Default);
});

builder.Services.AddKeyedSingleton<IService, FizzService>("fizz");
builder.Services.AddKeyedSingleton<IService, BuzzService>("buzz");
builder.Services.AddSingleton<IService, FizzBuzzService>();
var app = builder.Build();

app.MapGet("/fizz", ([FromKeyedServices("fizz")] IService service) =>
{
    return Results.Ok(service.Echo());
});

app.MapGet("/buzz", ([FromKeyedServices("buzz")] IService service) =>
{
    return Results.Ok(service.Echo());
});

app.MapGet("/fizzbuzz", ([FromServices] IService service) =>
{
    return Results.Ok(service.Echo());
});

app.Run();

public interface IService
{
    string Echo();
}

public class FizzService : IService
{
    public string Echo() => "Fizz";
}

public class BuzzService : IService
```

```
{
    public string Echo() => "Buzz";
}

public class FizzBuzzService : IService
{
    public string Echo()
    {
        return "FizzBuzz";
    }
}
[JsonSerializable(typeof(string[]))]
internal partial class AppJsonSerializerContext : JsonSerializerContext
{

}
```

When to suppress warnings

This warning should ***not*** be suppressed. Suppressing the warning leads to a NotSupportedException runtime exception `The FromKeyedServicesAttribute is not supported on parameters that are also annotated with IFromServiceMetadata.`

ASP.NET Core Middleware

Article • 06/17/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

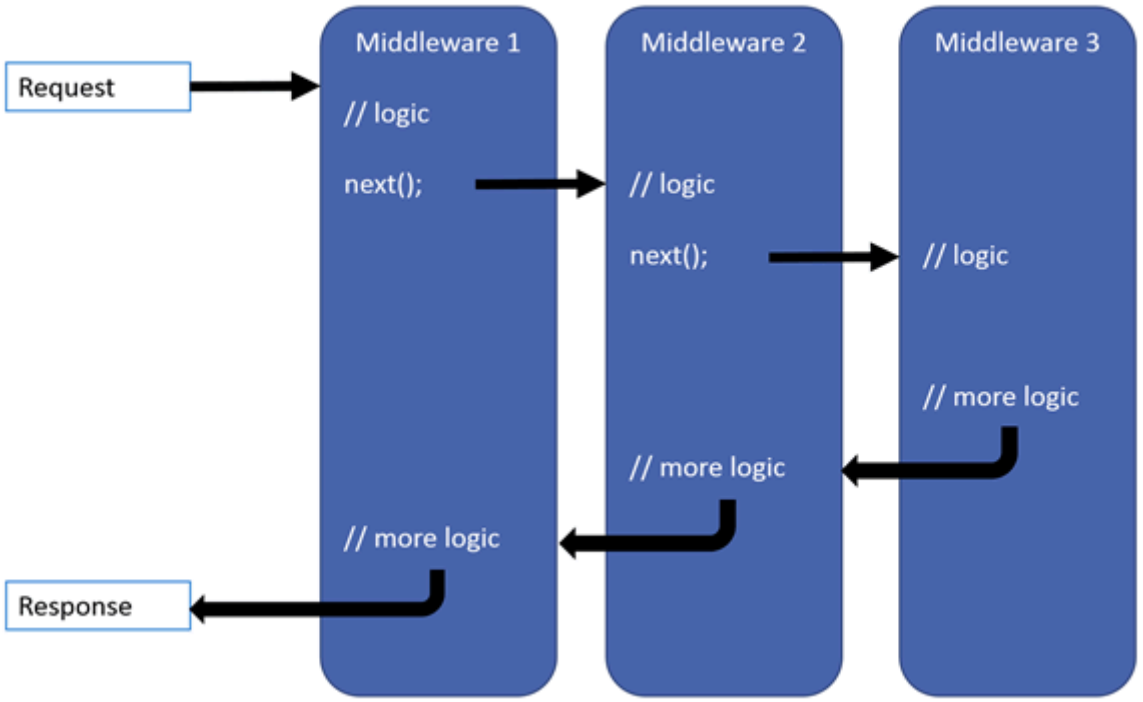
By Rick Anderson and Steve Smith

Middleware is software that's assembled into an app pipeline to handle requests and responses. Each component:

- Chooses whether to pass the request to the next component in the pipeline.
- Can perform work before and after the next component in the pipeline.

Request delegates are used to build the request pipeline. The request delegates handle each HTTP request.

Request delegates are configured using Run, Map, and Use extension methods. An individual request delegate can be specified in-line as an anonymous method (called in-line middleware), or it can be defined in a reusable class. These reusable classes and in-line anonymous methods are *middleware*, also called *middleware components*. Each middleware component in the request pipeline is responsible for invoking the next component in the pipeline or short-circuiting the pipeline. When a middleware short-circuits, it's called a *terminal middleware* because it prevents further middleware from processing the request.



Migrate HTTP handlers and modules to ASP.NET Core middleware explains the difference between request pipelines in ASP.NET Core and ASP.NET 4.x and provides additional middleware samples.

Middleware code analysis

ASP.NET Core includes many compiler platform analyzers that inspect application code for quality. For more information, see Code analysis in ASP.NET Core apps

Create a middleware pipeline with `WebApplication`

The ASP.NET Core request pipeline consists of a sequence of request delegates, called one after the other. The following diagram demonstrates the concept. The thread of execution follows the black arrows.

Each delegate can perform operations before and after the next delegate. Exception-handling delegates should be called early in the pipeline, so they can catch exceptions that occur in later stages of the pipeline.

The simplest possible ASP.NET Core app sets up a single request delegate that handles all requests. This case doesn't include an actual request pipeline. Instead, a single anonymous function is called in response to every HTTP request.

C#

```
var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

app.Run(async context =>
{
    await context.Response.WriteAsync("Hello world!");
});

app.Run();
```

Chain multiple request delegates together with Use. The `next` parameter represents the next delegate in the pipeline. You can short-circuit the pipeline by *not* calling the `next` parameter. You can typically perform actions both before and after the `next` delegate, as the following example demonstrates:

C#

```
var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

app.Use(async (context, next) =>
{
    // Do work that can write to the Response.
    await next.Invoke();
    // Do logging or other work that doesn't write to the Response.
});

app.Run(async context =>
{
    await context.Response.WriteAsync("Hello from 2nd delegate.");
});

app.Run();
```

Short-circuiting the request pipeline

When a delegate doesn't pass a request to the next delegate, it's called *short-circuiting the request pipeline*. Short-circuiting is often desirable because it avoids unnecessary work. For example, Static File Middleware can act as a *terminal middleware* by processing a request for a static file and short-circuiting the rest of the pipeline. Middleware added to the pipeline before the middleware that terminates further processing still processes code after their `next.Invoke` statements. However, see the following warning about attempting to write to a response that has already been sent.

> ⚠ **Warning**
>
> Don't call `next.Invoke` during or after the response has been sent to the client. After an HttpResponse has started, changes result in an exception. For example, setting headers and a status code throw an exception after the response starts. Writing to the response body after calling `next`:
>
> - May cause a protocol violation, such as writing more than the stated `Content-Length`.
> - May corrupt the body format, such as writing an HTML footer to a CSS file.

HasStarted is a useful hint to indicate if headers have been sent or the body has been written to.

For more information, see Short-circuit middleware after routing.

`Run` delegates

Run delegates don't receive a `next` parameter. The first `Run` delegate is always terminal and terminates the pipeline. `Run` is a convention. Some middleware components may expose `Run[Middleware]` methods that run at the end of the pipeline:

C#

```
var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

app.Use(async (context, next) =>
{
    // Do work that can write to the Response.
    await next.Invoke();
    // Do logging or other work that doesn't write to the Response.
});

app.Run(async context =>
{
    await context.Response.WriteAsync("Hello from 2nd delegate.");
});

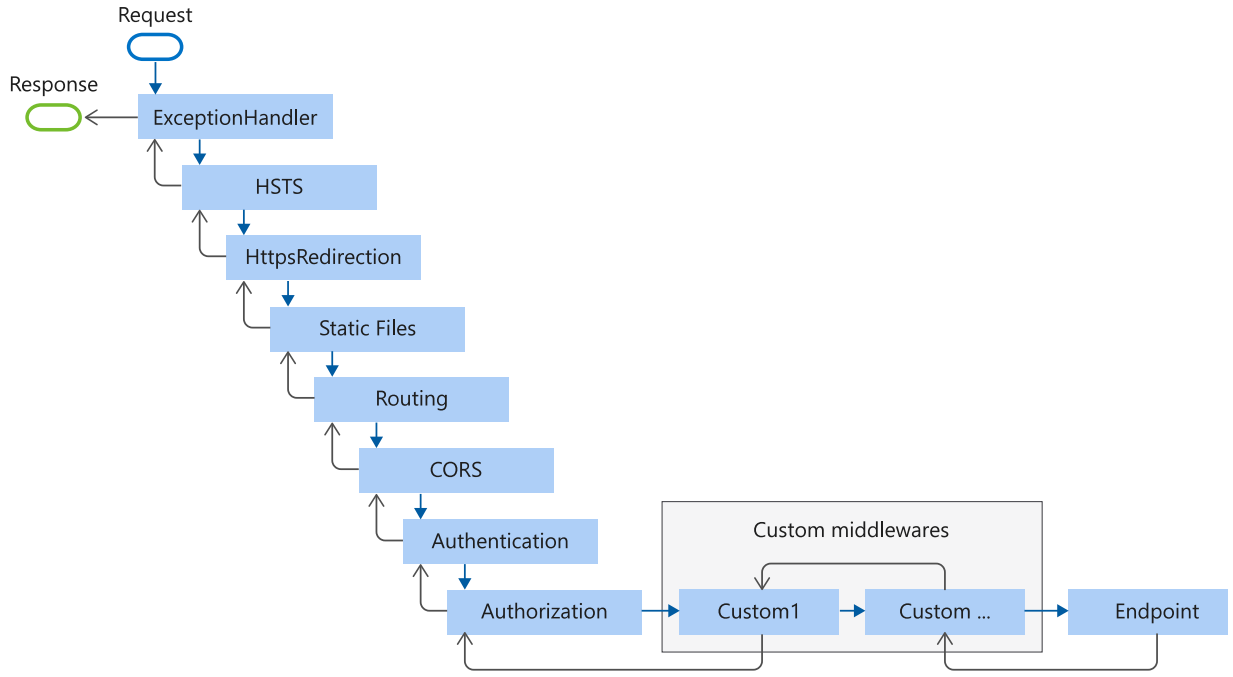
app.Run();
```

If you would like to see code comments translated to languages other than English, let us know in this GitHub discussion issue.

In the preceding example, the `Run` delegate writes `"Hello from 2nd delegate."` to the response and then terminates the pipeline. If another `Use` or `Run` delegate is added after the `Run` delegate, it's not called.

Prefer app.Use overload that requires passing the context to next

The non-allocating app.Use extension method:

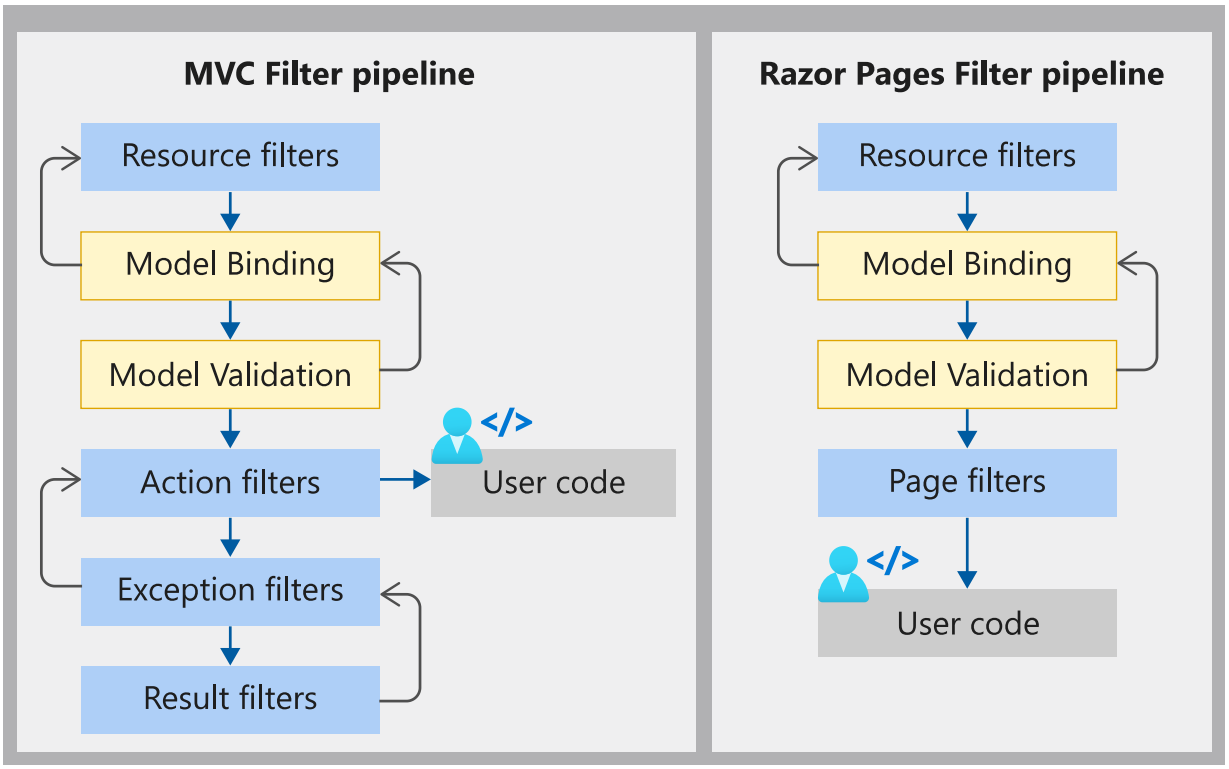


- Requires passing the context to `next`.

- Saves two internal per-request allocations that are required when using the other overload.

For more information, see this GitHub issue.

Middleware order



The following diagram shows the complete request processing pipeline for ASP.NET Core MVC and Razor Pages apps. You can see how, in a typical app, existing middlewares are ordered and where custom middlewares are added. You have full control over how to reorder existing middlewares or inject new custom middlewares as necessary for your scenarios.

The **Endpoint** middleware in the preceding diagram executes the filter pipeline for the corresponding app type—MVC or Razor Pages.

The **Routing** middleware in the preceding diagram is shown following **Static Files**. This is the order that the project templates implement by explicitly calling app.UseRouting. If you don't call `app.UseRouting`, the **Routing** middleware runs at the beginning of the pipeline by default. For more information, see Routing.

MVC Endpoint
(called by the Endpoint Middleware)

The order that middleware components are added in the `Program.cs` file defines the order in which the middleware components are invoked on requests and the reverse order for the response. The order is **critical** for security, performance, and functionality.

The following highlighted code in `Program.cs` adds security-related middleware components in the typical recommended order:

C#

```
using Microsoft.AspNetCore.Identity;
using Microsoft.EntityFrameworkCore;
using WebMiddleware.Data;

var builder = WebApplication.CreateBuilder(args);

var connectionString =
builder.Configuration.GetConnectionString("DefaultConnection")
    ?? throw new InvalidOperationException("Connection string
'DefaultConnection' not found.");
builder.Services.AddDbContext<ApplicationDbContext>(options =>
    options.UseSqlServer(connectionString));
builder.Services.AddDatabaseDeveloperPageExceptionFilter();

builder.Services.AddDefaultIdentity<IdentityUser>(options =>
options.SignIn.RequireConfirmedAccount = true)
    .AddEntityFrameworkStores<ApplicationDbContext>();
builder.Services.AddRazorPages();
builder.Services.AddControllersWithViews();
```

```
var app = builder.Build();

if (app.Environment.IsDevelopment())
{
    app.UseMigrationsEndPoint();
}
else
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();
// app.UseCookiePolicy();

app.UseRouting();
// app.UseRateLimiter();
// app.UseRequestLocalization();
// app.UseCors();

app.UseAuthentication();
app.UseAuthorization();
// app.UseSession();
// app.UseResponseCompression();
// app.UseResponseCaching();
app.MapRazorPages();
app.MapDefaultControllerRoute();

app.Run();
```

In the preceding code:

- Middleware that is not added when creating a new web app with individual users accounts is commented out.
- Not every middleware appears in this exact order, but many do. For example:
  - `UseCors`, `UseAuthentication`, and `UseAuthorization` must appear in the order shown.
  - `UseCors` currently must appear before `UseResponseCaching`. This requirement is explained in GitHub issue dotnet/aspnetcore #23218.
  - `UseRequestLocalization` must appear before any middleware that might check the request culture, for example, `app.UseStaticFiles()`.
  - UseRateLimiter must be called after `UseRouting` when rate limiting endpoint specific APIs are used. For example, if the [EnableRateLimiting] attribute is used, `UseRateLimiter` must be called after `UseRouting`. When calling only global limiters, `UseRateLimiter` can be called before `UseRouting`.

In some scenarios, middleware has different ordering. For example, caching and compression ordering is scenario specific, and there are multiple valid orderings. For example:

```
C#

app.UseResponseCaching();
app.UseResponseCompression();
```

With the preceding code, CPU usage could be reduced by caching the compressed response, but you might end up caching multiple representations of a resource using different compression algorithms such as Gzip or Brotli.

The following ordering combines static files to allow caching compressed static files:

```
C#

app.UseResponseCaching();
app.UseResponseCompression();
app.UseStaticFiles();
```

The following `Program.cs` code adds middleware components for common app scenarios:

1. Exception/error handling

    - When the app runs in the Development environment:
        - Developer Exception Page Middleware (UseDeveloperExceptionPage) reports app runtime errors.
        - Database Error Page Middleware (UseDatabaseErrorPage) reports database runtime errors.
    - When the app runs in the Production environment:
        - Exception Handler Middleware (UseExceptionHandler) catches exceptions thrown in the following middlewares.
        - HTTP Strict Transport Security Protocol (HSTS) Middleware (UseHsts) adds the `Strict-Transport-Security` header.

2. HTTPS Redirection Middleware (UseHttpsRedirection) redirects HTTP requests to HTTPS.
3. Static File Middleware (UseStaticFiles) returns static files and short-circuits further request processing.
4. Cookie Policy Middleware (UseCookiePolicy) conforms the app to the EU General Data Protection Regulation (GDPR) regulations.

5. Routing Middleware (UseRouting) to route requests.
6. Authentication Middleware (UseAuthentication) attempts to authenticate the user before they're allowed access to secure resources.
7. Authorization Middleware (UseAuthorization) authorizes a user to access secure resources.
8. Session Middleware (UseSession) establishes and maintains session state. If the app uses session state, call Session Middleware after Cookie Policy Middleware and before MVC Middleware.
9. Endpoint Routing Middleware (UseEndpoints with MapRazorPages) to add Razor Pages endpoints to the request pipeline.

C#

```
if (env.IsDevelopment())
{
    app.UseDeveloperExceptionPage();
    app.UseDatabaseErrorPage();
}
else
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}
app.UseHttpsRedirection();
app.UseStaticFiles();
app.UseCookiePolicy();
app.UseRouting();
app.UseAuthentication();
app.UseAuthorization();
app.UseSession();
app.MapRazorPages();
```

In the preceding example code, each middleware extension method is exposed on WebApplicationBuilder through the Microsoft.AspNetCore.Builder namespace.

UseExceptionHandler is the first middleware component added to the pipeline. Therefore, the Exception Handler Middleware catches any exceptions that occur in later calls.

Static File Middleware is called early in the pipeline so that it can handle requests and short-circuit without going through the remaining components. The Static File Middleware provides **no** authorization checks. Any files served by Static File Middleware, including those under *wwwroot*, are publicly available. For an approach to secure static files, see Static files in ASP.NET Core.

If the request isn't handled by the Static File Middleware, it's passed on to the Authentication Middleware (UseAuthentication), which performs authentication. Authentication doesn't short-circuit unauthenticated requests. Although Authentication Middleware authenticates requests, authorization (and rejection) occurs only after MVC selects a specific Razor Page or MVC controller and action.

The following example demonstrates a middleware order where requests for static files are handled by Static File Middleware before Response Compression Middleware. Static files aren't compressed with this middleware order. The Razor Pages responses can be compressed.

C#

```
// Static files aren't compressed by Static File Middleware.
app.UseStaticFiles();

app.UseRouting();

app.UseResponseCompression();

app.MapRazorPages();
```

For information about Single Page Applications, see Overview of Single Page Apps (SPAs) in ASP.NET Core.

UseCors and UseStaticFiles order

The order for calling `UseCors` and `UseStaticFiles` depends on the app. For more information, see UseCors and UseStaticFiles order

Forwarded Headers Middleware order

Forwarded Headers Middleware should run before other middleware. This ordering ensures that the middleware relying on forwarded headers information can consume the header values for processing. To run Forwarded Headers Middleware after diagnostics and error handling middleware, see Forwarded Headers Middleware order.

Branch the middleware pipeline

Map extensions are used as a convention for branching the pipeline. `Map` branches the request pipeline based on matches of the given request path. If the request path starts with the given path, the branch is executed.

C#

```
var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

app.Map("/map1", HandleMapTest1);

app.Map("/map2", HandleMapTest2);

app.Run(async context =>
{
    await context.Response.WriteAsync("Hello from non-Map delegate.");
});

app.Run();

static void HandleMapTest1(IApplicationBuilder app)
{
    app.Run(async context =>
    {
        await context.Response.WriteAsync("Map Test 1");
    });
}

static void HandleMapTest2(IApplicationBuilder app)
{
    app.Run(async context =>
    {
        await context.Response.WriteAsync("Map Test 2");
    });
}
```

The following table shows the requests and responses from `http://localhost:1234` using the preceding code.

Expand table

Request	Response
localhost:1234	Hello from non-Map delegate.
localhost:1234/map1	Map Test 1
localhost:1234/map2	Map Test 2
localhost:1234/map3	Hello from non-Map delegate.

When `Map` is used, the matched path segments are removed from `HttpRequest.Path` and appended to `HttpRequest.PathBase` for each request.

`Map` supports nesting, for example:

C#

```
app.Map("/level1", level1App => {
    level1App.Map("/level2a", level2AApp => {
        // "/level1/level2a" processing
    });
    level1App.Map("/level2b", level2BApp => {
        // "/level1/level2b" processing
    });
});
```

`Map` can also match multiple segments at once:

C#

```
var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

app.Map("/map1/seg1", HandleMultiSeg);

app.Run(async context =>
{
    await context.Response.WriteAsync("Hello from non-Map delegate.");
});

app.Run();

static void HandleMultiSeg(IApplicationBuilder app)
{
    app.Run(async context =>
    {
        await context.Response.WriteAsync("Map Test 1");
    });
}
```

MapWhen branches the request pipeline based on the result of the given predicate. Any predicate of type `Func<HttpContext, bool>` can be used to map requests to a new branch of the pipeline. In the following example, a predicate is used to detect the presence of a query string variable `branch`:

C#

```
var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

app.MapWhen(context => context.Request.Query.ContainsKey("branch"),
HandleBranch);
```

```
app.Run(async context =>
{
    await context.Response.WriteAsync("Hello from non-Map delegate.");
});

app.Run();

static void HandleBranch(IApplicationBuilder app)
{
    app.Run(async context =>
    {
        var branchVer = context.Request.Query["branch"];
        await context.Response.WriteAsync($"Branch used = {branchVer}");
    });
}
```

The following table shows the requests and responses from `http://localhost:1234` using the previous code:

Expand table

Request	Response
`localhost:1234`	`Hello from non-Map delegate.`
`localhost:1234/?branch=main`	`Branch used = main`

UseWhen also branches the request pipeline based on the result of the given predicate. Unlike with `MapWhen`, this branch is rejoined to the main pipeline if it doesn't short-circuit or contain a terminal middleware:

C#

```
var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

app.UseWhen(context => context.Request.Query.ContainsKey("branch"),
    appBuilder => HandleBranchAndRejoin(appBuilder));

app.Run(async context =>
{
    await context.Response.WriteAsync("Hello from non-Map delegate.");
});

app.Run();

void HandleBranchAndRejoin(IApplicationBuilder app)
{
    var logger =
```

```
app.ApplicationServices.GetRequiredService<ILogger<Program>>();

    app.Use(async (context, next) =>
    {
        var branchVer = context.Request.Query["branch"];
        logger.LogInformation("Branch used = {branchVer}", branchVer);

        // Do work that doesn't write to the Response.
        await next();
        // Do other work that doesn't write to the Response.
    });
}
```

In the preceding example, a response of `Hello from non-Map delegate.` is written for all requests. If the request includes a query string variable `branch`, its value is logged before the main pipeline is rejoined.

Built-in middleware

ASP.NET Core ships with the following middleware components. The *Order* column provides notes on middleware placement in the request processing pipeline and under what conditions the middleware may terminate request processing. When a middleware short-circuits the request processing pipeline and prevents further downstream middleware from processing a request, it's called a *terminal middleware*. For more information on short-circuiting, see the Create a middleware pipeline with WebApplication section.

Expand table

Middleware	Description	Order
Authentication	Provides authentication support.	Before `HttpContext.User` is needed. Terminal for OAuth callbacks.
Authorization	Provides authorization support.	Immediately after the Authentication Middleware.
Cookie Policy	Tracks consent from users for storing personal information and enforces minimum standards for cookie fields, such	Before middleware that issues cookies. Examples: Authentication, Session, MVC (TempData).

Middleware	Description	Order
	as `secure` and `SameSite`.	
CORS	Configures Cross-Origin Resource Sharing.	Before components that use CORS. `UseCors` currently must go before `UseResponseCaching` due to this bug.
DeveloperExceptionPage	Generates a page with error information that is intended for use only in the Development environment.	Before components that generate errors. The project templates automatically register this middleware as the first middleware in the pipeline when the environment is Development.
Diagnostics	Several separate middlewares that provide a developer exception page, exception handling, status code pages, and the default web page for new apps.	Before components that generate errors. Terminal for exceptions or serving the default web page for new apps.
Forwarded Headers	Forwards proxied headers onto the current request.	Before components that consume the updated fields. Examples: scheme, host, client IP, method.
Health Check	Checks the health of an ASP.NET Core app and its dependencies, such as checking database availability.	Terminal if a request matches a health check endpoint.
Header Propagation	Propagates HTTP headers from the incoming request to the outgoing HTTP Client requests.	
HTTP Logging	Logs HTTP Requests and Responses.	At the beginning of the middleware pipeline.
HTTP Method Override	Allows an incoming POST request to override the method.	Before components that consume the updated method.
HTTPS Redirection	Redirect all HTTP requests to HTTPS.	Before components that consume the URL.

Middleware	Description	Order
HTTP Strict Transport Security (HSTS)	Security enhancement middleware that adds a special response header.	Before responses are sent and after components that modify requests. Examples: Forwarded Headers, URL Rewriting.
MVC	Processes requests with MVC/Razor Pages.	Terminal if a request matches a route.
OWIN	Interop with OWIN-based apps, servers, and middleware.	Terminal if the OWIN Middleware fully processes the request.
Output Caching	Provides support for caching responses based on configuration.	Before components that require caching. `UseRouting` must come before `UseOutputCaching`. `UseCORS` must come before `UseOutputCaching`.
Response Caching	Provides support for caching responses. This requires client participation to work. Use output caching for complete server control.	Before components that require caching. `UseCORS` must come before `UseResponseCaching`. Is typically not beneficial for UI apps such as Razor Pages because browsers generally set request headers that prevent caching. Output caching benefits UI apps.
Request Decompression	Provides support for decompressing requests.	Before components that read the request body.
Response Compression	Provides support for compressing responses.	Before components that require compression.
Request Localization	Provides localization support.	Before localization sensitive components. Must appear after Routing Middleware when using RouteDataRequestCultureProvider.
Request Timeouts	Provides support for configuring request timeouts, global and per endpoint.	`UseRequestTimeouts` must come after `UseExceptionHandler`, `UseDeveloperExceptionPage`, and `UseRouting`.
Endpoint Routing	Defines and constrains request routes.	Terminal for matching routes.

Middleware	Description	Order
SPA	Handles all requests from this point in the middleware chain by returning the default page for the Single Page Application (SPA)	Late in the chain, so that other middleware for serving static files, MVC actions, etc., takes precedence.
Session	Provides support for managing user sessions.	Before components that require Session.
Static Files	Provides support for serving static files and directory browsing.	Terminal if a request matches a file.
URL Rewrite	Provides support for rewriting URLs and redirecting requests.	Before components that consume the URL.
W3CLogging	Generates server access logs in the W3C Extended Log File Format.	At the beginning of the middleware pipeline.
WebSockets	Enables the WebSockets protocol.	Before components that are required to accept WebSocket requests.

Rate limiting middleware in ASP.NET Core

Article • 06/17/2024

By Arvin Kahbazi, Maarten Balliauw, and Rick Anderson

The `Microsoft.AspNetCore.RateLimiting` middleware provides rate limiting middleware. Apps configure rate limiting policies and then attach the policies to endpoints. Apps using rate limiting should be carefully load tested and reviewed before deploying. See Testing endpoints with rate limiting in this article for more information.

For an introduction to rate limiting, see Rate limiting middleware.

Rate limiter algorithms

The RateLimiterOptionsExtensions class provides the following extension methods for rate limiting:

- Fixed window
- Sliding window
- Token bucket
- Concurrency

Fixed window limiter

The AddFixedWindowLimiter method uses a fixed time window to limit requests. When the time window expires, a new time window starts and the request limit is reset.

Consider the following code:

C#

```
using Microsoft.AspNetCore.RateLimiting;
using System.Threading.RateLimiting;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRateLimiter(_ => _
    .AddFixedWindowLimiter(policyName: "fixed", options =>
    {
        options.PermitLimit = 4;
        options.Window = TimeSpan.FromSeconds(12);
        options.QueueProcessingOrder = QueueProcessingOrder.OldestFirst;
```

```
        options.QueueLimit = 2;
    }));

var app = builder.Build();

app.UseRateLimiter();

static string GetTicks() => (DateTime.Now.Ticks &
0x11111).ToString("00000");

app.MapGet("/", () => Results.Ok($"Hello {GetTicks()}"))
                          .RequireRateLimiting("fixed");

app.Run();
```

The preceding code:

- Calls AddRateLimiter to add a rate limiting service to the service collection.
- Calls `AddFixedWindowLimiter` to create a fixed window limiter with a policy name of `"fixed"` and sets:
- PermitLimit to 4 and the time Window to 12. A maximum of 4 requests per each 12-second window are allowed.
- QueueProcessingOrder to OldestFirst.
- QueueLimit to 2.
- Calls UseRateLimiter to enable rate limiting.

Apps should use Configuration to set limiter options. The following code updates the preceding code using MyRateLimitOptions for configuration:

C#

```
using System.Threading.RateLimiting;
using Microsoft.AspNetCore.RateLimiting;
using WebRateLimitAuth.Models;

var builder = WebApplication.CreateBuilder(args);
builder.Services.Configure<MyRateLimitOptions>(
    builder.Configuration.GetSection(MyRateLimitOptions.MyRateLimit));

var myOptions = new MyRateLimitOptions();
builder.Configuration.GetSection(MyRateLimitOptions.MyRateLimit).Bind(myOpti
ons);
var fixedPolicy = "fixed";

builder.Services.AddRateLimiter(_ => _
    .AddFixedWindowLimiter(policyName: fixedPolicy, options =>
    {
        options.PermitLimit = myOptions.PermitLimit;
        options.Window = TimeSpan.FromSeconds(myOptions.Window);
        options.QueueProcessingOrder = QueueProcessingOrder.OldestFirst;
```

```
        options.QueueLimit = myOptions.QueueLimit;
    }));

var app = builder.Build();

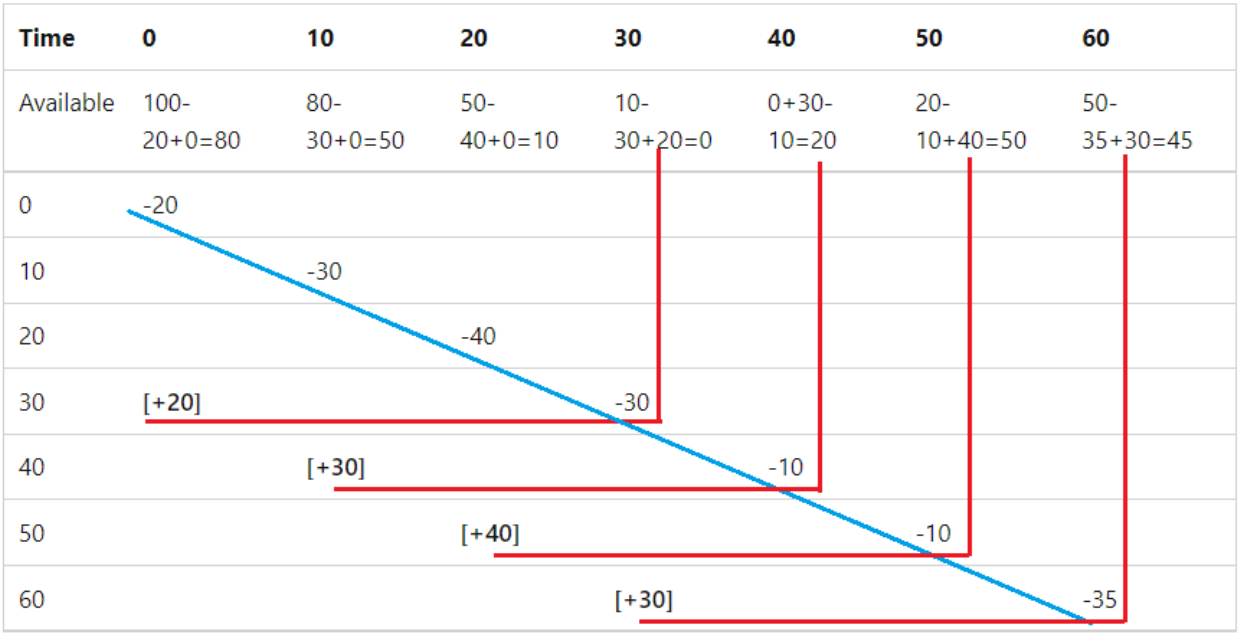
app.UseRateLimiter();

static string GetTicks() => (DateTime.Now.Ticks &
0x11111).ToString("00000");

app.MapGet("/", () => Results.Ok($"Fixed Window Limiter {GetTicks()}"))
                            .RequireRateLimiting(fixedPolicy);

app.Run();
```

UseRateLimiter must be called after `UseRouting` when rate limiting endpoint specific APIs are used. For example, if the [EnableRateLimiting] attribute is used, `UseRateLimiter` must be called after `UseRouting`. When calling only global limiters, `UseRateLimiter` can be called before `UseRouting`.



Sliding window limiter

A sliding window algorithm:

- Is similar to the fixed window limiter but adds segments per window. The window slides one segment each segment interval. The segment interval is (window time)/(segments per window).
- Limits the requests for a window to `permitLimit` requests.
- Each time window is divided in `n` segments per window.
- Requests taken from the expired time segment one window back (`n` segments prior to the current segment) are added to the current segment. We refer to the most expired time segment one window back as the expired segment.

Consider the following table that shows a sliding window limiter with a 30-second window, three segments per window, and a limit of 100 requests:

- The top row and first column shows the time segment.
- The second row shows the remaining requests available. The remaining requests are calculated as the available requests minus the processed requests plus the recycled requests.
- Requests at each time moves along the diagonal blue line.
- From time 30 on, the request taken from the expired time segment are added back to the request limit, as shown in the red lines.

The following table shows the data in the previous graph in a different format. The **Available** column shows the requests available from the previous segment (The **Carry over** from the previous row). The first row shows 100 available requests because there's no previous segment.

Expand table

Time	Available	Taken	Recycled from expired	Carry over
0	100	20	0	80
10	80	30	0	50
20	50	40	0	10
30	10	30	20	0
40	0	10	30	20
50	20	10	40	50
60	50	35	30	45

The following code uses the sliding window rate limiter:

C#

```
using Microsoft.AspNetCore.RateLimiting;
using System.Threading.RateLimiting;
using WebRateLimitAuth.Models;

var builder = WebApplication.CreateBuilder(args);
```

```
var myOptions = new MyRateLimitOptions();
builder.Configuration.GetSection(MyRateLimitOptions.MyRateLimit).Bind(myOpti
ons);
var slidingPolicy = "sliding";

builder.Services.AddRateLimiter(_ => _
    .AddSlidingWindowLimiter(policyName: slidingPolicy, options =>
    {
        options.PermitLimit = myOptions.PermitLimit;
        options.Window = TimeSpan.FromSeconds(myOptions.Window);
        options.SegmentsPerWindow = myOptions.SegmentsPerWindow;
        options.QueueProcessingOrder = QueueProcessingOrder.OldestFirst;
        options.QueueLimit = myOptions.QueueLimit;
    }));

var app = builder.Build();

app.UseRateLimiter();

static string GetTicks() => (DateTime.Now.Ticks &
0x11111).ToString("00000");

app.MapGet("/", () => Results.Ok($"Sliding Window Limiter {GetTicks()}"))
                          .RequireRateLimiting(slidingPolicy);

app.Run();
```

Token bucket limiter

The token bucket limiter is similar to the sliding window limiter, but rather than adding back the requests taken from the expired segment, a fixed number of tokens are added each replenishment period. The tokens added each segment can't increase the available tokens to a number higher than the token bucket limit. The following table shows a token bucket limiter with a limit of 100 tokens and a 10-second replenishment period.

Expand table

Time	Available	Taken	Added	Carry over
0	100	20	0	80
10	80	10	20	90
20	90	5	15	100
30	100	30	20	90
40	90	6	16	100
50	100	40	20	80

Time	Available	Taken	Added	Carry over
60	80	50	20	50

The following code uses the token bucket limiter:

C#

```
using Microsoft.AspNetCore.RateLimiting;
using System.Threading.RateLimiting;
using WebRateLimitAuth.Models;

var builder = WebApplication.CreateBuilder(args);

var tokenPolicy = "token";
var myOptions = new MyRateLimitOptions();
builder.Configuration.GetSection(MyRateLimitOptions.MyRateLimit).Bind(myOpti
ons);

builder.Services.AddRateLimiter(_ => _
    .AddTokenBucketLimiter(policyName: tokenPolicy, options =>
    {
        options.TokenLimit = myOptions.TokenLimit;
        options.QueueProcessingOrder = QueueProcessingOrder.OldestFirst;
        options.QueueLimit = myOptions.QueueLimit;
        options.ReplenishmentPeriod =
TimeSpan.FromSeconds(myOptions.ReplenishmentPeriod);
        options.TokensPerPeriod = myOptions.TokensPerPeriod;
        options.AutoReplenishment = myOptions.AutoReplenishment;
    }));

var app = builder.Build();

app.UseRateLimiter();

static string GetTicks() => (DateTime.Now.Ticks &
0x11111).ToString("00000");

app.MapGet("/", () => Results.Ok($"Token Limiter {GetTicks()}"))
                            .RequireRateLimiting(tokenPolicy);

app.Run();
```

When AutoReplenishment is set to `true`, an internal timer replenishes the tokens every ReplenishmentPeriod; when set to `false`, the app must call TryReplenish on the limiter.

Concurrency limiter

The concurrency limiter limits the number of concurrent requests. Each request reduces the concurrency limit by one. When a request completes, the limit is increased by one.

Unlike the other requests limiters that limit the total number of requests for a specified period, the concurrency limiter limits only the number of concurrent requests and doesn't cap the number of requests in a time period.

The following code uses the concurrency limiter:

C#

```
using Microsoft.AspNetCore.RateLimiting;
using System.Threading.RateLimiting;
using WebRateLimitAuth.Models;

var builder = WebApplication.CreateBuilder(args);

var concurrencyPolicy = "Concurrency";
var myOptions = new MyRateLimitOptions();
builder.Configuration.GetSection(MyRateLimitOptions.MyRateLimit).Bind(myOpti
ons);

builder.Services.AddRateLimiter(_ => _
    .AddConcurrencyLimiter(policyName: concurrencyPolicy, options =>
    {
        options.PermitLimit = myOptions.PermitLimit;
        options.QueueProcessingOrder = QueueProcessingOrder.OldestFirst;
        options.QueueLimit = myOptions.QueueLimit;
    }));

var app = builder.Build();

app.UseRateLimiter();

static string GetTicks() => (DateTime.Now.Ticks &
0x11111).ToString("00000");

app.MapGet("/", async () =>
{
    await Task.Delay(500);
    return Results.Ok($"Concurrency Limiter {GetTicks()}");

}).RequireRateLimiting(concurrencyPolicy);

app.Run();
```

Create chained limiters

The CreateChained API allows passing in multiple PartitionedRateLimiter which are combined into one `PartitionedRateLimiter`. The combined limiter runs all the input limiters in sequence.

The following code uses `CreateChained`:

C#

```
using System.Globalization;
using System.Threading.RateLimiting;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRateLimiter(_ =>
{
    _.OnRejected = (context, _) =>
    {
        if (context.Lease.TryGetMetadata(MetadataName.RetryAfter, out var
retryAfter))
        {
            context.HttpContext.Response.Headers.RetryAfter =
                ((int)
retryAfter.TotalSeconds).ToString(NumberFormatInfo.InvariantInfo);
        }

        context.HttpContext.Response.StatusCode =
StatusCodes.Status429TooManyRequests;
        context.HttpContext.Response.WriteAsync("Too many requests. Please
try again later.");

        return new ValueTask();
    };
    _.GlobalLimiter = PartitionedRateLimiter.CreateChained(
        PartitionedRateLimiter.Create<HttpContext, string>(httpContext =>
        {
            var userAgent =
httpContext.Request.Headers.UserAgent.ToString();

            return RateLimitPartition.GetFixedWindowLimiter
            (userAgent, _ =>
                new FixedWindowRateLimiterOptions
                {
                    AutoReplenishment = true,
                    PermitLimit = 4,
                    Window = TimeSpan.FromSeconds(2)
                });
        }),
        PartitionedRateLimiter.Create<HttpContext, string>(httpContext =>
        {
            var userAgent =
httpContext.Request.Headers.UserAgent.ToString();

            return RateLimitPartition.GetFixedWindowLimiter
            (userAgent, _ =>
                new FixedWindowRateLimiterOptions
                {
                    AutoReplenishment = true,
                    PermitLimit = 20,
                    Window = TimeSpan.FromSeconds(30)
                });
```

```
        }));
});

var app = builder.Build();
app.UseRateLimiter();

static string GetTicks() => (DateTime.Now.Ticks &
0x11111).ToString("00000");

app.MapGet("/", () => Results.Ok($"Hello {GetTicks()}"));

app.Run();
```

For more information, see the CreateChained source code

`EnableRateLimiting` and `DisableRateLimiting` attributes

The [EnableRateLimiting] and [DisableRateLimiting] attributes can be applied to a Controller, action method, or Razor Page. For Razor Pages, the attribute must be applied to the Razor Page and not the page handlers. For example, `[EnableRateLimiting]` can't be applied to `OnGet`, `OnPost`, or any other page handler.

The `[DisableRateLimiting]` attribute ***disables*** rate limiting to the Controller, action method, or Razor Page regardless of named rate limiters or global limiters applied. For example, consider the following code which calls RequireRateLimiting to apply the `fixedPolicy` rate limiting to all controller endpoints:

C#

```
using Microsoft.AspNetCore.RateLimiting;
using System.Threading.RateLimiting;
using WebRateLimitAuth.Models;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();
builder.Services.AddControllersWithViews();

builder.Services.Configure<MyRateLimitOptions>(
    builder.Configuration.GetSection(MyRateLimitOptions.MyRateLimit));

var myOptions = new MyRateLimitOptions();
builder.Configuration.GetSection(MyRateLimitOptions.MyRateLimit).Bind(myOpti
ons);
var fixedPolicy = "fixed";

builder.Services.AddRateLimiter(_ => _
```

```
    .AddFixedWindowLimiter(policyName: fixedPolicy, options =>
    {
        options.PermitLimit = myOptions.PermitLimit;
        options.Window = TimeSpan.FromSeconds(myOptions.Window);
        options.QueueProcessingOrder = QueueProcessingOrder.OldestFirst;
        options.QueueLimit = myOptions.QueueLimit;
    }));

var slidingPolicy = "sliding";

builder.Services.AddRateLimiter(_ => _
    .AddSlidingWindowLimiter(policyName: slidingPolicy, options =>
    {
        options.PermitLimit = myOptions.SlidingPermitLimit;
        options.Window = TimeSpan.FromSeconds(myOptions.Window);
        options.SegmentsPerWindow = myOptions.SegmentsPerWindow;
        options.QueueProcessingOrder = QueueProcessingOrder.OldestFirst;
        options.QueueLimit = myOptions.QueueLimit;
    }));

var app = builder.Build();
app.UseRateLimiter();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.MapRazorPages().RequireRateLimiting(slidingPolicy);
app.MapDefaultControllerRoute().RequireRateLimiting(fixedPolicy);

app.Run();
```

In the following code, `[DisableRateLimiting]` disables rate limiting and overrides `[EnableRateLimiting("fixed")]` applied to the `Home2Controller` and `app.MapDefaultControllerRoute().RequireRateLimiting(fixedPolicy)` called in `Program.cs`:

C#

```
[EnableRateLimiting("fixed")]
public class Home2Controller : Controller
{
    private readonly ILogger<Home2Controller> _logger;

    public Home2Controller(ILogger<Home2Controller> logger)
    {
        _logger = logger;
```

```
    }

    public ActionResult Index()
    {
        return View();
    }

    [EnableRateLimiting("sliding")]
    public ActionResult Privacy()
    {
        return View();
    }

    [DisableRateLimiting]
    public ActionResult NoLimit()
    {
        return View();
    }

    [ResponseCache(Duration = 0, Location = ResponseCacheLocation.None,
NoStore = true)]
    public IActionResult Error()
    {
        return View(new ErrorViewModel { RequestId = Activity.Current?.Id ??
HttpContext.TraceIdentifier });
    }
}
```

In the preceding code, the `[EnableRateLimiting("sliding")]` is ***not*** applied to the `Privacy` action method because `Program.cs` called `app.MapDefaultControllerRoute().RequireRateLimiting(fixedPolicy)`.

Consider the following code which doesn't call `RequireRateLimiting` on `MapRazorPages` or `MapDefaultControllerRoute`:

C#

```
using Microsoft.AspNetCore.RateLimiting;
using System.Threading.RateLimiting;
using WebRateLimitAuth.Models;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();
builder.Services.AddControllersWithViews();

builder.Services.Configure<MyRateLimitOptions>(
    builder.Configuration.GetSection(MyRateLimitOptions.MyRateLimit));

var myOptions = new MyRateLimitOptions();
builder.Configuration.GetSection(MyRateLimitOptions.MyRateLimit).Bind(myOpti
```

```
ons);
var fixedPolicy = "fixed";

builder.Services.AddRateLimiter(_ => _
    .AddFixedWindowLimiter(policyName: fixedPolicy, options =>
    {
        options.PermitLimit = myOptions.PermitLimit;
        options.Window = TimeSpan.FromSeconds(myOptions.Window);
        options.QueueProcessingOrder = QueueProcessingOrder.OldestFirst;
        options.QueueLimit = myOptions.QueueLimit;
    }));

var slidingPolicy = "sliding";

builder.Services.AddRateLimiter(_ => _
    .AddSlidingWindowLimiter(policyName: slidingPolicy, options =>
    {
        options.PermitLimit = myOptions.SlidingPermitLimit;
        options.Window = TimeSpan.FromSeconds(myOptions.Window);
        options.SegmentsPerWindow = myOptions.SegmentsPerWindow;
        options.QueueProcessingOrder = QueueProcessingOrder.OldestFirst;
        options.QueueLimit = myOptions.QueueLimit;
    }));

var app = builder.Build();

app.UseRateLimiter();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.MapRazorPages();
app.MapDefaultControllerRoute();  // RequireRateLimiting not called

app.Run();
```

Consider the following controller:

C#

```
[EnableRateLimiting("fixed")]
public class Home2Controller : Controller
{
    private readonly ILogger<Home2Controller> _logger;

    public Home2Controller(ILogger<Home2Controller> logger)
    {
```

```
        _logger = logger;
    }

    public ActionResult Index()
    {
        return View();
    }

    [EnableRateLimiting("sliding")]
    public ActionResult Privacy()
    {
        return View();
    }

    [DisableRateLimiting]
    public ActionResult NoLimit()
    {
        return View();
    }

    [ResponseCache(Duration = 0, Location = ResponseCacheLocation.None,
NoStore = true)]
    public IActionResult Error()
    {
        return View(new ErrorViewModel { RequestId = Activity.Current?.Id ??
HttpContext.TraceIdentifier });
    }
}
```

In the preceding controller:

- The `"fixed"` policy rate limiter is applied to all action methods that don't have `EnableRateLimiting` and `DisableRateLimiting` attributes.
- The `"sliding"` policy rate limiter is applied to the `Privacy` action.
- Rate limiting is disabled on the `NoLimit` action method.

Applying attributes to Razor Pages

For Razor Pages, the attribute must be applied to the Razor Page and not the page handlers. For example, `[EnableRateLimiting]` can't be applied to `OnGet`, `OnPost`, or any other page handler.

The `DisableRateLimiting` attribute disables rate limiting on a Razor Page. `EnableRateLimiting` is only applied to a Razor Page if `MapRazorPages().RequireRateLimiting(Policy)` has ***not*** been called.

Limiter algorithm comparison

The fixed, sliding, and token limiters all limit the maximum number of requests in a time period. The concurrency limiter limits only the number of concurrent requests and doesn't cap the number of requests in a time period. The cost of an endpoint should be considered when selecting a limiter. The cost of an endpoint includes the resources used, for example, time, data access, CPU, and I/O.

Rate limiter samples

The following samples aren't meant for production code but are examples on how to use the limiters.

Limiter with `OnRejected`, `RetryAfter`, and `GlobalLimiter`

The following sample:

- Creates a RateLimiterOptions.OnRejected callback that is called when a request exceeds the specified limit. `retryAfter` can be used with the TokenBucketRateLimiter, FixedWindowLimiter, and SlidingWindowLimiter because these algorithms are able to estimate when more permits will be added. The `ConcurrencyLimiter` has no way of calculating when permits will be available.
- Adds the following limiters:
  - A `SampleRateLimiterPolicy` which implements the `IRateLimiterPolicy<TPartitionKey>` interface. The `SampleRateLimiterPolicy` class is shown later in this article.
  - A `SlidingWindowLimiter`:
    - With a partition for each authenticated user.
    - One shared partition for all anonymous users.
  - A GlobalLimiter that is applied to all requests. The global limiter will be executed first, followed by the endpoint-specific limiter, if one exists. The `GlobalLimiter` creates a partition for each IPAddress.

C#

```
// Preceding code removed for brevity.

The `SampleRateLimiterPolicy` class

C#

```
using System.Threading.RateLimiting;
using Microsoft.AspNetCore.RateLimiting;
using Microsoft.Extensions.Options;
using WebRateLimitAuth.Models;

namespace WebRateLimitAuth;

public class SampleRateLimiterPolicy : IRateLimiterPolicy<string>
```

```
{
    private Func<OnRejectedContext, CancellationToken, ValueTask>?
_onRejected;
    private readonly MyRateLimitOptions _options;

    public SampleRateLimiterPolicy(ILogger<SampleRateLimiterPolicy> logger,
                                   IOptions<MyRateLimitOptions> options)
    {
        _onRejected = (ctx, token) =>
        {
            ctx.HttpContext.Response.StatusCode =
StatusCodes.Status429TooManyRequests;
            logger.LogWarning($"Request rejected by
{nameof(SampleRateLimiterPolicy)}");
            return ValueTask.CompletedTask;
        };
        _options = options.Value;
    }

    public Func<OnRejectedContext, CancellationToken, ValueTask>? OnRejected
=> _onRejected;

    public RateLimitPartition<string> GetPartition(HttpContext httpContext)
    {
        return RateLimitPartition.GetSlidingWindowLimiter(string.Empty,
            _ => new SlidingWindowRateLimiterOptions
            {
                PermitLimit = _options.PermitLimit,
                QueueProcessingOrder = QueueProcessingOrder.OldestFirst,
                QueueLimit = _options.QueueLimit,
                Window = TimeSpan.FromSeconds(_options.Window),
                SegmentsPerWindow = _options.SegmentsPerWindow
            });
    }
}
```

In the preceding code, OnRejected uses OnRejectedContext to set the response status to 429 Too Many Requests. The default rejected status is 503 Service Unavailable.

Limiter with authorization

The following sample uses JSON Web Tokens (JWT) and creates a partition with the JWT access token. In a production app, the JWT would typically be provided by a server acting as a Security token service (STS). For local development, the dotnet user-jwts command line tool can be used to create and manage app-specific local JWTs.

C#

```
using System.Threading.RateLimiting;
using Microsoft.AspNetCore.Authentication;
```

```
using Microsoft.Extensions.Primitives;
using WebRateLimitAuth.Models;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddAuthorization();
builder.Services.AddAuthentication("Bearer").AddJwtBearer();

var myOptions = new MyRateLimitOptions();
builder.Configuration.GetSection(MyRateLimitOptions.MyRateLimit).Bind(myOpti
ons);
var jwtPolicyName = "jwt";

builder.Services.AddRateLimiter(limiterOptions =>
{
    limiterOptions.RejectionStatusCode =
StatusCodes.Status429TooManyRequests;
    limiterOptions.AddPolicy(policyName: jwtPolicyName, partitioner:
httpContext =>
    {
        var accessToken =
httpContext.Features.Get<IAuthenticateResultFeature>()?

.AuthenticateResult?.Properties?.GetTokenValue("access_token")?.ToString()
                           ?? string.Empty;

        if (!StringValues.IsNullOrEmpty(accessToken))
        {
            return RateLimitPartition.GetTokenBucketLimiter(accessToken, _
=>
                new TokenBucketRateLimiterOptions
                {
                    TokenLimit = myOptions.TokenLimit2,
                    QueueProcessingOrder = QueueProcessingOrder.OldestFirst,
                    QueueLimit = myOptions.QueueLimit,
                    ReplenishmentPeriod =
TimeSpan.FromSeconds(myOptions.ReplenishmentPeriod),
                    TokensPerPeriod = myOptions.TokensPerPeriod,
                    AutoReplenishment = myOptions.AutoReplenishment
                });
        }

        return RateLimitPartition.GetTokenBucketLimiter("Anon", _ =>
            new TokenBucketRateLimiterOptions
            {
                TokenLimit = myOptions.TokenLimit,
                QueueProcessingOrder = QueueProcessingOrder.OldestFirst,
                QueueLimit = myOptions.QueueLimit,
                ReplenishmentPeriod =
TimeSpan.FromSeconds(myOptions.ReplenishmentPeriod),
                TokensPerPeriod = myOptions.TokensPerPeriod,
                AutoReplenishment = true
            });
    });
});
```

```
var app = builder.Build();

app.UseAuthorization();
app.UseRateLimiter();

app.MapGet("/", () => "Hello, World!");

app.MapGet("/jwt", (HttpContext context) => $"Hello
{GetUserEndPointMethod(context)}")
    .RequireRateLimiting(jwtPolicyName)
    .RequireAuthorization();

app.MapPost("/post", (HttpContext context) => $"Hello
{GetUserEndPointMethod(context)}")
    .RequireRateLimiting(jwtPolicyName)
    .RequireAuthorization();

app.Run();

static string GetUserEndPointMethod(HttpContext context) =>
    $"Hello {context.User.Identity?.Name ?? "Anonymous"} " +
    $"Endpoint:{context.Request.Path} Method: {context.Request.Method}";
```

Limiter with `ConcurrencyLimiter`, `TokenBucketRateLimiter`, and authorization

The following sample:

- Adds a `ConcurrencyLimiter` with a policy name of `"get"` that is used on the Razor Pages.
- Adds a `TokenBucketRateLimiter` with a partition for each authorized user and a partition for all anonymous users.
- Sets RateLimiterOptions.RejectionStatusCode to 429 Too Many Requests.

C#

```
var getPolicyName = "get";
var postPolicyName = "post";
var myOptions = new MyRateLimitOptions();
builder.Configuration.GetSection(MyRateLimitOptions.MyRateLimit).Bind(myOpti
ons);

builder.Services.AddRateLimiter(_ => _
    .AddConcurrencyLimiter(policyName: getPolicyName, options =>
    {
        options.PermitLimit = myOptions.PermitLimit;
        options.QueueProcessingOrder = QueueProcessingOrder.OldestFirst;
        options.QueueLimit = myOptions.QueueLimit;
```

```
    })
    .AddPolicy(policyName: postPolicyName, partitioner: httpContext =>
    {
        string userName = httpContext.User.Identity?.Name ?? string.Empty;

        if (!StringValues.IsNullOrEmpty(userName))
        {
            return RateLimitPartition.GetTokenBucketLimiter(userName, _ =>
                new TokenBucketRateLimiterOptions
                {
                    TokenLimit = myOptions.TokenLimit2,
                    QueueProcessingOrder = QueueProcessingOrder.OldestFirst,
                    QueueLimit = myOptions.QueueLimit,
                    ReplenishmentPeriod =
TimeSpan.FromSeconds(myOptions.ReplenishmentPeriod),
                    TokensPerPeriod = myOptions.TokensPerPeriod,
                    AutoReplenishment = myOptions.AutoReplenishment
                });
        }

        return RateLimitPartition.GetTokenBucketLimiter("Anon", _ =>
            new TokenBucketRateLimiterOptions
            {
                TokenLimit = myOptions.TokenLimit,
                QueueProcessingOrder = QueueProcessingOrder.OldestFirst,
                QueueLimit = myOptions.QueueLimit,
                ReplenishmentPeriod =
TimeSpan.FromSeconds(myOptions.ReplenishmentPeriod),
                TokensPerPeriod = myOptions.TokensPerPeriod,
                AutoReplenishment = true
            });
    }));
```

See the samples repository for the complete Program.cs file.

Testing endpoints with rate limiting

Before deploying an app using rate limiting to production, stress test the app to validate the rate limiters and options used. For example, create a JMeter script with a tool like BlazeMeter or Apache JMeter HTTP(S) Test Script Recorder and load the script to Azure Load Testing.

Creating partitions with user input makes the app vulnerable to Denial of Service (DoS) Attacks. For example, creating partitions on client IP addresses makes the app vulnerable to Denial of Service Attacks that employ IP Source Address Spoofing. For more information, see BCP 38 RFC 2827 Network Ingress Filtering: Defeating Denial of Service Attacks that employ IP Source Address Spoofing.

Middleware in Minimal API apps

Article • 07/26/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

WebApplication automatically adds the following middleware in Minimal API applications depending on certain conditions:

- UseDeveloperExceptionPage is added first when the HostingEnvironment is `"Development"`.
- UseRouting is added second if user code didn't already call `UseRouting` and if there are endpoints configured, for example `app.MapGet`.
- UseEndpoints is added at the end of the middleware pipeline if any endpoints are configured.
- UseAuthentication is added immediately after `UseRouting` if user code didn't already call `UseAuthentication` and if IAuthenticationSchemeProvider can be detected in the service provider. `IAuthenticationSchemeProvider` is added by default when using AddAuthentication, and services are detected using IServiceProviderIsService.
- UseAuthorization is added next if user code didn't already call `UseAuthorization` and if IAuthorizationHandlerProvider can be detected in the service provider. `IAuthorizationHandlerProvider` is added by default when using AddAuthorization, and services are detected using `IServiceProviderIsService`.
- User configured middleware and endpoints are added between `UseRouting` and `UseEndpoints`.

The following code is effectively what the automatic middleware being added to the app produces:

C#

```
if (isDevelopment)
{
    app.UseDeveloperExceptionPage();
}
```

```
app.UseRouting();

if (isAuthenticationConfigured)
{
    app.UseAuthentication();
}

if (isAuthorizationConfigured)
{
    app.UseAuthorization();
}

// user middleware/endpoints
app.CustomMiddleware(...);
app.MapGet("/", () => "hello world");
// end user middleware/endpoints

app.UseEndpoints(e => {});
```

In some cases, the default middleware configuration isn't correct for the app and requires modification. For example, UseCors should be called before UseAuthentication and UseAuthorization. The app needs to call `UseAuthentication` and `UseAuthorization` if `UseCors` is called:

C#

```
app.UseCors();
app.UseAuthentication();
app.UseAuthorization();
```

If middleware should be run before route matching occurs, UseRouting should be called and the middleware should be placed before the call to `UseRouting`. UseEndpoints isn't required in this case as it is automatically added as described previously:

C#

```
app.Use((context, next) =>
{
    return next(context);
});

app.UseRouting();

// other middleware and endpoints
```

When adding a terminal middleware:

- The middleware must be added after `UseEndpoints`.
- The app needs to call `UseRouting` and `UseEndpoints` so that the terminal middleware can be placed at the correct location.

C#

```
app.UseRouting();

app.MapGet("/", () => "hello world");

app.UseEndpoints(e => {});

app.Run(context =>
{
    context.Response.StatusCode = 404;
    return Task.CompletedTask;
});
```

Terminal middleware is middleware that runs if no endpoint handles the request.

Test ASP.NET Core middleware

Article • 01/11/2024

By Chris Ross

Middleware can be tested in isolation with TestServer. It allows you to:

- Instantiate an app pipeline containing only the components that you need to test.
- Send custom requests to verify middleware behavior.

Advantages:

- Requests are sent in-memory rather than being serialized over the network.
- This avoids additional concerns, such as port management and HTTPS certificates.
- Exceptions in the middleware can flow directly back to the calling test.
- It's possible to customize server data structures, such as HttpContext, directly in the test.

Set up the TestServer

In the test project, create a test:

- Build and start a host that uses TestServer.
- Add any required services that the middleware uses.
- Add a package reference to the project for the Microsoft.AspNetCore.TestHost NuGet package.
- Configure the processing pipeline to use the middleware for the test.

```
C#

[Fact]
public async Task MiddlewareTest_ReturnsNotFoundForRequest()
{
```

```
    using var host = await new HostBuilder()
        .ConfigureWebHost(webBuilder =>
        {
            webBuilder
                .UseTestServer()
                .ConfigureServices(services =>
                {
                    services.AddMyServices();
                })
                .Configure(app =>
                {
                    app.UseMiddleware<MyMiddleware>();
                });
        })
        .StartAsync();

    ...
}
```

> **Note**
>
> For guidance on adding packages to .NET apps, see the articles under *Install and manage packages* at **Package consumption workflow (NuGet documentation)**. Confirm correct package versions at **NuGet.org**.

Send requests with HttpClient

Send a request using HttpClient:

C#

```
[Fact]
public async Task MiddlewareTest_ReturnsNotFoundForRequest()
{
    using var host = await new HostBuilder()
        .ConfigureWebHost(webBuilder =>
        {
            webBuilder
                .UseTestServer()
                .ConfigureServices(services =>
                {
                    services.AddMyServices();
                })
                .Configure(app =>
                {
                    app.UseMiddleware<MyMiddleware>();
                });
        })
        .StartAsync();
```

```
    var response = await host.GetTestClient().GetAsync("/");

    ...
}
```

Assert the result. First, make an assertion the opposite of the result that you expect. An initial run with a false positive assertion confirms that the test fails when the middleware is performing correctly. Run the test and confirm that the test fails.

In the following example, the middleware should return a 404 status code (*Not Found*) when the root endpoint is requested. Make the first test run with `Assert.NotEqual( ... );`, which should fail:

C#

```
[Fact]
public async Task MiddlewareTest_ReturnsNotFoundForRequest()
{
    using var host = await new HostBuilder()
        .ConfigureWebHost(webBuilder =>
        {
            webBuilder
                .UseTestServer()
                .ConfigureServices(services =>
                {
                    services.AddMyServices();
                })
                .Configure(app =>
                {
                    app.UseMiddleware<MyMiddleware>();
                });
        })
        .StartAsync();

    var response = await host.GetTestClient().GetAsync("/");

    Assert.NotEqual(HttpStatusCode.NotFound, response.StatusCode);
}
```

Change the assertion to test the middleware under normal operating conditions. The final test uses `Assert.Equal( ... );`. Run the test again to confirm that it passes.

C#

```
[Fact]
public async Task MiddlewareTest_ReturnsNotFoundForRequest()
{
    using var host = await new HostBuilder()
```

```
        .ConfigureWebHost(webBuilder =>
        {
            webBuilder
                .UseTestServer()
                .ConfigureServices(services =>
                {
                    services.AddMyServices();
                })
                .Configure(app =>
                {
                    app.UseMiddleware<MyMiddleware>();
                });
        })
        .StartAsync();

    var response = await host.GetTestClient().GetAsync("/");

    Assert.Equal(HttpStatusCode.NotFound, response.StatusCode);
}
```

Send requests with HttpContext

A test app can also send a request using SendAsync(Action<HttpContext>, CancellationToken). In the following example, several checks are made when `https://example.com/A/Path/?and=query` is processed by the middleware:

C#

```
[Fact]
public async Task TestMiddleware_ExpectedResponse()
{
    using var host = await new HostBuilder()
        .ConfigureWebHost(webBuilder =>
        {
            webBuilder
                .UseTestServer()
                .ConfigureServices(services =>
                {
                    services.AddMyServices();
                })
                .Configure(app =>
                {
                    app.UseMiddleware<MyMiddleware>();
                });
        })
        .StartAsync();

    var server = host.GetTestServer();
    server.BaseAddress = new Uri("https://example.com/A/Path/");

    var context = await server.SendAsync(c =>
```

```
    {
        c.Request.Method = HttpMethods.Post;
        c.Request.Path = "/and/file.txt";
        c.Request.QueryString = new QueryString("?and=query");
    });

    Assert.True(context.RequestAborted.CanBeCanceled);
    Assert.Equal(HttpProtocol.Http11, context.Request.Protocol);
    Assert.Equal("POST", context.Request.Method);
    Assert.Equal("https", context.Request.Scheme);
    Assert.Equal("example.com", context.Request.Host.Value);
    Assert.Equal("/A/Path", context.Request.PathBase.Value);
    Assert.Equal("/and/file.txt", context.Request.Path.Value);
    Assert.Equal("?and=query", context.Request.QueryString.Value);
    Assert.NotNull(context.Request.Body);
    Assert.NotNull(context.Request.Headers);
    Assert.NotNull(context.Response.Headers);
    Assert.NotNull(context.Response.Body);
    Assert.Equal(404, context.Response.StatusCode);
    Assert.Null(context.Features.Get<IHttpResponseFeature>().ReasonPhrase);
}
```

SendAsync permits direct configuration of an HttpContext object rather than using the HttpClient abstractions. Use SendAsync to manipulate structures only available on the server, such as HttpContext.Items or HttpContext.Features.

As with the earlier example that tested for a *404 - Not Found* response, check the opposite for each `Assert` statement in the preceding test. The check confirms that the test fails correctly when the middleware is operating normally. After you've confirmed that the false positive test works, set the final `Assert` statements for the expected conditions and values of the test. Run it again to confirm that the test passes.

Add request routes

Additional routes can be added by configuration using the test `HttpClient`:

C#

```
    [Fact]
    public async Task TestWithEndpoint_ExpectedResponse ()
    {
        using var host = await new HostBuilder()
            .ConfigureWebHost(webBuilder =>
            {
                webBuilder
                    .UseTestServer()
                    .ConfigureServices(services =>
                    {
                        services.AddRouting();
```

```
                    })
                    .Configure(app =>
                    {
                        app.UseRouting();
                        app.UseMiddleware<MyMiddleware>();
                        app.UseEndpoints(endpoints =>
                        {
                            endpoints.MapGet("/hello", () =>
                                TypedResults.Text("Hello Tests"));
                        });
                    });
            })
            .StartAsync();

        var client = host.GetTestClient();

        var response = await client.GetAsync("/hello");

        Assert.True(response.IsSuccessStatusCode);
        var responseBody = await response.Content.ReadAsStringAsync();
        Assert.Equal("Hello Tests", responseBody);
```

Additional routes can also be added using the approach `server.SendAsync`.

TestServer limitations

TestServer:

- Was created to replicate server behaviors to test middleware.
- Does ***not*** try to replicate all HttpClient behaviors.
- Attempts to give the client access to as much control over the server as possible, and with as much visibility into what's happening on the server as possible. For example it may throw exceptions not normally thrown by `HttpClient` in order to directly communicate server state.
- Doesn't set some transport specific headers by default as those aren't usually relevant to middleware. For more information, see the next section.
- Ignores the `Stream` position passed through StreamContent. HttpClient sends the entire stream from the start position, even when positioning is set. For more information, see this GitHub issue.

Content-Length and Transfer-Encoding headers

TestServer does ***not*** set transport related request or response headers such as Content-Length or Transfer-Encoding. Applications should avoid depending on these headers because their usage varies by client, scenario, and protocol. If `Content-Length`

and `Transfer-Encoding` are necessary to test a specific scenario, they can be specified in the test when composing the HttpRequestMessage or HttpContext. For more information, see the following GitHub issues:

- dotnet/aspnetcore#21677
- dotnet/aspnetcore#18463
- dotnet/aspnetcore#13273

Response Caching Middleware in ASP.NET Core

Article • 07/16/2024

By John Luo and Rick Anderson

This article explains how to configure Response Caching Middleware in an ASP.NET Core app. The middleware determines when responses are cacheable, stores responses, and serves responses from cache. For an introduction to HTTP caching and the [ResponseCache] attribute, see Response Caching.

The Response caching middleware:

- Enables caching server responses based on HTTP cache headers. Implements the standard HTTP caching semantics. Caches based on HTTP cache headers like proxies do.
- Is typically not beneficial for UI apps such as Razor Pages because browsers generally set request headers that prevent caching. Output caching, which is available in ASP.NET Core 7.0 and later, benefits UI apps. With output caching, configuration decides what should be cached independently of HTTP headers.
- May be beneficial for public GET or HEAD API requests from clients where the Conditions for caching are met.

To test response caching, use Fiddler, or another tool that can explicitly set request headers. Setting headers explicitly is preferred for testing caching. For more information, see Troubleshooting.

Configuration

In `Program.cs`, add the Response Caching Middleware services AddResponseCaching to the service collection and configure the app to use the middleware with the UseResponseCaching extension method. `UseResponseCaching` adds the middleware to the request processing pipeline:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddResponseCaching();

var app = builder.Build();
```

```
app.UseHttpsRedirection();

// UseCors must be called before UseResponseCaching
//app.UseCors();

app.UseResponseCaching();
```

> ⚠ **Warning**
>
> UseCors must be called before UseResponseCaching when using CORS middleware.

The sample app adds headers to control caching on subsequent requests:

- Cache-Control: Caches cacheable responses for up to 10 seconds.
- Vary: Configures the middleware to serve a cached response only if the Accept-Encoding header of subsequent requests matches that of the original request.

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddResponseCaching();

var app = builder.Build();

app.UseHttpsRedirection();

// UseCors must be called before UseResponseCaching
//app.UseCors();

app.UseResponseCaching();

app.Use(async (context, next) =>
{
    context.Response.GetTypedHeaders().CacheControl =
        new Microsoft.Net.Http.Headers.CacheControlHeaderValue()
        {
            Public = true,
            MaxAge = TimeSpan.FromSeconds(10)
        };
    context.Response.Headers[Microsoft.Net.Http.Headers.HeaderNames.Vary] =
        new string[] { "Accept-Encoding" };

    await next();
});

app.MapGet("/", () => DateTime.Now.Millisecond);
```

```
app.Run();
```

The preceding headers are not written to the response and are overridden when a controller, action, or Razor Page:

- Has a [ResponseCache] attribute. This applies even if a property isn't set. For example, omitting the VaryByHeader property will cause the corresponding header to be removed from the response.

Response Caching Middleware only caches server responses that result in a 200 (OK) status code. Any other responses, including error pages, are ignored by the middleware.

> ⚠ **Warning**
>
> Responses containing content for authenticated clients must be marked as not cacheable to prevent the middleware from storing and serving those responses. See **Conditions for caching** for details on how the middleware determines if a response is cacheable.

The preceding code typically doesn't return a cached value to a browser. Use Fiddler or another tool that can explicitly set request headers and is preferred for testing caching. For more information, see Troubleshooting in this article.

Options

Response caching options are shown in the following table.

Expand table

Option	Description
MaximumBodySize	The largest cacheable size for the response body in bytes. The default value is `64 * 1024 * 1024` (64 MB).
SizeLimit	The size limit for the response cache middleware in bytes. The default value is `100 * 1024 * 1024` (100 MB).
UseCaseSensitivePaths	Determines if responses are cached on case-sensitive paths. The default value is `false`.

The following example configures the middleware to:

- Cache responses with a body size smaller than or equal to 1,024 bytes.

- Store the responses by case-sensitive paths. For example, `/page1` and `/Page1` are stored separately.

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddResponseCaching(options =>
{
    options.MaximumBodySize = 1024;
    options.UseCaseSensitivePaths = true;
});

var app = builder.Build();

app.UseHttpsRedirection();

// UseCors must be called before UseResponseCaching
//app.UseCors();

app.UseResponseCaching();

app.Use(async (context, next) =>
{
    context.Response.GetTypedHeaders().CacheControl =
        new Microsoft.Net.Http.Headers.CacheControlHeaderValue()
        {
            Public = true,
            MaxAge = TimeSpan.FromSeconds(10)
        };
    context.Response.Headers[Microsoft.Net.Http.Headers.HeaderNames.Vary] =
        new string[] { "Accept-Encoding" };

    await next(context);
});

app.MapGet("/", () => DateTime.Now.Millisecond);

app.Run();
```

VaryByQueryKeys

When using MVC, web API controllers, or Razor Pages page models, the [ResponseCache] attribute specifies the parameters necessary for setting the appropriate headers for response caching. The only parameter of the `[ResponseCache]` attribute that strictly requires the middleware is VaryByQueryKeys, which doesn't correspond to an actual HTTP header. For more information, see Response caching in ASP.NET Core.

When not using the `[ResponseCache]` attribute, response caching can be varied with `VaryByQueryKeys`. Use the ResponseCachingFeature directly from the HttpContext.Features:

```
C#

var responseCachingFeature =
context.HttpContext.Features.Get<IResponseCachingFeature>();

if (responseCachingFeature != null)
{
    responseCachingFeature.VaryByQueryKeys = new[] { "MyKey" };
}
```

Using a single value equal to `*` in `VaryByQueryKeys` varies the cache by all request query parameters.

HTTP headers used by Response Caching Middleware

The following table provides information on HTTP headers that affect response caching.

Expand table

Header	Details
`Authorization`	The response isn't cached if the header exists.
`Cache-Control`	The middleware only considers caching responses marked with the `public` cache directive. Control caching with the following parameters: • max-age • max-stale† • min-fresh • must-revalidate • no-cache • no-store • only-if-cached • private • public • s-maxage • proxy-revalidate‡ †If no limit is specified to `max-stale`, the middleware takes no action. ‡`proxy-revalidate` has the same effect as `must-revalidate`.

Header	Details
	For more information, see RFC 9111: Request Directives.
`Pragma`	A `Pragma: no-cache` header in the request produces the same effect as `Cache-Control: no-cache`. This header is overridden by the relevant directives in the `Cache-Control` header, if present. Considered for backward compatibility with HTTP/1.0.
`Set-Cookie`	The response isn't cached if the header exists. Any middleware in the request processing pipeline that sets one or more cookies prevents the Response Caching Middleware from caching the response (for example, the cookie-based TempData provider).
`Vary`	The `Vary` header is used to vary the cached response by another header. For example, cache responses by encoding by including the `Vary: Accept-Encoding` header, which caches responses for requests with headers `Accept-Encoding: gzip` and `Accept-Encoding: text/plain` separately. A response with a header value of `*` is never stored.
`Expires`	A response deemed stale by this header isn't stored or retrieved unless overridden by other `Cache-Control` headers.
`If-None-Match`	The full response is served from cache if the value isn't `*` and the `ETag` of the response doesn't match any of the values provided. Otherwise, a 304 (Not Modified) response is served.
`If-Modified-Since`	If the `If-None-Match` header isn't present, a full response is served from cache if the cached response date is newer than the value provided. Otherwise, a *304 - Not Modified* response is served.
`Date`	When serving from cache, the `Date` header is set by the middleware if it wasn't provided on the original response.
`Content-Length`	When serving from cache, the `Content-Length` header is set by the middleware if it wasn't provided on the original response.
`Age`	The `Age` header sent in the original response is ignored. The middleware computes a new value when serving a cached response.

Caching respects request Cache-Control directives

The middleware respects the rules of RFC 9111: HTTP Caching (Section 5.2. Cache-Control). The rules require a cache to honor a valid `Cache-Control` header sent by the client. Under the specification, a client can make requests with a `no-cache` header value

and force the server to generate a new response for every request. Currently, there's no developer control over this caching behavior when using the middleware because the middleware adheres to the official caching specification.

For more control over caching behavior, explore other caching features of ASP.NET Core. See the following topics:

- Cache in-memory in ASP.NET Core
- Distributed caching in ASP.NET Core
- Cache Tag Helper in ASP.NET Core MVC
- Distributed Cache Tag Helper in ASP.NET Core

Troubleshooting

The Response Caching Middleware uses IMemoryCache, which has a limited capacity. When the capacity is exceeded, the memory cache is compacted.

If caching behavior isn't as expected, confirm that responses are cacheable and capable of being served from the cache. Examine the request's incoming headers and the response's outgoing headers. Enable logging to help with debugging.

When testing and troubleshooting caching behavior, a browser typically sets request headers that prevent caching. For example, a browser may set the `Cache-Control` header to `no-cache` or `max-age=0` when refreshing a page. Fiddler and other tools can explicitly set request headers and are preferred for testing caching.

Conditions for caching

- The request must result in a server response with a 200 (OK) status code.
- The request method must be GET or HEAD.
- Response Caching Middleware must be placed before middleware that require caching. For more information, see ASP.NET Core Middleware.
- The `Authorization` header must not be present.
- `Cache-Control` header parameters must be valid, and the response must be marked `public` and not marked `private`.
- The `Pragma: no-cache` header must not be present if the `Cache-Control` header isn't present, as the `Cache-Control` header overrides the `Pragma` header when present.
- The `Set-Cookie` header must not be present.
- `Vary` header parameters must be valid and not equal to `*`.

- The `Content-Length` header value (if set) must match the size of the response body.
- The IHttpSendFileFeature isn't used.
- The response must not be stale as specified by the `Expires` header and the `max-age` and `s-maxage` cache directives.
- Response buffering must be successful. The size of the response must be smaller than the configured or default SizeLimit. The body size of the response must be smaller than the configured or default MaximumBodySize.
- The response must be cacheable according to RFC 9111: HTTP Caching. For example, the `no-store` directive must not exist in request or response header fields. See RFC 9111: HTTP Caching (Section 3: *Storing Responses in Caches*) for details.

> **Note**
>
> The Antiforgery system for generating secure tokens to prevent Cross-Site Request Forgery (CSRF) attacks sets the `Cache-Control` and `Pragma` headers to `no-cache` so that responses aren't cached. For information on how to disable antiforgery tokens for HTML form elements, see **Prevent Cross-Site Request Forgery (XSRF/CSRF) attacks in ASP.NET Core**.

Write custom ASP.NET Core middleware

Article • 07/26/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

By Fiyaz Hasan, Rick Anderson, and Steve Smith

Middleware is software that's assembled into an app pipeline to handle requests and responses. ASP.NET Core provides a rich set of built-in middleware components, but in some scenarios you might want to write a custom middleware.

This topic describes how to write *convention-based* middleware. For an approach that uses strong typing and per-request activation, see Factory-based middleware activation in ASP.NET Core.

Middleware class

Middleware is generally encapsulated in a class and exposed with an extension method. Consider the following inline middleware, which sets the culture for the current request from a query string:

C#

```
using System.Globalization;

var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

app.UseHttpsRedirection();
```

```
app.Use(async (context, next) =>
{
    var cultureQuery = context.Request.Query["culture"];
    if (!string.IsNullOrWhiteSpace(cultureQuery))
    {
        var culture = new CultureInfo(cultureQuery);

        CultureInfo.CurrentCulture = culture;
        CultureInfo.CurrentUICulture = culture;
    }

    // Call the next delegate/middleware in the pipeline.
    await next(context);
});

app.Run(async (context) =>
{
    await context.Response.WriteAsync(
        $"CurrentCulture.DisplayName:
{CultureInfo.CurrentCulture.DisplayName}");
});

app.Run();
```

The preceding highlighted inline middleware is used to demonstrate creating a middleware component by calling Microsoft.AspNetCore.Builder.UseExtensions.Use. The preceding `Use` extension method adds a middleware delegate defined in-line to the application's request pipeline.

There are two overloads available for the `Use` extension:

- One takes a HttpContext and a `Func<Task>`. Invoke the `Func<Task>` without any parameters.
- The other takes a `HttpContext` and a RequestDelegate. Invoke the `RequestDelegate` by passing the `HttpContext`.

Prefer using the later overload as it saves two internal per-request allocations that are required when using the other overload.

Test the middleware by passing in the culture. For example, request `https://localhost:5001/?culture=es-es`.

For ASP.NET Core's built-in localization support, see Globalization and localization in ASP.NET Core.

The following code moves the middleware delegate to a class:

```
C#
```

```
using System.Globalization;

namespace Middleware.Example;

public class RequestCultureMiddleware
{
    private readonly RequestDelegate _next;

    public RequestCultureMiddleware(RequestDelegate next)
    {
        _next = next;
    }

    public async Task InvokeAsync(HttpContext context)
    {
        var cultureQuery = context.Request.Query["culture"];
        if (!string.IsNullOrWhiteSpace(cultureQuery))
        {
            var culture = new CultureInfo(cultureQuery);

            CultureInfo.CurrentCulture = culture;
            CultureInfo.CurrentUICulture = culture;
        }

        // Call the next delegate/middleware in the pipeline.
        await _next(context);
    }
}
```

The middleware class must include:

- A public constructor with a parameter of type RequestDelegate.
- A public method named `Invoke` or `InvokeAsync`. This method must:
  - Return a `Task`.
  - Accept a first parameter of type HttpContext.

Additional parameters for the constructor and `Invoke`/`InvokeAsync` are populated by dependency injection (DI).

Typically, an extension method is created to expose the middleware through IApplicationBuilder:

C#

```
using System.Globalization;

namespace Middleware.Example;

public class RequestCultureMiddleware
{
```

```
    private readonly RequestDelegate _next;

    public RequestCultureMiddleware(RequestDelegate next)
    {
        _next = next;
    }

    public async Task InvokeAsync(HttpContext context)
    {
        var cultureQuery = context.Request.Query["culture"];
        if (!string.IsNullOrWhiteSpace(cultureQuery))
        {
            var culture = new CultureInfo(cultureQuery);

            CultureInfo.CurrentCulture = culture;
            CultureInfo.CurrentUICulture = culture;
        }

        // Call the next delegate/middleware in the pipeline.
        await _next(context);
    }
}

public static class RequestCultureMiddlewareExtensions
{
    public static IApplicationBuilder UseRequestCulture(
        this IApplicationBuilder builder)
    {
        return builder.UseMiddleware<RequestCultureMiddleware>();
    }
}
```

The following code calls the middleware from `Program.cs`:

C#

```
using Middleware.Example;
using System.Globalization;

var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

app.UseHttpsRedirection();

app.UseRequestCulture();

app.Run(async (context) =>
{
    await context.Response.WriteAsync(
        $"CurrentCulture.DisplayName:
{CultureInfo.CurrentCulture.DisplayName}");
});
```

```
app.Run();
```

Middleware dependencies

Middleware should follow the Explicit Dependencies Principle by exposing its dependencies in its constructor. Middleware is constructed once per *application lifetime*.

Middleware components can resolve their dependencies from dependency injection (DI) through constructor parameters. UseMiddleware can also accept additional parameters directly.

Per-request middleware dependencies

Middleware is constructed at app startup and therefore has application life time. Scoped lifetime services used by middleware constructors aren't shared with other dependency-injected types during each request. To share a *scoped* service between middleware and other types, add these services to the `InvokeAsync` method's signature. The `InvokeAsync` method can accept additional parameters that are populated by DI:

C#

```
namespace Middleware.Example;

public class MyCustomMiddleware
{
    private readonly RequestDelegate _next;

    public MyCustomMiddleware(RequestDelegate next)
    {
        _next = next;
    }

    // IMessageWriter is injected into InvokeAsync
    public async Task InvokeAsync(HttpContext httpContext, IMessageWriter
svc)
    {
        svc.Write(DateTime.Now.Ticks.ToString());
        await _next(httpContext);
    }
}

public static class MyCustomMiddlewareExtensions
{
    public static IApplicationBuilder UseMyCustomMiddleware(
        this IApplicationBuilder builder)
    {
```

```
        return builder.UseMiddleware<MyCustomMiddleware>();
    }
}
```

Lifetime and registration options contains a complete sample of middleware with *scoped* lifetime services.

The following code is used to test the preceding middleware:

C#

```
using Middleware.Example;
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddScoped<IMessageWriter, LoggingMessageWriter>();

var app = builder.Build();

app.UseHttpsRedirection();

app.UseMyCustomMiddleware();

app.MapGet("/", () => "Hello World!");

app.Run();
```

The `IMessageWriter` interface and implementation:

C#

```
namespace Middleware.Example;

public interface IMessageWriter
{
    void Write(string message);
}

public class LoggingMessageWriter : IMessageWriter
{

    private readonly ILogger<LoggingMessageWriter> _logger;

    public LoggingMessageWriter(ILogger<LoggingMessageWriter> logger) =>
        _logger = logger;

    public void Write(string message) =>
        _logger.LogInformation(message);
}
```

Request and response operations in ASP.NET Core

Article • 07/26/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

By Justin Kotalik

This article explains how to read from the request body and write to the response body. Code for these operations might be required when writing middleware. Outside of writing middleware, custom code isn't generally required because the operations are handled by MVC and Razor Pages.

There are two abstractions for the request and response bodies: Stream and Pipe. For request reading, HttpRequest.Body is a Stream, and `HttpRequest.BodyReader` is a PipeReader. For response writing, HttpResponse.Body is a Stream, and `HttpResponse.BodyWriter` is a PipeWriter.

Pipelines are recommended over streams. Streams can be easier to use for some simple operations, but pipelines have a performance advantage and are easier to use in most scenarios. ASP.NET Core is starting to use pipelines instead of streams internally. Examples include:

- `FormReader`
- `TextReader`
- `TextWriter`
- `HttpResponse.WriteAsync`

Streams aren't being removed from the framework. Streams continue to be used throughout .NET, and many stream types don't have pipe equivalents, such as `FileStreams` and `ResponseCompression`.

Stream examples

Suppose the goal is to create a middleware that reads the entire request body as a list of strings, splitting on new lines. A simple stream implementation might look like the following example:

> **⚠ Warning**
>
> The following code:
>
> - Is used to demonstrate the problems with not using a pipe to read the request body.
> - Is not intended to be used in production apps.

C#

```
private async Task<List<string>> GetListOfStringsFromStream(Stream
requestBody)
{
    // Build up the request body in a string builder.
    StringBuilder builder = new StringBuilder();

    // Rent a shared buffer to write the request body into.
    byte[] buffer = ArrayPool<byte>.Shared.Rent(4096);

    while (true)
    {
        var bytesRemaining = await requestBody.ReadAsync(buffer, offset: 0,
buffer.Length);
        if (bytesRemaining == 0)
        {
            break;
        }

        // Append the encoded string into the string builder.
        var encodedString = Encoding.UTF8.GetString(buffer, 0,
bytesRemaining);
        builder.Append(encodedString);
    }

    ArrayPool<byte>.Shared.Return(buffer);

    var entireRequestBody = builder.ToString();

    // Split on \n in the string.
    return new List<string>(entireRequestBody.Split("\n"));
}
```

If you would like to see code comments translated to languages other than English, let us know in this GitHub discussion issue.

This code works, but there are some issues:

- Before appending to the `StringBuilder`, the example creates another string (`encodedString`) that is thrown away immediately. This process occurs for all bytes in the stream, so the result is extra memory allocation the size of the entire request body.
- The example reads the entire string before splitting on new lines. It's more efficient to check for new lines in the byte array.

Here's an example that fixes some of the preceding issues:

> **⚠ Warning**
>
> The following code:
>
> - Is used to demonstrate the solutions to some problems in the preceding code while not solving all the problems.
> - Is not intended to be used in production apps.

C#

```
private async Task<List<string>>
GetListOfStringsFromStreamMoreEfficient(Stream requestBody)
{
    StringBuilder builder = new StringBuilder();
    byte[] buffer = ArrayPool<byte>.Shared.Rent(4096);
    List<string> results = new List<string>();

    while (true)
    {
        var bytesRemaining = await requestBody.ReadAsync(buffer, offset: 0,
buffer.Length);

        if (bytesRemaining == 0)
        {
            results.Add(builder.ToString());
            break;
        }

        // Instead of adding the entire buffer into the StringBuilder
        // only add the remainder after the last \n in the array.
        var prevIndex = 0;
        int index;
        while (true)
        {
            index = Array.IndexOf(buffer, (byte)'\n', prevIndex);
            if (index == -1)
            {
```

```
                break;
            }

            var encodedString = Encoding.UTF8.GetString(buffer, prevIndex,
index - prevIndex);

            if (builder.Length > 0)
            {
                // If there was a remainder in the string buffer, include it
in the next string.
                results.Add(builder.Append(encodedString).ToString());
                builder.Clear();
            }
            else
            {
                results.Add(encodedString);
            }

            // Skip past last \n
            prevIndex = index + 1;
        }

        var remainingString = Encoding.UTF8.GetString(buffer, prevIndex,
bytesRemaining - prevIndex);
        builder.Append(remainingString);
    }

    ArrayPool<byte>.Shared.Return(buffer);

    return results;
}
```

This preceding example:

- Doesn't buffer the entire request body in a `StringBuilder` unless there aren't any newline characters.
- Doesn't call `Split` on the string.

However, there are still a few issues:

- If newline characters are sparse, much of the request body is buffered in the string.
- The code continues to create strings (`remainingString`) and adds them to the string buffer, which results in an extra allocation.

These issues are fixable, but the code is becoming progressively more complicated with little improvement. Pipelines provide a way to solve these problems with minimal code complexity.

Pipelines

The following example shows how the same scenario can be handled using a PipeReader:

C#

```
private async Task<List<string>> GetListOfStringFromPipe(PipeReader reader)
{
    List<string> results = new List<string>();

    while (true)
    {
        ReadResult readResult = await reader.ReadAsync();
        var buffer = readResult.Buffer;

        SequencePosition? position = null;

        do
        {
            // Look for a EOL in the buffer
            position = buffer.PositionOf((byte)'\n');

            if (position != null)
            {
                var readOnlySequence = buffer.Slice(0, position.Value);
                AddStringToList(results, in readOnlySequence);

                // Skip the line + the \n character (basically position)
                buffer = buffer.Slice(buffer.GetPosition(1,
position.Value));
            }
        }
        while (position != null);

        if (readResult.IsCompleted && buffer.Length > 0)
        {
            AddStringToList(results, in buffer);
        }

        reader.AdvanceTo(buffer.Start, buffer.End);

        // At this point, buffer will be updated to point one byte after the
last
        // \n character.
        if (readResult.IsCompleted)
        {
            break;
        }
    }

    return results;
}

private static void AddStringToList(List<string> results, in
```

```
ReadOnlySequence<byte> readOnlySequence)
{
    // Separate method because Span/ReadOnlySpan cannot be used in async
methods
    ReadOnlySpan<byte> span = readOnlySequence.IsSingleSegment ?
readOnlySequence.First.Span : readOnlySequence.ToArray().AsSpan();
    results.Add(Encoding.UTF8.GetString(span));
}
```

This example fixes many issues that the streams implementations had:

- There's no need for a string buffer because the `PipeReader` handles bytes that haven't been used.
- Encoded strings are directly added to the list of returned strings.
- Other than the `ToArray` call, and the memory used by the string, string creation is allocation free.

Adapters

The `Body`, `BodyReader`, and `BodyWriter` properties are available for `HttpRequest` and `HttpResponse`. When you set `Body` to a different stream, a new set of adapters automatically adapt each type to the other. If you set `HttpRequest.Body` to a new stream, `HttpRequest.BodyReader` is automatically set to a new `PipeReader` that wraps `HttpRequest.Body`.

StartAsync

`HttpResponse.StartAsync` is used to indicate that headers are unmodifiable and to run `OnStarting` callbacks. When using Kestrel as a server, calling `StartAsync` before using the `PipeReader` guarantees that memory returned by `GetMemory` belongs to Kestrel's internal Pipe rather than an external buffer.

Request decompression in ASP.NET Core

Article • 09/27/2024

> **Important**
>

>
> For the current release, see the **.NET 8 version of this article**.

By David Acker

Request decompression middleware:

- Enables API endpoints to accept requests with compressed content.
- Uses the Content-Encoding HTTP header to automatically identify and decompress requests which contain compressed content.
- Eliminates the need to write code to handle compressed requests.

When the `Content-Encoding` header value on a request matches one of the available decompression providers, the middleware:

- Uses the matching provider to wrap the HttpRequest.Body in an appropriate decompression stream.
- Removes the `Content-Encoding` header, indicating that the request body is no longer compressed.

Requests that don't include a `Content-Encoding` header are ignored by the request decompression middleware.

Decompression:

- Occurs when the body of the request is read. That is, decompression occurs at the endpoint on model binding. The request body isn't decompressed eagerly.
- When attempting to read the decompressed request body with invalid compressed data for the specified `Content-Encoding`, an exception is thrown. Brotli can throw System.InvalidOperationException: Decoder ran into invalid data. Deflate and GZip can throw System.IO.InvalidDataException: The archive entry was compressed using an unsupported compression method.

If the middleware encounters a request with compressed content but is unable to decompress it, the request is passed to the next delegate in the pipeline. For example, a request with an unsupported `Content-Encoding` header value or multiple `Content-Encoding` header values is passed to the next delegate in the pipeline.

Configuration

The following code uses AddRequestDecompression(IServiceCollection) and UseRequestDecompression to enable request decompression for the default `Content-Encoding` types:

```
C#

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRequestDecompression();

var app = builder.Build();

app.UseRequestDecompression();

app.MapPost("/", (HttpRequest request) => Results.Stream(request.Body));

app.Run();
```

Default decompression providers

The `Content-Encoding` header values that the request decompression middleware supports by default are listed in the following table:

Expand table

Content-Encoding header values	Description
`br`	Brotli compressed data format
`deflate`	DEFLATE compressed data format
`gzip`	Gzip file format

Custom decompression providers

Support for custom encodings can be added by creating custom decompression provider classes that implement IDecompressionProvider:

```
C#

public class CustomDecompressionProvider : IDecompressionProvider
{
    public Stream GetDecompressionStream(Stream stream)
    {
        // Perform custom decompression logic here
        return stream;
    }
}
```

Custom decompression providers are registered with RequestDecompressionOptions along with their corresponding `Content-Encoding` header values:

```
C#

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRequestDecompression(options =>
{
    options.DecompressionProviders.Add("custom", new
CustomDecompressionProvider());
});

var app = builder.Build();

app.UseRequestDecompression();

app.MapPost("/", (HttpRequest request) => Results.Stream(request.Body));

app.Run();
```

Request size limits

In order to protect against zip bombs or decompression bombs:

- The maximum size of the decompressed request body is limited to the request body size limit enforced by the endpoint or server.
- If the number of bytes read from the decompressed request body stream exceeds the limit, an InvalidOperationException is thrown to prevent additional bytes from being read from the stream.

In order of precedence, the maximum request size for an endpoint is set by:

1. IRequestSizeLimitMetadata.MaxRequestBodySize, such as RequestSizeLimitAttribute or DisableRequestSizeLimitAttribute for MVC endpoints.
2. The global server size limit IHttpMaxRequestBodySizeFeature.MaxRequestBodySize. `MaxRequestBodySize` can be overridden per request with IHttpMaxRequestBodySizeFeature.MaxRequestBodySize, but defaults to the limit configured for the web server implementation.

Expand table

Web server implementation	`MaxRequestBodySize` configuration
HTTP.sys	HttpSysOptions.MaxRequestBodySize
IIS	IISServerOptions.MaxRequestBodySize
Kestrel	KestrelServerLimits.MaxRequestBodySize

> ⚠ **Warning**
>
> Disabling the request body size limit poses a security risk in regards to uncontrolled resource consumption, particularly if the request body is being buffered. Ensure that safeguards are in place to mitigate the risk of denial-of-service (DoS) attacks.

Factory-based middleware activation in ASP.NET Core

Article • 07/26/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

IMiddlewareFactory/IMiddleware is an extensibility point for middleware activation that offers the following benefits:

- Activation per client request (injection of scoped services)
- Strong typing of middleware

UseMiddleware extension methods check if a middleware's registered type implements IMiddleware. If it does, the IMiddlewareFactory instance registered in the container is used to resolve the IMiddleware implementation instead of using the convention-based middleware activation logic. The middleware is registered as a scoped or transient service in the app's service container.

IMiddleware is activated per client request (connection), so scoped services can be injected into the middleware's constructor.

IMiddleware

IMiddleware defines middleware for the app's request pipeline. The InvokeAsync(HttpContext, RequestDelegate) method handles requests and returns a Task that represents the execution of the middleware.

Middleware activated by convention:

C#

```
public class ConventionalMiddleware
{
    private readonly RequestDelegate _next;

    public ConventionalMiddleware(RequestDelegate next)
```

```
        => _next = next;

    public async Task InvokeAsync(HttpContext context, SampleDbContext
dbContext)
    {
        var keyValue = context.Request.Query["key"];

        if (!string.IsNullOrWhiteSpace(keyValue))
        {
            dbContext.Requests.Add(new Request("Conventional", keyValue));

            await dbContext.SaveChangesAsync();
        }

        await _next(context);
    }
}
```

Middleware activated by MiddlewareFactory:

C#

```
public class FactoryActivatedMiddleware : IMiddleware
{
    private readonly SampleDbContext _dbContext;

    public FactoryActivatedMiddleware(SampleDbContext dbContext)
        => _dbContext = dbContext;

    public async Task InvokeAsync(HttpContext context, RequestDelegate next)
    {
        var keyValue = context.Request.Query["key"];

        if (!string.IsNullOrWhiteSpace(keyValue))
        {
            _dbContext.Requests.Add(new Request("Factory", keyValue));

            await _dbContext.SaveChangesAsync();
        }

        await next(context);
    }
}
```

Extensions are created for the middleware:

C#

```
public static class MiddlewareExtensions
{
    public static IApplicationBuilder UseConventionalMiddleware(
        this IApplicationBuilder app)
```

```
        => app.UseMiddleware<ConventionalMiddleware>();

    public static IApplicationBuilder UseFactoryActivatedMiddleware(
        this IApplicationBuilder app)
        => app.UseMiddleware<FactoryActivatedMiddleware>();
}
```

It isn't possible to pass objects to the factory-activated middleware with UseMiddleware:

C#

```
public static IApplicationBuilder UseFactoryActivatedMiddleware(
    this IApplicationBuilder app, bool option)
{
    // Passing 'option' as an argument throws a NotSupportedException at
runtime.
    return app.UseMiddleware<FactoryActivatedMiddleware>(option);
}
```

The factory-activated middleware is added to the built-in container in `Program.cs`:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddDbContext<SampleDbContext>
    (options => options.UseInMemoryDatabase("SampleDb"));

builder.Services.AddTransient<FactoryActivatedMiddleware>();
```

Both middleware are registered in the request processing pipeline, also in `Program.cs`:

C#

```
var app = builder.Build();

app.UseConventionalMiddleware();
app.UseFactoryActivatedMiddleware();
```

IMiddlewareFactory

IMiddlewareFactory provides methods to create middleware. The middleware factory implementation is registered in the container as a scoped service.

The default IMiddlewareFactory implementation, MiddlewareFactory, is found in the Microsoft.AspNetCore.Http package.

Middleware activation with a third-party container in ASP.NET Core

Article • 07/26/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

This article demonstrates how to use IMiddlewareFactory and IMiddleware as an extensibility point for middleware activation with a third-party container. For introductory information on `IMiddlewareFactory` and `IMiddleware`, see Factory-based middleware activation in ASP.NET Core.

View or download sample code (how to download)

The sample app demonstrates middleware activation by an `IMiddlewareFactory` implementation, `SimpleInjectorMiddlewareFactory`. The sample uses the Simple Injector dependency injection (DI) container.

The sample's middleware implementation records the value provided by a query string parameter (`key`). The middleware uses an injected database context (a scoped service) to record the query string value in an in-memory database.

> **Note**
>
> The sample app uses Simple Injector purely for demonstration purposes. Use of Simple Injector isn't an endorsement. Middleware activation approaches described in the Simple Injector documentation and GitHub issues are recommended by the maintainers of Simple Injector. For more information, see the Simple Injector documentation and Simple Injector GitHub repository.

IMiddlewareFactory

IMiddlewareFactory provides methods to create middleware.

In the sample app, a middleware factory is implemented to create a `SimpleInjectorActivatedMiddleware` instance. The middleware factory uses the Simple Injector container to resolve the middleware:

C#

```
public class SimpleInjectorMiddlewareFactory : IMiddlewareFactory
{
    private readonly Container _container;

    public SimpleInjectorMiddlewareFactory(Container container)
    {
        _container = container;
    }

    public IMiddleware Create(Type middlewareType)
    {
        return _container.GetInstance(middlewareType) as IMiddleware;
    }

    public void Release(IMiddleware middleware)
    {
        // The container is responsible for releasing resources.
    }
}
```

IMiddleware

IMiddleware defines middleware for the app's request pipeline.

Middleware activated by an `IMiddlewareFactory` implementation (`Middleware/SimpleInjectorActivatedMiddleware.cs`):

C#

```
public class SimpleInjectorActivatedMiddleware : IMiddleware
{
    private readonly AppDbContext _db;

    public SimpleInjectorActivatedMiddleware(AppDbContext db)
    {
        _db = db;
    }

    public async Task InvokeAsync(HttpContext context, RequestDelegate next)
    {
        var keyValue = context.Request.Query["key"];

        if (!string.IsNullOrWhiteSpace(keyValue))
```

```
        {
            _db.Add(new Request()
                {
                    DT = DateTime.UtcNow,
                    MiddlewareActivation =
"SimpleInjectorActivatedMiddleware",
                    Value = keyValue
                });

            await _db.SaveChangesAsync();
        }

        await next(context);
    }
}
```

An extension is created for the middleware (`Middleware/MiddlewareExtensions.cs`):

C#

```
public static class MiddlewareExtensions
{
    public static IApplicationBuilder UseSimpleInjectorActivatedMiddleware(
        this IApplicationBuilder builder)
    {
        return builder.UseMiddleware<SimpleInjectorActivatedMiddleware>();
    }
}
```

`Startup.ConfigureServices` must perform several tasks:

- Set up the Simple Injector container.
- Register the factory and middleware.
- Make the app's database context available from the Simple Injector container.

C#

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddRazorPages();

    // Replace the default middleware factory with the
    // SimpleInjectorMiddlewareFactory.
    services.AddTransient<IMiddlewareFactory>(_ =>
    {
        return new SimpleInjectorMiddlewareFactory(_container);
    });

    // Wrap ASP.NET Core requests in a Simple Injector execution
    // context.
    services.UseSimpleInjectorAspNetRequestScoping(_container);
```

```
    // Provide the database context from the Simple
    // Injector container whenever it's requested from
    // the default service container.
    services.AddScoped<AppDbContext>(provider =>
        _container.GetInstance<AppDbContext>());

    _container.Options.DefaultScopedLifestyle = new AsyncScopedLifestyle();

    _container.Register<AppDbContext>(() =>
    {
        var optionsBuilder = new DbContextOptionsBuilder<DbContext>();
        optionsBuilder.UseInMemoryDatabase("InMemoryDb");
        return new AppDbContext(optionsBuilder.Options);
    }, Lifestyle.Scoped);

    _container.Register<SimpleInjectorActivatedMiddleware>();

    _container.Verify();
}
```

The middleware is registered in the request processing pipeline in `Startup.Configure`:

C#

```
public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }
    else
    {
        app.UseExceptionHandler("/Error");
    }

    app.UseSimpleInjectorActivatedMiddleware();

    app.UseStaticFiles();
    app.UseRouting();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapRazorPages();
    });
}
```

WebApplication and WebApplicationBuilder in Minimal API apps

Article • 07/26/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

`WebApplication`

The following code is generated by an ASP.NET Core template:

```
C#

var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

app.MapGet("/", () => "Hello World!");

app.Run();
```

The preceding code can be created via `dotnet new web` on the command line or selecting the Empty Web template in Visual Studio.

The following code creates a WebApplication (`app`) without explicitly creating a WebApplicationBuilder:

```
C#

var app = WebApplication.Create(args);

app.MapGet("/", () => "Hello World!");

app.Run();
```

WebApplication.Create initializes a new instance of the WebApplication class with preconfigured defaults.

Working with ports

When a web app is created with Visual Studio or `dotnet new`, a `Properties/launchSettings.json` file is created that specifies the ports the app responds to. In the port setting samples that follow, running the app from Visual Studio returns an error dialog `Unable to connect to web server 'AppName'`. Visual Studio returns an error because it's expecting the port specified in `Properties/launchSettings.json`, but the app is using the port specified by `app.Run("http://localhost:3000")`. Run the following port changing samples from the command line.

The following sections set the port the app responds to.

C#

```
var app = WebApplication.Create(args);

app.MapGet("/", () => "Hello World!");

app.Run("http://localhost:3000");
```

In the preceding code, the app responds to port `3000`.

Multiple ports

In the following code, the app responds to port `3000` and `4000`.

C#

```
var app = WebApplication.Create(args);

app.Urls.Add("http://localhost:3000");
app.Urls.Add("http://localhost:4000");

app.MapGet("/", () => "Hello World");

app.Run();
```

Set the port from the command line

The following command makes the app respond to port `7777`:

.NET CLI

```
dotnet run --urls="https://localhost:7777"
```

If the Kestrel endpoint is also configured in the `appsettings.json` file, the `appsettings.json` file specified URL is used. For more information, see Kestrel endpoint configuration

Read the port from environment

The following code reads the port from the environment:

C#

```
var app = WebApplication.Create(args);

var port = Environment.GetEnvironmentVariable("PORT") ?? "3000";

app.MapGet("/", () => "Hello World");

app.Run($"http://localhost:{port}");
```

The preferred way to set the port from the environment is to use the `ASPNETCORE_URLS` environment variable, which is shown in the following section.

Set the ports via the ASPNETCORE_URLS environment variable

The `ASPNETCORE_URLS` environment variable is available to set the port:

```
ASPNETCORE_URLS=http://localhost:3000
```

`ASPNETCORE_URLS` supports multiple URLs:

```
ASPNETCORE_URLS=http://localhost:3000;https://localhost:5000
```

Listen on all interfaces

The following samples demonstrate listening on all interfaces

http://*:3000

```
C#

var app = WebApplication.Create(args);

app.Urls.Add("http://*:3000");

app.MapGet("/", () => "Hello World");

app.Run();
```

http://+:3000

```
C#

var app = WebApplication.Create(args);

app.Urls.Add("http://+:3000");

app.MapGet("/", () => "Hello World");

app.Run();
```

`http://0.0.0.0:3000`

```
C#

var app = WebApplication.Create(args);

app.Urls.Add("http://0.0.0.0:3000");

app.MapGet("/", () => "Hello World");

app.Run();
```

Listen on all interfaces using ASPNETCORE_URLS

The preceding samples can use `ASPNETCORE_URLS`

```

ASPNETCORE_URLS=http://*:3000;https://+:5000;http://0.0.0.0:5005
```

Listen on all interfaces using ASPNETCORE_HTTPS_PORTS

The preceding samples can use `ASPNETCORE_HTTPS_PORTS` and `ASPNETCORE_HTTP_PORTS`.

```
ASPNETCORE_HTTP_PORTS=3000;5005
ASPNETCORE_HTTPS_PORTS=5000
```

For more information, see Configure endpoints for the ASP.NET Core Kestrel web server

Specify HTTPS with development certificate

C#

```
var app = WebApplication.Create(args);

app.Urls.Add("https://localhost:3000");

app.MapGet("/", () => "Hello World");

app.Run();
```

For more information on the development certificate, see Trust the ASP.NET Core HTTPS development certificate on Windows and macOS.

Specify HTTPS using a custom certificate

The following sections show how to specify the custom certificate using the `appsettings.json` file and via configuration.

Specify the custom certificate with `appsettings.json`

JSON

```
{
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "Microsoft.AspNetCore": "Warning"
    }
  },
  "AllowedHosts": "*",
```

```
  "Kestrel": {
    "Certificates": {
      "Default": {
        "Path": "cert.pem",
        "KeyPath": "key.pem"
      }
    }
  }
}
```

Specify the custom certificate via configuration

C#

```
var builder = WebApplication.CreateBuilder(args);

// Configure the cert and the key
builder.Configuration["Kestrel:Certificates:Default:Path"] = "cert.pem";
builder.Configuration["Kestrel:Certificates:Default:KeyPath"] = "key.pem";

var app = builder.Build();

app.Urls.Add("https://localhost:3000");

app.MapGet("/", () => "Hello World");

app.Run();
```

Use the certificate APIs

C#

```
using System.Security.Cryptography.X509Certificates;

var builder = WebApplication.CreateBuilder(args);

builder.WebHost.ConfigureKestrel(options =>
{
    options.ConfigureHttpsDefaults(httpsOptions =>
    {
        var certPath = Path.Combine(builder.Environment.ContentRootPath,
"cert.pem");
        var keyPath = Path.Combine(builder.Environment.ContentRootPath,
"key.pem");

        httpsOptions.ServerCertificate =
X509Certificate2.CreateFromPemFile(certPath,
                                           keyPath);
    });
```

```
});

var app = builder.Build();

app.Urls.Add("https://localhost:3000");

app.MapGet("/", () => "Hello World");

app.Run();
```

Read the environment

C#

```
var app = WebApplication.Create(args);

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/oops");
}

app.MapGet("/", () => "Hello World");
app.MapGet("/oops", () => "Oops! An error happened.");

app.Run();
```

For more information using the environment, see Use multiple environments in ASP.NET Core

Configuration

The following code reads from the configuration system:

C#

```
var app = WebApplication.Create(args);

var message = app.Configuration["HelloKey"] ?? "Config failed!";

app.MapGet("/", () => message);

app.Run();
```

For more information, see Configuration in ASP.NET Core

Logging

The following code writes a message to the log on application startup:

```
C#
```

```
var app = WebApplication.Create(args);

app.Logger.LogInformation("The app started");

app.MapGet("/", () => "Hello World");

app.Run();
```

For more information, see Logging in .NET Core and ASP.NET Core

Access the Dependency Injection (DI) container

The following code shows how to get services from the DI container during application startup:

```
C#
```

```

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddControllers();
builder.Services.AddScoped<SampleService>();

var app = builder.Build();

app.MapControllers();

using (var scope = app.Services.CreateScope())
{
    var sampleService =
scope.ServiceProvider.GetRequiredService<SampleService>();
    sampleService.DoSomething();
}

app.Run();
```

The following code shows how to access keys from the DI container using the [FromKeyedServices] attribute:

```
C#
```

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddKeyedSingleton<ICache, BigCache>("big");
builder.Services.AddKeyedSingleton<ICache, SmallCache>("small");
```

```
var app = builder.Build();

app.MapGet("/big", ([FromKeyedServices("big")] ICache bigCache) =>
bigCache.Get("date"));

app.MapGet("/small", ([FromKeyedServices("small")] ICache smallCache) =>
smallCache.Get("date"));

app.Run();

public interface ICache
{
    object Get(string key);
}
public class BigCache : ICache
{
    public object Get(string key) => $"Resolving {key} from big cache.";
}

public class SmallCache : ICache
{
    public object Get(string key) => $"Resolving {key} from small cache.";
}
```

For more information on DI, see Dependency injection in ASP.NET Core.

WebApplicationBuilder

This section contains sample code using WebApplicationBuilder.

Change the content root, application name, and environment

The following code sets the content root, application name, and environment:

C#

```
var builder = WebApplication.CreateBuilder(new WebApplicationOptions
{
    Args = args,
    ApplicationName = typeof(Program).Assembly.FullName,
    ContentRootPath = Directory.GetCurrentDirectory(),
    EnvironmentName = Environments.Staging,
    WebRootPath = "customwwwroot"
});

Console.WriteLine($"Application Name:
{builder.Environment.ApplicationName}");
```

```
Console.WriteLine($"Environment Name:
{builder.Environment.EnvironmentName}");
Console.WriteLine($"ContentRoot Path:
{builder.Environment.ContentRootPath}");
Console.WriteLine($"WebRootPath: {builder.Environment.WebRootPath}");

var app = builder.Build();
```

WebApplication.CreateBuilder initializes a new instance of the WebApplicationBuilder class with preconfigured defaults.

For more information, see ASP.NET Core fundamentals overview

Change the content root, app name, and environment by using environment variables or command line

The following table shows the environment variable and command-line argument used to change the content root, app name, and environment:

Expand table

feature	Environment variable	Command-line argument
Application name	ASPNETCORE_APPLICATIONNAME	--applicationName
Environment name	ASPNETCORE_ENVIRONMENT	--environment
Content root	ASPNETCORE_CONTENTROOT	--contentRoot

Add configuration providers

The following sample adds the INI configuration provider:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Configuration.AddIniFile("appsettings.ini");

var app = builder.Build();
```

For detailed information, see File configuration providers in Configuration in ASP.NET Core.

Read configuration

By default the WebApplicationBuilder reads configuration from multiple sources, including:

- `appSettings.json` and `appSettings.{environment}.json`
- Environment variables
- The command line

For a complete list of configuration sources read, see Default configuration in Configuration in ASP.NET Core.

The following code reads `HelloKey` from configuration and displays the value at the `/` endpoint. If the configuration value is null, "Hello" is assigned to `message`:

C#

```
var builder = WebApplication.CreateBuilder(args);

var message = builder.Configuration["HelloKey"] ?? "Hello";

var app = builder.Build();

app.MapGet("/", () => message);

app.Run();
```

Read the environment

C#

```
var builder = WebApplication.CreateBuilder(args);

if (builder.Environment.IsDevelopment())
{
    Console.WriteLine($"Running in development.");
}

var app = builder.Build();

app.MapGet("/", () => "Hello World!");

app.Run();
```

Add logging providers

C#

```
var builder = WebApplication.CreateBuilder(args);

// Configure JSON logging to the console.
builder.Logging.AddJsonConsole();

var app = builder.Build();

app.MapGet("/", () => "Hello JSON console!");

app.Run();
```

Add services

C#

```
var builder = WebApplication.CreateBuilder(args);

// Add the memory cache services.
builder.Services.AddMemoryCache();

// Add a custom scoped service.
builder.Services.AddScoped<ITodoRepository, TodoRepository>();
var app = builder.Build();
```

Customize the IHostBuilder

Existing extension methods on IHostBuilder can be accessed using the Host property:

C#

```
var builder = WebApplication.CreateBuilder(args);

// Wait 30 seconds for graceful shutdown.
builder.Host.ConfigureHostOptions(o => o.ShutdownTimeout =
TimeSpan.FromSeconds(30));

var app = builder.Build();

app.MapGet("/", () => "Hello World!");

app.Run();
```

Customize the IWebHostBuilder

Extension methods on IWebHostBuilder can be accessed using the WebApplicationBuilder.WebHost property.

C#

```
var builder = WebApplication.CreateBuilder(args);

// Change the HTTP server implemenation to be HTTP.sys based
builder.WebHost.UseHttpSys();

var app = builder.Build();

app.MapGet("/", () => "Hello HTTP.sys");

app.Run();
```

Change the web root

By default, the web root is relative to the content root in the `wwwroot` folder. Web root is where the static files middleware looks for static files. Web root can be changed with `WebHostOptions`, the command line, or with the UseWebRoot method:

C#

```
var builder = WebApplication.CreateBuilder(new WebApplicationOptions
{
    Args = args,
    // Look for static files in webroot
    WebRootPath = "webroot"
});

var app = builder.Build();

app.Run();
```

Custom dependency injection (DI) container

The following example uses Autofac:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Host.UseServiceProviderFactory(new AutofacServiceProviderFactory());

// Register services directly with Autofac here. Don't
// call builder.Populate(), that happens in AutofacServiceProviderFactory.
builder.Host.ConfigureContainer<ContainerBuilder>(builder =>
builder.RegisterModule(new MyApplicationModule()));
```

```
var app = builder.Build();
```

Add Middleware

Any existing ASP.NET Core middleware can be configured on the `WebApplication`:

C#

```
var app = WebApplication.Create(args);

// Setup the file server to serve static files.
app.UseFileServer();

app.MapGet("/", () => "Hello World!");

app.Run();
```

For more information, see ASP.NET Core Middleware

Developer exception page

WebApplication.CreateBuilder initializes a new instance of the WebApplicationBuilder class with preconfigured defaults. The developer exception page is enabled in the preconfigured defaults. When the following code is run in the development environment, navigating to `/` renders a friendly page that shows the exception.

C#

```
var builder = WebApplication.CreateBuilder(args);

var app = builder.Build();

app.MapGet("/", () =>
{
    throw new InvalidOperationException("Oops, the '/' route has thrown an
exception.");
});

app.Run();
```

.NET Generic Host in ASP.NET Core

Article • 09/10/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

This article provides information on using the .NET Generic Host in ASP.NET Core.

The ASP.NET Core templates create a WebApplicationBuilder and WebApplication, which provide a streamlined way to configure and run web applications without a `Startup` class. For more information on `WebApplicationBuilder` and `WebApplication`, see Migrate from ASP.NET Core 5.0 to 6.0.

For information on using the .NET Generic Host in console apps, see .NET Generic Host.

Host definition

A *host* is an object that encapsulates an app's resources, such as:

- Dependency injection (DI)
- Logging
- Configuration
- `IHostedService` implementations

When a host starts, it calls IHostedService.StartAsync on each implementation of IHostedService registered in the service container's collection of hosted services. In a web app, one of the `IHostedService` implementations is a web service that starts an HTTP server implementation.

Including all of the app's interdependent resources in one object enables control over app startup and graceful shutdown.

Set up a host

The host is typically configured, built, and run by code in the `Program.cs`. The following code creates a host with an `IHostedService` implementation added to the DI container:

C#

```
await Host.CreateDefaultBuilder(args)
    .ConfigureServices(services =>
    {
        services.AddHostedService<SampleHostedService>();
    })
    .Build()
    .RunAsync();
```

For an HTTP workload, call ConfigureWebHostDefaults after CreateDefaultBuilder:

C#

```
await Host.CreateDefaultBuilder(args)
    .ConfigureWebHostDefaults(webBuilder =>
    {
        webBuilder.UseStartup<Startup>();
    })
    .Build()
    .RunAsync();
```

Default builder settings

The CreateDefaultBuilder method:

- Sets the content root to the path returned by GetCurrentDirectory.
- Loads host configuration from:
  - Environment variables prefixed with `DOTNET_`.
  - Command-line arguments.
- Loads app configuration from:
  - `appsettings.json`.
  - `appsettings.{Environment}.json`.
  - User secrets when the app runs in the `Development` environment.
  - Environment variables.
  - Command-line arguments.
- Adds the following logging providers:
  - Console
  - Debug
  - EventSource
  - EventLog (only when running on Windows)

- Enables scope validation and dependency validation when the environment is Development.

The ConfigureWebHostDefaults method:

- Loads host configuration from environment variables prefixed with `ASPNETCORE_`.
- Sets Kestrel server as the web server and configures it using the app's hosting configuration providers. For the Kestrel server's default options, see Configure options for the ASP.NET Core Kestrel web server.
- Adds Host Filtering middleware.
- Adds Forwarded Headers middleware if `ASPNETCORE_FORWARDEDHEADERS_ENABLED` equals `true`.
- Enables IIS integration. For the IIS default options, see Host ASP.NET Core on Windows with IIS.

The Settings for all app types and Settings for web apps sections later in this article show how to override default builder settings.

Framework-provided services

The following services are registered automatically:

- IHostApplicationLifetime
- IHostLifetime
- IHostEnvironment / IWebHostEnvironment

For more information on framework-provided services, see Dependency injection in ASP.NET Core.

IHostApplicationLifetime

Inject the IHostApplicationLifetime (formerly `IApplicationLifetime`) service into any class to handle post-startup and graceful shutdown tasks. Three properties on the interface are cancellation tokens used to register app start and app stop event handler methods. The interface also includes a `StopApplication` method, which allows apps to request a graceful shutdown.

When performing a graceful shutdown, the host:

- Triggers the ApplicationStopping event handlers, which allows the app to run logic before the shutdown process begins.

- Stops the server, which disables new connections. The server waits for requests on existing connections to complete, for as long as the shutdown timeout allows. The server sends the connection close header for further requests on existing connections.
- Triggers the ApplicationStopped event handlers, which allows the app to run logic after the application has shutdown.

The following example is an `IHostedService` implementation that registers `IHostApplicationLifetime` event handlers:

C#

```
public class HostApplicationLifetimeEventsHostedService : IHostedService
{
    private readonly IHostApplicationLifetime _hostApplicationLifetime;

    public HostApplicationLifetimeEventsHostedService(
        IHostApplicationLifetime hostApplicationLifetime)
        => _hostApplicationLifetime = hostApplicationLifetime;

    public Task StartAsync(CancellationToken cancellationToken)
    {
        _hostApplicationLifetime.ApplicationStarted.Register(OnStarted);
        _hostApplicationLifetime.ApplicationStopping.Register(OnStopping);
        _hostApplicationLifetime.ApplicationStopped.Register(OnStopped);

        return Task.CompletedTask;
    }

    public Task StopAsync(CancellationToken cancellationToken)
        => Task.CompletedTask;

    private void OnStarted()
    {
        // ...
    }

    private void OnStopping()
    {
        // ...
    }

    private void OnStopped()
    {
        // ...
    }
}
```

IHostLifetime

The IHostLifetime implementation controls when the host starts and when it stops. The last implementation registered is used.

`Microsoft.Extensions.Hosting.Internal.ConsoleLifetime` is the default `IHostLifetime` implementation. `ConsoleLifetime`:

- Listens for `Ctrl`+`C`/SIGINT (Windows), `⌘`+`C` (macOS), or SIGTERM and calls StopApplication to start the shutdown process.
- Unblocks extensions such as RunAsync and WaitForShutdownAsync.

IHostEnvironment

Inject the IHostEnvironment service into a class to get information about the following settings:

- ApplicationName
- EnvironmentName
- ContentRootPath

Web apps implement the `IWebHostEnvironment` interface, which inherits `IHostEnvironment` and adds the WebRootPath.

Host configuration

Host configuration is used for the properties of the IHostEnvironment implementation.

Host configuration is available from HostBuilderContext.Configuration inside ConfigureAppConfiguration. After `ConfigureAppConfiguration`, `HostBuilderContext.Configuration` is replaced with the app config.

To add host configuration, call ConfigureHostConfiguration on `IHostBuilder`. `ConfigureHostConfiguration` can be called multiple times with additive results. The host uses whichever option sets a value last on a given key.

The environment variable provider with prefix `DOTNET_` and command-line arguments are included by `CreateDefaultBuilder`. For web apps, the environment variable provider with prefix `ASPNETCORE_` is added. The prefix is removed when the environment variables are read. For example, the environment variable value for `ASPNETCORE_ENVIRONMENT` becomes the host configuration value for the `environment` key.

The following example creates host configuration:

```
```

C#

```
Host.CreateDefaultBuilder(args)
    .ConfigureHostConfiguration(hostConfig =>
    {
        hostConfig.SetBasePath(Directory.GetCurrentDirectory());
        hostConfig.AddJsonFile("hostsettings.json", optional: true);
        hostConfig.AddEnvironmentVariables(prefix: "PREFIX_");
        hostConfig.AddCommandLine(args);
    });
```

App configuration

App configuration is created by calling ConfigureAppConfiguration on `IHostBuilder`. `ConfigureAppConfiguration` can be called multiple times with additive results. The app uses whichever option sets a value last on a given key.

The configuration created by `ConfigureAppConfiguration` is available at HostBuilderContext.Configuration for subsequent operations and as a service from DI. The host configuration is also added to the app configuration.

For more information, see Configuration in ASP.NET Core.

Settings for all app types

This section lists host settings that apply to both HTTP and non-HTTP workloads. By default, environment variables used to configure these settings can have a `DOTNET_` or `ASPNETCORE_` prefix, which appear in the following list of settings as the `{PREFIX_}` placeholder. For more information, see the Default builder settings section and Configuration: Environment variables.

ApplicationName

The IHostEnvironment.ApplicationName property is set from host configuration during host construction.

Key: `applicationName`
Type: `string`
Default: The name of the assembly that contains the app's entry point.
Environment variable: `{PREFIX_}APPLICATIONNAME`

To set this value, use the environment variable.

ContentRoot

The IHostEnvironment.ContentRootPath property determines where the host begins searching for content files. If the path doesn't exist, the host fails to start.

Key: `contentRoot`
Type: `string`
Default: The folder where the app assembly resides.
Environment variable: `{PREFIX_}CONTENTROOT`

To set this value, use the environment variable or call `UseContentRoot` on `IHostBuilder`:

```
C#

Host.CreateDefaultBuilder(args)
    .UseContentRoot("/path/to/content/root")
    // ...
```

For more information, see:

- Fundamentals: Content root
- WebRoot

EnvironmentName

The IHostEnvironment.EnvironmentName property can be set to any value. Framework-defined values include `Development`, `Staging`, and `Production`. Values aren't case-sensitive.

Key: `environment`
Type: `string`
Default: `Production`
Environment variable: `{PREFIX_}ENVIRONMENT`

To set this value, use the environment variable or call `UseEnvironment` on `IHostBuilder`:

```
C#

Host.CreateDefaultBuilder(args)
    .UseEnvironment("Development")
    // ...
```

ShutdownTimeout

HostOptions.ShutdownTimeout sets the timeout for StopAsync. The default value is 30 seconds. During the timeout period, the host:

- Triggers IHostApplicationLifetime.ApplicationStopping.
- Attempts to stop hosted services, logging errors for services that fail to stop.

If the timeout period expires before all of the hosted services stop, any remaining active services are stopped when the app shuts down. The services stop even if they haven't finished processing. If services require more time to stop, increase the timeout.

Key: `shutdownTimeoutSeconds`
Type: `int`
Default: 30 seconds
Environment variable: `{PREFIX_}SHUTDOWNTIMEOUTSECONDS`

To set this value, use the environment variable or configure `HostOptions`. The following example sets the timeout to 20 seconds:

C#

```
Host.CreateDefaultBuilder(args)
    .ConfigureServices((hostContext, services) =>
    {
        services.Configure<HostOptions>(options =>
        {
            options.ShutdownTimeout = TimeSpan.FromSeconds(20);
        });
    });
```

Disable app configuration reload on change

By default, `appsettings.json` and `appsettings.{Environment}.json` are reloaded when the file changes. To disable this reload behavior in ASP.NET Core 5.0 or later, set the `hostBuilder:reloadConfigOnChange` key to `false`.

Key: `hostBuilder:reloadConfigOnChange`
Type: `bool` (`true` or `false`)
Default: `true`
Command-line argument: `hostBuilder:reloadConfigOnChange`
Environment variable: `{PREFIX_}hostBuilder:reloadConfigOnChange`

> ⚠ **Warning**

The colon (`:`) separator doesn't work with environment variable hierarchical keys on all platforms. For more information, see **Environment variables**.

Settings for web apps

Some host settings apply only to HTTP workloads. By default, environment variables used to configure these settings can have a `DOTNET_` or `ASPNETCORE_` prefix, which appear in the following list of settings as the `{PREFIX_}` placeholder.

Extension methods on `IWebHostBuilder` are available for these settings. Code samples that show how to call the extension methods assume `webBuilder` is an instance of `IWebHostBuilder`, as in the following example:

C#

```
Host.CreateDefaultBuilder(args)
    .ConfigureWebHostDefaults(webBuilder =>
    {
        // ...
    });
```

CaptureStartupErrors

When `false`, errors during startup result in the host exiting. When `true`, the host captures exceptions during startup and attempts to start the server.

Key: `captureStartupErrors`
Type: `bool` (`true`/`1` or `false`/`0`)
Default: Defaults to `false` unless the app runs with Kestrel behind IIS, where the default is `true`.
Environment variable: `{PREFIX_}CAPTURESTARTUPERRORS`

To set this value, use configuration or call `CaptureStartupErrors`:

C#

```
webBuilder.CaptureStartupErrors(true);
```

DetailedErrors

When enabled, or when the environment is `Development`, the app captures detailed errors.

Key: `detailedErrors`
Type: `bool` (`true`/`1` or `false`/`0`)
Default: `false`
Environment variable: `{PREFIX_}DETAILEDERRORS`

To set this value, use configuration or call `UseSetting`:

```
C#

webBuilder.UseSetting(WebHostDefaults.DetailedErrorsKey, "true");
```

HostingStartupAssemblies

A semicolon-delimited string of hosting startup assemblies to load on startup. Although the configuration value defaults to an empty string, the hosting startup assemblies always include the app's assembly. When hosting startup assemblies are provided, they're added to the app's assembly for loading when the app builds its common services during startup.

Key: `hostingStartupAssemblies`
Type: `string`
Default: Empty string
Environment variable: `{PREFIX_}HOSTINGSTARTUPASSEMBLIES`

To set this value, use configuration or call `UseSetting`:

```
C#

webBuilder.UseSetting(
    WebHostDefaults.HostingStartupAssembliesKey, "assembly1;assembly2");
```

HostingStartupExcludeAssemblies

A semicolon-delimited string of hosting startup assemblies to exclude on startup.

Key: `hostingStartupExcludeAssemblies`
Type: `string`
Default: Empty string
Environment variable: `{PREFIX_}HOSTINGSTARTUPEXCLUDEASSEMBLIES`

To set this value, use configuration or call `UseSetting`:

```
C#

webBuilder.UseSetting(
    WebHostDefaults.HostingStartupExcludeAssembliesKey,
"assembly1;assembly2");
```

HTTPS_Port

Set the HTTPS port to redirect to if you get a non-HTTPS connection. Used in enforcing HTTPS. This setting doesn't cause the server to listen on the specified port. That is, it's possible to accidentally redirect requests to an unused port.

Key: `https_port` **Type**: `string`
Default: A default value isn't set.
Environment variable: `{PREFIX_}HTTPS_PORT`

To set this value, use configuration or call `UseSetting`:

```
C#

webBuilder.UseSetting("https_port", "8080");
```

HTTPS_Ports

The ports to listen on for HTTPS connections.

Key: `https_ports`
Type: `string`
Default: A default value isn't set.
Environment variable: `{PREFIX_}HTTPS_PORTS`

To set this value, use configuration or call `UseSetting`:

```
C#

webBuilder.UseSetting("https_ports", "8080");
```

PreferHostingUrls

Indicates whether the host should listen on the URLs configured with the `IWebHostBuilder` instead of those URLs configured with the `IServer` implementation.

Key: `preferHostingUrls`
Type: `bool` (`true`/`1` or `false`/`0`)
Default: `false`
Environment variable: `{PREFIX_}PREFERHOSTINGURLS`

To set this value, use the environment variable or call `PreferHostingUrls`:

```
C#

webBuilder.PreferHostingUrls(true);
```

PreventHostingStartup

Prevents the automatic loading of hosting startup assemblies, including hosting startup assemblies configured by the app's assembly. For more information, see Use hosting startup assemblies in ASP.NET Core.

Key: `preventHostingStartup`
Type: `bool` (`true`/`1` or `false`/`0`)
Default: `false`
Environment variable: `{PREFIX_}PREVENTHOSTINGSTARTUP`

To set this value, use the environment variable or call `UseSetting` :

```
C#

webBuilder.UseSetting(WebHostDefaults.PreventHostingStartupKey, "true");
```

StartupAssembly

The assembly to search for the `Startup` class.

Key: `startupAssembly`
Type: `string`
Default: The app's assembly
Environment variable: `{PREFIX_}STARTUPASSEMBLY`

To set this value, use the environment variable or call `UseStartup`. `UseStartup` can take an assembly name (`string`) or a type (`TStartup`). If multiple `UseStartup` methods are called, the last one takes precedence.

```
C#

webBuilder.UseStartup("StartupAssemblyName");
```

```
C#

webBuilder.UseStartup<Startup>();
```

SuppressStatusMessages

When enabled, suppresses hosting startup status messages.

Key: `suppressStatusMessages`
Type: `bool` (`true`/`1` or `false`/`0`)
Default: `false`
Environment variable: `{PREFIX_}SUPPRESSSTATUSMESSAGES`

To set this value, use configuration or call `UseSetting`:

```
C#

webBuilder.UseSetting(WebHostDefaults.SuppressStatusMessagesKey, "true");
```

URLs

A semicolon-delimited list of IP addresses or host addresses with ports and protocols that the server should listen on for requests. For example, `http://localhost:123`. Use "*" to indicate that the server should listen for requests on any IP address or hostname using the specified port and protocol (for example, `http://*:5000`). The protocol (`http://` or `https://`) must be included with each URL. Supported formats vary among servers.

Key: `urls`
Type: `string`
Default: `http://localhost:5000` and `https://localhost:5001`
Environment variable: `{PREFIX_}URLS`

To set this value, use the environment variable or call `UseUrls`:

```
C#

webBuilder.UseUrls("http://*:5000;http://localhost:5001;https://hostname:5002");
```

Kestrel has its own endpoint configuration API. For more information, see Configure endpoints for the ASP.NET Core Kestrel web server.

WebRoot

The IWebHostEnvironment.WebRootPath property determines the relative path to the app's static assets. If the path doesn't exist, a no-op file provider is used.

Key: `webroot`
Type: `string`
Default: The default is `wwwroot`. The path to *{content root}/wwwroot* must exist.
Environment variable: `{PREFIX_}WEBROOT`

To set this value, use the environment variable or call `UseWebRoot` on `IWebHostBuilder`:

```
C#

webBuilder.UseWebRoot("public");
```

For more information, see:

- Fundamentals: Web root
- ContentRoot

Manage the host lifetime

Call methods on the built IHost implementation to start and stop the app. These methods affect all IHostedService implementations that are registered in the service container.

The difference between `Run*` and `Start*` methods is that `Run*` methods wait for the host to complete before returning, whereas `Start*` methods return immediately. The `Run*` methods are typically used in console apps, whereas the `Start*` methods are typically used in long-running services.

Run

Run runs the app and blocks the calling thread until the host is shut down.

RunAsync

RunAsync runs the app and returns a Task that completes when the cancellation token or shutdown is triggered.

RunConsoleAsync

RunConsoleAsync enables console support, builds and starts the host, and waits for Ctrl+C/SIGINT (Windows), ⌘+C (macOS), or SIGTERM to shut down.

Start

Start starts the host synchronously.

StartAsync

StartAsync starts the host and returns a Task that completes when the cancellation token or shutdown is triggered.

WaitForStartAsync is called at the start of `StartAsync`, which waits until it's complete before continuing. This method can be used to delay startup until signaled by an external event.

StopAsync

StopAsync attempts to stop the host within the provided timeout.

WaitForShutdown

WaitForShutdown blocks the calling thread until shutdown is triggered by the IHostLifetime, such as via Ctrl+C/SIGINT (Windows), ⌘+C (macOS), or SIGTERM.

WaitForShutdownAsync

WaitForShutdownAsync returns a Task that completes when shutdown is triggered via the given token and calls StopAsync.

- Background tasks with hosted services in ASP.NET Core
- GitHub link to Generic Host source

> **Note**
>
> Documentation links to .NET reference source usually load the repository's default branch, which represents the current development for the next release of .NET. To select a tag for a specific release, use the **Switch branches or tags** dropdown list. For more information, see How to select a version tag of ASP.NET Core source code (dotnet/AspNetCore.Docs #26205).

ASP.NET Core Web Host

Article • 09/10/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

ASP.NET Core apps configure and launch a *host*. The host is responsible for app startup and lifetime management. At a minimum, the host configures a server and a request processing pipeline. The host can also set up logging, dependency injection, and configuration.

This article covers the Web Host, which remains available only for backward compatibility. The ASP.NET Core templates create a WebApplicationBuilder and WebApplication, which is recommended for web apps. For more information on `WebApplicationBuilder` and `WebApplication`, see Migrate from ASP.NET Core 5.0 to 6.0

Set up a host

Create a host using an instance of IWebHostBuilder. This is typically performed in the app's entry point, the `Main` method in `Program.cs`. A typical app calls CreateDefaultBuilder to start setting up a host:

C#

```
public class Program
{
    public static void Main(string[] args)
    {
        CreateWebHostBuilder(args).Build().Run();
    }

    public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
        WebHost.CreateDefaultBuilder(args)
            .UseStartup<Startup>();
}
```

The code that calls `CreateDefaultBuilder` is in a method named `CreateWebHostBuilder`, which separates it from the code in `Main` that calls `Run` on the builder object. This separation is required if you use Entity Framework Core tools. The tools expect to find a `CreateWebHostBuilder` method that they can call at design time to configure the host without running the app. An alternative is to implement `IDesignTimeDbContextFactory`. For more information, see Design-time DbContext Creation.

`CreateDefaultBuilder` performs the following tasks:

- Configures Kestrel server as the web server using the app's hosting configuration providers. For the Kestrel server's default options, see Configure options for the ASP.NET Core Kestrel web server.
- Sets the content root to the path returned by Directory.GetCurrentDirectory.
- Loads host configuration from:
  - Environment variables prefixed with `ASPNETCORE_` (for example, `ASPNETCORE_ENVIRONMENT`).
  - Command-line arguments.
- Loads app configuration in the following order from:
  - `appsettings.json`.
  - `appsettings.{Environment}.json`.
  - User secrets when the app runs in the `Development` environment using the entry assembly.
  - Environment variables.
  - Command-line arguments.
- Configures logging for console and debug output. Logging includes log filtering rules specified in a Logging configuration section of an `appsettings.json` or `appsettings.{Environment}.json` file.
- When running behind IIS with the ASP.NET Core Module, `CreateDefaultBuilder` enables IIS Integration, which configures the app's base address and port. IIS Integration also configures the app to capture startup errors. For the IIS default options, see Host ASP.NET Core on Windows with IIS.
- Sets ServiceProviderOptions.ValidateScopes to `true` if the app's environment is Development. For more information, see Scope validation.

The configuration defined by `CreateDefaultBuilder` can be overridden and augmented by ConfigureAppConfiguration, ConfigureLogging, and other methods and extension methods of IWebHostBuilder. A few examples follow:

- ConfigureAppConfiguration is used to specify additional `IConfiguration` for the app. The following `ConfigureAppConfiguration` call adds a delegate to include app configuration in the `appsettings.xml` file. `ConfigureAppConfiguration` may be

called multiple times. Note that this configuration doesn't apply to the host (for example, server URLs or environment). See the Host configuration values section.

```
C#

WebHost.CreateDefaultBuilder(args)
    .ConfigureAppConfiguration((hostingContext, config) =>
    {
        config.AddXmlFile("appsettings.xml", optional: true,
reloadOnChange: true);
    })
    ...
```

- The following `ConfigureLogging` call adds a delegate to configure the minimum logging level (SetMinimumLevel) to LogLevel.Warning. This setting overrides the settings in `appsettings.Development.json` (`LogLevel.Debug`) and `appsettings.Production.json` (`LogLevel.Error`) configured by `CreateDefaultBuilder`. `ConfigureLogging` may be called multiple times.

```
C#

WebHost.CreateDefaultBuilder(args)
    .ConfigureLogging(logging =>
    {
        logging.SetMinimumLevel(LogLevel.Warning);
    })
    ...
```

- The following call to `ConfigureKestrel` overrides the default Limits.MaxRequestBodySize of 30,000,000 bytes established when Kestrel was configured by `CreateDefaultBuilder`:

```
C#

WebHost.CreateDefaultBuilder(args)
    .ConfigureKestrel((context, options) =>
    {
        options.Limits.MaxRequestBodySize = 20000000;
    });
```

The content root determines where the host searches for content files, such as MVC view files. When the app is started from the project's root folder, the project's root folder is used as the content root. This is the default used in Visual Studio and the dotnet new templates.

For more information on app configuration, see Configuration in ASP.NET Core.

> **Note**
>
> As an alternative to using the static `CreateDefaultBuilder` method, creating a host from WebHostBuilder is a supported approach with ASP.NET Core 2.x.

When setting up a host, Configure and ConfigureServices methods can be provided. If a `Startup` class is specified, it must define a `Configure` method. For more information, see App startup in ASP.NET Core. Multiple calls to `ConfigureServices` append to one another. Multiple calls to `Configure` or `UseStartup` on the `WebHostBuilder` replace previous settings.

Host configuration values

WebHostBuilder relies on the following approaches to set the host configuration values:

- Host builder configuration, which includes environment variables with the format `ASPNETCORE_{configurationKey}`. For example, `ASPNETCORE_ENVIRONMENT`.
- Extensions such as UseContentRoot and UseConfiguration (see the Override configuration section).
- UseSetting and the associated key. When setting a value with `UseSetting`, the value is set as a string regardless of the type.

The host uses whichever option sets a value last. For more information, see Override configuration in the next section.

Application Key (Name)

The `IWebHostEnvironment.ApplicationName` property is automatically set when UseStartup or Configure is called during host construction. The value is set to the name of the assembly containing the app's entry point. To set the value explicitly, use the WebHostDefaults.ApplicationKey:

Key: applicationName
Type: *string*
Default: The name of the assembly containing the app's entry point.
Set using: `UseSetting`
Environment variable: `ASPNETCORE_APPLICATIONNAME`

```
C#
```

```
WebHost.CreateDefaultBuilder(args)
    .UseSetting(WebHostDefaults.ApplicationKey, "CustomApplicationName")
```

Capture Startup Errors

This setting controls the capture of startup errors.

Key: captureStartupErrors
Type: *bool* (`true` or `1`)
Default: Defaults to `false` unless the app runs with Kestrel behind IIS, where the default is `true`.
Set using: `CaptureStartupErrors`
Environment variable: `ASPNETCORE_CAPTURESTARTUPERRORS`

When `false`, errors during startup result in the host exiting. When `true`, the host captures exceptions during startup and attempts to start the server.

C#

```
WebHost.CreateDefaultBuilder(args)
    .CaptureStartupErrors(true)
```

Content root

This setting determines where ASP.NET Core begins searching for content files.

Key: contentRoot
Type: *string*
Default: Defaults to the folder where the app assembly resides.
Set using: `UseContentRoot`
Environment variable: `ASPNETCORE_CONTENTROOT`

The content root is also used as the base path for the web root. If the content root path doesn't exist, the host fails to start.

C#

```
WebHost.CreateDefaultBuilder(args)
    .UseContentRoot("c:\\<content-root>")
```

For more information, see:

- Fundamentals: Content root
- Web root

Detailed Errors

Determines if detailed errors should be captured.

Key: detailedErrors
Type: *bool* (`true` or `1`)
Default: false
Set using: `UseSetting`
Environment variable: `ASPNETCORE_DETAILEDERRORS`

When enabled (or when the Environment is set to `Development`), the app captures detailed exceptions.

```
C#

WebHost.CreateDefaultBuilder(args)
    .UseSetting(WebHostDefaults.DetailedErrorsKey, "true")
```

Environment

Sets the app's environment.

Key: environment
Type: *string*
Default: Production
Set using: `UseEnvironment`
Environment variable: `ASPNETCORE_ENVIRONMENT`

The environment can be set to any value. Framework-defined values include `Development`, `Staging`, and `Production`. Values aren't case sensitive. By default, the *Environment* is read from the `ASPNETCORE_ENVIRONMENT` environment variable. When using Visual Studio, environment variables may be set in the `launchSettings.json` file. For more information, see Use multiple environments in ASP.NET Core.

```
C#

WebHost.CreateDefaultBuilder(args)
    .UseEnvironment(EnvironmentName.Development)
```

Hosting Startup Assemblies

Sets the app's hosting startup assemblies.

Key: hostingStartupAssemblies
Type: *string*
Default: Empty string
Set using: `UseSetting`
Environment variable: `ASPNETCORE_HOSTINGSTARTUPASSEMBLIES`

A semicolon-delimited string of hosting startup assemblies to load on startup.

Although the configuration value defaults to an empty string, the hosting startup assemblies always include the app's assembly. When hosting startup assemblies are provided, they're added to the app's assembly for loading when the app builds its common services during startup.

C#

```
WebHost.CreateDefaultBuilder(args)
    .UseSetting(WebHostDefaults.HostingStartupAssembliesKey,
"assembly1;assembly2")
```

HTTPS Port

Set the HTTPS port to redirect to if you get a non-HTTPS connection. Used in enforcing HTTPS. This setting doesn't cause the server to listen on the specified port. That is, it's possible to accidentally redirect requests to an unused port.

Key: https_port
Type: *string*
Default: A default value isn't set.
Set using: `UseSetting`
Environment variable: `ASPNETCORE_HTTPS_PORT`

C#

```
WebHost.CreateDefaultBuilder(args)
    .UseSetting("https_port", "8080")
```

HTTPS Ports

Set the ports to listen on for HTTPS connections.

Key: https_ports **Type**: *string*
Default: A default value isn't set.
Set using: `UseSetting`
Environment variable: `ASPNETCORE_HTTPS_PORTS`

```
C#

WebHost.CreateDefaultBuilder(args)
    .UseSetting("https_ports", "8080")
```

Hosting Startup Exclude Assemblies

A semicolon-delimited string of hosting startup assemblies to exclude on startup.

Key: hostingStartupExcludeAssemblies
Type: *string*
Default: Empty string
Set using: `UseSetting`
Environment variable: `ASPNETCORE_HOSTINGSTARTUPEXCLUDEASSEMBLIES`

```
C#

WebHost.CreateDefaultBuilder(args)
    .UseSetting(WebHostDefaults.HostingStartupExcludeAssembliesKey,
"assembly1;assembly2")
```

Prefer Hosting URLs

Indicates whether the host should listen on the URLs configured with the `WebHostBuilder` instead of those configured with the `IServer` implementation.

Key: preferHostingUrls
Type: *bool* (`true` or `1`)
Default: false
Set using: `PreferHostingUrls`
Environment variable: `ASPNETCORE_PREFERHOSTINGURLS`

```
C#

WebHost.CreateDefaultBuilder(args)
```

```
    .PreferHostingUrls(true)
```

Prevent Hosting Startup

Prevents the automatic loading of hosting startup assemblies, including hosting startup assemblies configured by the app's assembly. For more information, see Use hosting startup assemblies in ASP.NET Core.

Key: preventHostingStartup
Type: *bool* (`true` or `1`)
Default: false
Set using: `UseSetting`
Environment variable: `ASPNETCORE_PREVENTHOSTINGSTARTUP`

C#

```
WebHost.CreateDefaultBuilder(args)
    .UseSetting(WebHostDefaults.PreventHostingStartupKey, "true")
```

Server URLs

Indicates the IP addresses or host addresses with ports and protocols that the server should listen on for requests.

Key: urls
Type: *string*
Default: http://localhost:5000
Set using: `UseUrls`
Environment variable: `ASPNETCORE_URLS`

Set to a semicolon-separated (;) list of URL prefixes to which the server should respond. For example, `http://localhost:123`. Use "*" to indicate that the server should listen for requests on any IP address or hostname using the specified port and protocol (for example, `http://*:5000`). The protocol (`http://` or `https://`) must be included with each URL. Supported formats vary among servers.

C#

```
WebHost.CreateDefaultBuilder(args)
    .UseUrls("http://*:5000;http://localhost:5001;https://hostname:5002")
```

Kestrel has its own endpoint configuration API. For more information, see Configure endpoints for the ASP.NET Core Kestrel web server.

Shutdown Timeout

Specifies the amount of time to wait for Web Host to shut down.

Key: shutdownTimeoutSeconds
Type: *int*
Default: 5
Set using: `UseShutdownTimeout`
Environment variable: `ASPNETCORE_SHUTDOWNTIMEOUTSECONDS`

Although the key accepts an *int* with `UseSetting` (for example, `.UseSetting(WebHostDefaults.ShutdownTimeoutKey, "10")`), the UseShutdownTimeout extension method takes a TimeSpan.

During the timeout period, hosting:

- Triggers IApplicationLifetime.ApplicationStopping.
- Attempts to stop hosted services, logging any errors for services that fail to stop.

If the timeout period expires before all of the hosted services stop, any remaining active services are stopped when the app shuts down. The services stop even if they haven't finished processing. If services require additional time to stop, increase the timeout.

C#

```
WebHost.CreateDefaultBuilder(args)
    .UseShutdownTimeout(TimeSpan.FromSeconds(10))
```

Startup Assembly

Determines the assembly to search for the `Startup` class.

Key: startupAssembly
Type: *string*
Default: The app's assembly
Set using: `UseStartup`
Environment variable: `ASPNETCORE_STARTUPASSEMBLY`

The assembly by name (`string`) or type (`TStartup`) can be referenced. If multiple `UseStartup` methods are called, the last one takes precedence.

C#

```
WebHost.CreateDefaultBuilder(args)
    .UseStartup("StartupAssemblyName")
```

C#

```
WebHost.CreateDefaultBuilder(args)
    .UseStartup<TStartup>()
```

Web root

Sets the relative path to the app's static assets.

Key: webroot
Type: *string*
Default: The default is `wwwroot`. The path to *{content root}/wwwroot* must exist. If the path doesn't exist, a no-op file provider is used.
Set using: `UseWebRoot`
Environment variable: `ASPNETCORE_WEBROOT`

C#

```
WebHost.CreateDefaultBuilder(args)
    .UseWebRoot("public")
```

For more information, see:

- Fundamentals: Web root
- Content root

Override configuration

Use Configuration to configure Web Host. In the following example, host configuration is optionally specified in a `hostsettings.json` file. Any configuration loaded from the `hostsettings.json` file may be overridden by command-line arguments. The built configuration (in `config`) is used to configure the host with UseConfiguration. `IWebHostBuilder` configuration is added to the app's configuration, but the converse isn't true—`ConfigureAppConfiguration` doesn't affect the `IWebHostBuilder` configuration.

Overriding the configuration provided by `UseUrls` with `hostsettings.json` config first, command-line argument config second:

C#

```
public class Program
{
    public static void Main(string[] args)
    {
        CreateWebHostBuilder(args).Build().Run();
    }

    public static IWebHostBuilder CreateWebHostBuilder(string[] args)
    {
        var config = new ConfigurationBuilder()
            .SetBasePath(Directory.GetCurrentDirectory())
            .AddJsonFile("hostsettings.json", optional: true)
            .AddCommandLine(args)
            .Build();

        return WebHost.CreateDefaultBuilder(args)
            .UseUrls("http://*:5000")
            .UseConfiguration(config)
            .Configure(app =>
            {
                app.Run(context =>
                    context.Response.WriteAsync("Hello, World!"));
            });
    }
}
```

`hostsettings.json`:

JSON

```
{
    urls: "http://*:5005"
}
```

> ⓘ **Note**
>
> UseConfiguration only copies keys from the provided `IConfiguration` to the host builder configuration. Therefore, setting `reloadOnChange: true` for JSON, INI, and XML settings files has no effect.

To specify the host run on a particular URL, the desired value can be passed in from a command prompt when executing dotnet run. The command-line argument overrides

the `urls` value from the `hostsettings.json` file, and the server listens on port 8080:

.NET CLI

```
dotnet run --urls "http://*:8080"
```

Manage the host

Run

The `Run` method starts the web app and blocks the calling thread until the host is shut down:

C#

```
host.Run();
```

Start

Run the host in a non-blocking manner by calling its `Start` method:

C#

```
using (host)
{
    host.Start();
    Console.ReadLine();
}
```

If a list of URLs is passed to the `Start` method, it listens on the URLs specified:

C#

```
var urls = new List<string>()
{
    "http://*:5000",
    "http://localhost:5001"
};

var host = new WebHostBuilder()
    .UseKestrel()
    .UseStartup<Startup>()
    .Start(urls.ToArray());

using (host)
{
```

```
    Console.ReadLine();
}
```

The app can initialize and start a new host using the pre-configured defaults of `CreateDefaultBuilder` using a static convenience method. These methods start the server without console output and with WaitForShutdown wait for a break (Ctrl-C/SIGINT or SIGTERM):

Start(RequestDelegate app)

Start with a `RequestDelegate`:

C#

```
using (var host = WebHost.Start(app => app.Response.WriteAsync("Hello,
World!")))
{
    Console.WriteLine("Use Ctrl-C to shutdown the host...");
    host.WaitForShutdown();
}
```

Make a request in the browser to `http://localhost:5000` to receive the response "Hello World!" `WaitForShutdown` blocks until a break (Ctrl-C/SIGINT or SIGTERM) is issued. The app displays the `Console.WriteLine` message and waits for a keypress to exit.

Start(string url, RequestDelegate app)

Start with a URL and `RequestDelegate`:

C#

```
using (var host = WebHost.Start("http://localhost:8080", app =>
app.Response.WriteAsync("Hello, World!")))
{
    Console.WriteLine("Use Ctrl-C to shutdown the host...");
    host.WaitForShutdown();
}
```

Produces the same result as **Start(RequestDelegate app)**, except the app responds on `http://localhost:8080`.

Start(Action<IRouteBuilder> routeBuilder)

Use an instance of `IRouteBuilder` (Microsoft.AspNetCore.Routing) to use routing middleware:

C#

```
using (var host = WebHost.Start(router => router
    .MapGet("hello/{name}", (req, res, data) =>
        res.WriteAsync($"Hello, {data.Values["name"]}!"))
    .MapGet("buenosdias/{name}", (req, res, data) =>
        res.WriteAsync($"Buenos dias, {data.Values["name"]}!"))
    .MapGet("throw/{message?}", (req, res, data) =>
        throw new Exception((string)data.Values["message"] ?? "Uh oh!"))
    .MapGet("{greeting}/{name}", (req, res, data) =>
        res.WriteAsync($"{data.Values["greeting"]},
{data.Values["name"]}!"))
    .MapGet("", (req, res, data) => res.WriteAsync("Hello, World!"))))
{
    Console.WriteLine("Use Ctrl-C to shutdown the host...");
    host.WaitForShutdown();
}
```

Use the following browser requests with the example:

Expand table

Request	Response
`http://localhost:5000/hello/Martin`	Hello, Martin!
`http://localhost:5000/buenosdias/Catrina`	Buenos dias, Catrina!
`http://localhost:5000/throw/ooops!`	Throws an exception with string "ooops!"
`http://localhost:5000/throw`	Throws an exception with string "Uh oh!"
`http://localhost:5000/Sante/Kevin`	Sante, Kevin!
`http://localhost:5000`	Hello World!

`WaitForShutdown` blocks until a break (Ctrl-C/SIGINT or SIGTERM) is issued. The app displays the `Console.WriteLine` message and waits for a keypress to exit.

Start(string url, Action<IRouteBuilder> routeBuilder)

Use a URL and an instance of `IRouteBuilder`:

C#

```
using (var host = WebHost.Start("http://localhost:8080", router => router
    .MapGet("hello/{name}", (req, res, data) =>
        res.WriteAsync($"Hello, {data.Values["name"]}!"))
    .MapGet("buenosdias/{name}", (req, res, data) =>
        res.WriteAsync($"Buenos dias, {data.Values["name"]}!"))
```

```
    .MapGet("throw/{message?}", (req, res, data) =>
        throw new Exception((string)data.Values["message"] ?? "Uh oh!"))
    .MapGet("{greeting}/{name}", (req, res, data) =>
        res.WriteAsync($"{data.Values["greeting"]},
{data.Values["name"]}!"))
    .MapGet("", (req, res, data) => res.WriteAsync("Hello, World!"))))
{
    Console.WriteLine("Use Ctrl-C to shut down the host...");
    host.WaitForShutdown();
}
```

Produces the same result as **Start(Action<IRouteBuilder> routeBuilder)**, except the app responds at `http://localhost:8080`.

StartWith(Action<IApplicationBuilder> app)

Provide a delegate to configure an `IApplicationBuilder`:

C#

```
using (var host = WebHost.StartWith(app =>
    app.Use(next =>
    {
        return async context =>
        {
            await context.Response.WriteAsync("Hello World!");
        };
    })))
{
    Console.WriteLine("Use Ctrl-C to shut down the host...");
    host.WaitForShutdown();
}
```

Make a request in the browser to `http://localhost:5000` to receive the response "Hello World!" `WaitForShutdown` blocks until a break (Ctrl-C/SIGINT or SIGTERM) is issued. The app displays the `Console.WriteLine` message and waits for a keypress to exit.

StartWith(string url, Action<IApplicationBuilder> app)

Provide a URL and a delegate to configure an `IApplicationBuilder`:

C#

```
using (var host = WebHost.StartWith("http://localhost:8080", app =>
    app.Use(next =>
    {
        return async context =>
        {
            await context.Response.WriteAsync("Hello World!");
```

```
        };
    }))
{
    Console.WriteLine("Use Ctrl-C to shut down the host...");
    host.WaitForShutdown();
}
```

Produces the same result as **StartWith(Action<IApplicationBuilder> app)**, except the app responds on `http://localhost:8080`.

IWebHostEnvironment interface

The `IWebHostEnvironment` interface provides information about the app's web hosting environment. Use constructor injection to obtain the `IWebHostEnvironment` in order to use its properties and extension methods:

C#

```
public class CustomFileReader
{
    private readonly IWebHostEnvironment _env;

    public CustomFileReader(IWebHostEnvironment env)
    {
        _env = env;
    }

    public string ReadFile(string filePath)
    {
        var fileProvider = _env.WebRootFileProvider;
        // Process the file here
    }
}
```

A convention-based approach can be used to configure the app at startup based on the environment. Alternatively, inject the `IWebHostEnvironment` into the `Startup` constructor for use in `ConfigureServices`:

C#

```
public class Startup
{
    public Startup(IWebHostEnvironment env)
    {
        HostingEnvironment = env;
    }

    public IWebHostEnvironment HostingEnvironment { get; }
```

```
    public void ConfigureServices(IServiceCollection services)
    {
        if (HostingEnvironment.IsDevelopment())
        {
            // Development configuration
        }
        else
        {
            // Staging/Production configuration
        }

        var contentRootPath = HostingEnvironment.ContentRootPath;
    }
}
```

> **Note**
>
> In addition to the `IsDevelopment` extension method, `IWebHostEnvironment` offers `IsStaging`, `IsProduction`, and `IsEnvironment(string environmentName)` methods. For more information, see Use multiple environments in ASP.NET Core.

The `IWebHostEnvironment` service can also be injected directly into the `Configure` method for setting up the processing pipeline:

C#

```
public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    if (env.IsDevelopment())
    {
        // In Development, use the Developer Exception Page
        app.UseDeveloperExceptionPage();
    }
    else
    {
        // In Staging/Production, route exceptions to /error
        app.UseExceptionHandler("/error");
    }

    var contentRootPath = env.ContentRootPath;
}
```

`IWebHostEnvironment` can be injected into the `Invoke` method when creating custom middleware:

C#

```
public async Task Invoke(HttpContext context, IWebHostEnvironment env)
{
    if (env.IsDevelopment())
    {
        // Configure middleware for Development
    }
    else
    {
        // Configure middleware for Staging/Production
    }

    var contentRootPath = env.ContentRootPath;
}
```

IHostApplicationLifetime interface

`IHostApplicationLifetime` allows for post-startup and shutdown activities. Three properties on the interface are cancellation tokens used to register `Action` methods that define startup and shutdown events.

Expand table

Cancellation Token	Triggered when...
`ApplicationStarted`	The host has fully started.
`ApplicationStopped`	The host is completing a graceful shutdown. All requests should be processed. Shutdown blocks until this event completes.
`ApplicationStopping`	The host is performing a graceful shutdown. Requests may still be processing. Shutdown blocks until this event completes.

C#

```
public class Startup
{
    public void Configure(IApplicationBuilder app, IHostApplicationLifetime
appLifetime)
    {
        appLifetime.ApplicationStarted.Register(OnStarted);
        appLifetime.ApplicationStopping.Register(OnStopping);
        appLifetime.ApplicationStopped.Register(OnStopped);

        Console.CancelKeyPress += (sender, eventArgs) =>
        {
            appLifetime.StopApplication();
            // Don't terminate the process immediately, wait for the Main
thread to exit gracefully.
```

```
            eventArgs.Cancel = true;
        };
    }

    private void OnStarted()
    {
        // Perform post-startup activities here
    }

    private void OnStopping()
    {
        // Perform on-stopping activities here
    }

    private void OnStopped()
    {
        // Perform post-stopped activities here
    }
}
```

`StopApplication` requests termination of the app. The following class uses `StopApplication` to gracefully shut down an app when the class's `Shutdown` method is called:

C#

```
public class MyClass
{
    private readonly IHostApplicationLifetime _appLifetime;

    public MyClass(IHostApplicationLifetime appLifetime)
    {
        _appLifetime = appLifetime;
    }

    public void Shutdown()
    {
        _appLifetime.StopApplication();
    }
}
```

Scope validation

CreateDefaultBuilder sets ServiceProviderOptions.ValidateScopes to `true` if the app's environment is Development.

When `ValidateScopes` is set to `true`, the default service provider performs checks to verify that:

- Scoped services aren't directly or indirectly resolved from the root service provider.
- Scoped services aren't directly or indirectly injected into singletons.

The root service provider is created when BuildServiceProvider is called. The root service provider's lifetime corresponds to the app/server's lifetime when the provider starts with the app and is disposed when the app shuts down.

Scoped services are disposed by the container that created them. If a scoped service is created in the root container, the service's lifetime is effectively promoted to singleton because it's only disposed by the root container when app/server is shut down. Validating service scopes catches these situations when `BuildServiceProvider` is called.

To always validate scopes, including in the Production environment, configure the ServiceProviderOptions with UseDefaultServiceProvider on the host builder:

C#

```
WebHost.CreateDefaultBuilder(args)
    .UseDefaultServiceProvider((context, options) => {
        options.ValidateScopes = true;
    })
```

> For the current release, see the **.NET 8 version of this article**.

Application configuration in ASP.NET Core is performed using one or more configuration providers. Configuration providers read configuration data from key-value pairs using a variety of configuration sources:

- Settings files, such as `appsettings.json`
- Environment variables
- Azure Key Vault
- Azure App Configuration
- Command-line arguments
- Custom providers, installed or created
- Directory files
- In-memory .NET objects

This article provides information on configuration in ASP.NET Core. For information on using configuration in console apps, see .NET Configuration.

For Blazor configuration guidance, which adds to or supersedes the guidance in this node, see ASP.NET Core Blazor configuration.

Application and Host Configuration

ASP.NET Core apps configure and launch a *host*. The host is responsible for app startup and lifetime management. The ASP.NET Core templates create a WebApplicationBuilder which contains the host. While some configuration can be done in both the host and the application configuration providers, generally, only configuration that is necessary for the host should be done in host configuration.

Application configuration is the highest priority and is detailed in the next section. Host configuration follows application configuration, and is described in this article.

Default application configuration sources

ASP.NET Core web apps created with dotnet new or Visual Studio generate the following code:

```
C#

var builder = WebApplication.CreateBuilder(args);
```

WebApplication.CreateBuilder initializes a new instance of the WebApplicationBuilder class with preconfigured defaults. The initialized `WebApplicationBuilder` (`builder`) provides default configuration for the app in the following order, from highest to lowest priority:

1. Command-line arguments using the Command-line configuration provider.
2. Non-prefixed environment variables using the Non-prefixed environment variables configuration provider.
3. User secrets when the app runs in the `Development` environment.
4. `appsettings.{Environment}.json` using the JSON configuration provider. For example, `appsettings.Production.json` and `appsettings.Development.json`.
5. appsettings.json using the JSON configuration provider.
6. A fallback to the host configuration described in the next section.

Default host configuration sources

The following list contains the default host configuration sources from highest to lowest priority for WebApplicationBuilder:

1. Command-line arguments using the Command-line configuration provider
2. `DOTNET_`-prefixed environment variables using the Environment variables configuration provider.
3. `ASPNETCORE_`-prefixed environment variables using the Environment variables configuration provider.

For the .NET Generic Host and Web Host, the default host configuration sources from highest to lowest priority is:

1. `ASPNETCORE_`-prefixed environment variables using the Environment variables configuration provider.

2. Command-line arguments using the Command-line configuration provider
3. `DOTNET_`-prefixed environment variables using the Environment variables configuration provider.

When a configuration value is set in host and application configuration, the application configuration is used.

Host variables

The following variables are locked in early when initializing the host builders and can't be influenced by application config:

- Application name
- Environment name, for example `Development`, `Production`, and `Staging`
- Content root
- Web root
- Whether to scan for hosting startup assemblies and which assemblies to scan for.
- Variables read by app and library code from HostBuilderContext.Configuration in IHostBuilder.ConfigureAppConfiguration callbacks.

Every other host setting is read from application config instead of host config.

`URLS` is one of the many common host settings that is not a bootstrap setting. Like every other host setting not in the previous list, `URLS` is read later from application config. Host config is a fallback for application config, so host config can be used to set `URLS`, but it will be overridden by any configuration source in application config like `appsettings.json`.

For more information, see Change the content root, app name, and environment and Change the content root, app name, and environment by environment variables or command line

The remaining sections in this article refer to application configuration.

Application configuration providers

The following code displays the enabled configuration providers in the order they were added:

```
C#

public class Index2Model : PageModel
{
```

```
    private IConfigurationRoot ConfigRoot;

    public Index2Model(IConfiguration configRoot)
    {
        ConfigRoot = (IConfigurationRoot)configRoot;
    }

    public ContentResult OnGet()
    {
        string str = "";
        foreach (var provider in ConfigRoot.Providers.ToList())
        {
            str += provider.ToString() + "\n";
        }

        return Content(str);
    }
}
```

The preceding list of highest to lowest priority default configuration sources shows the providers in the opposite order they are added to template generated application. For example, the JSON configuration provider is added before the Command-line configuration provider.

Configuration providers that are added later have higher priority and override previous key settings. For example, if `MyKey` is set in both `appsettings.json` and the environment, the environment value is used. Using the default configuration providers, the Command-line configuration provider overrides all other providers.

For more information on `CreateBuilder`, see Default builder settings.

`appsettings.json`

Consider the following `appsettings.json` file:

JSON

```
{
  "Position": {
    "Title": "Editor",
    "Name": "Joe Smith"
  },
  "MyKey": "My appsettings.json Value",
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "Microsoft": "Warning",
      "Microsoft.Hosting.Lifetime": "Information"
    }
```

```
  },
  "AllowedHosts": "*"
}
```

The following code from the sample download displays several of the preceding configurations settings:

C#

```
public class TestModel : PageModel
{
    // requires using Microsoft.Extensions.Configuration;
    private readonly IConfiguration Configuration;

    public TestModel(IConfiguration configuration)
    {
        Configuration = configuration;
    }

    public ContentResult OnGet()
    {
        var myKeyValue = Configuration["MyKey"];
        var title = Configuration["Position:Title"];
        var name = Configuration["Position:Name"];
        var defaultLogLevel = Configuration["Logging:LogLevel:Default"];

        return Content($"MyKey value: {myKeyValue} \n" +
                       $"Title: {title} \n" +
                       $"Name: {name} \n" +
                       $"Default Log Level: {defaultLogLevel}");
    }
}
```

The default JsonConfigurationProvider loads configuration in the following order:

1. `appsettings.json`
2. `appsettings.{Environment}.json` : For example, the `appsettings.Production.json` and `appsettings.Development.json` files. The environment version of the file is loaded based on the IHostingEnvironment.EnvironmentName. For more information, see Use multiple environments in ASP.NET Core.

`appsettings.{Environment}.json` values override keys in `appsettings.json`. For example, by default:

- In development, `appsettings.Development.json` configuration overwrites values found in `appsettings.json`.

- In production, `appsettings.Production.json` configuration overwrites values found in `appsettings.json`. For example, when deploying the app to Azure.

If a configuration value must be guaranteed, see GetValue. The preceding example only reads strings and doesn't support a default value.

Using the default configuration, the `appsettings.json` and `appsettings.{Environment}.json` files are enabled with reloadOnChange: true. Changes made to the `appsettings.json` and `appsettings.{Environment}.json` file ***after*** the app starts are read by the JSON configuration provider.

Comments in appsettings.json

Comments in `appsettings.json` and `appsettings.{Environment}.json` files are supported using JavaScript or C# style comments.

Bind hierarchical configuration data using the options pattern

The preferred way to read related configuration values is using the options pattern. For example, to read the following configuration values:

JSON

```
  "Position": {
    "Title": "Editor",
    "Name": "Joe Smith"
  }
```

Create the following `PositionOptions` class:

C#

```
public class PositionOptions
{
    public const string Position = "Position";

    public string Title { get; set; } = String.Empty;
    public string Name { get; set; } = String.Empty;
}
```

An options class:

- Must be non-abstract with a public parameterless constructor.

- All public read-write properties of the type are bound.
- Fields are ***not*** bound. In the preceding code, `Position` is not bound. The `Position` field is used so the string `"Position"` doesn't need to be hard coded in the app when binding the class to a configuration provider.

The following code:

- Calls ConfigurationBinder.Bind to bind the `PositionOptions` class to the `Position` section.
- Displays the `Position` configuration data.

C#

```
public class Test22Model : PageModel
{
    private readonly IConfiguration Configuration;

    public Test22Model(IConfiguration configuration)
    {
        Configuration = configuration;
    }

    public ContentResult OnGet()
    {
        var positionOptions = new PositionOptions();

Configuration.GetSection(PositionOptions.Position).Bind(positionOptions);

        return Content($"Title: {positionOptions.Title} \n" +
                       $"Name: {positionOptions.Name}");
    }
}
```

In the preceding code, by default, changes to the JSON configuration file after the app has started are read.

ConfigurationBinder.Get<T> binds and returns the specified type. `ConfigurationBinder.Get<T>` may be more convenient than using `ConfigurationBinder.Bind`. The following code shows how to use `ConfigurationBinder.Get<T>` with the `PositionOptions` class:

C#

```
public class Test21Model : PageModel
{
    private readonly IConfiguration Configuration;
    public PositionOptions? positionOptions { get; private set; }
```

```
    public Test21Model(IConfiguration configuration)
    {
        Configuration = configuration;
    }

    public ContentResult OnGet()
    {
        positionOptions = Configuration.GetSection(PositionOptions.Position)
                                                        .Get<PositionOptions>
();

        return Content($"Title: {positionOptions.Title} \n" +
                       $"Name: {positionOptions.Name}");
    }
}
```

In the preceding code, by default, changes to the JSON configuration file after the app has started are read.

An alternative approach when using the ***options pattern*** is to bind the `Position` section and add it to the dependency injection service container. In the following code, `PositionOptions` is added to the service container with Configure and bound to configuration:

C#

```
using ConfigSample.Options;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();

builder.Services.Configure<PositionOptions>(
    builder.Configuration.GetSection(PositionOptions.Position));

var app = builder.Build();
```

Using the preceding code, the following code reads the position options:

C#

```
public class Test2Model : PageModel
{
    private readonly PositionOptions _options;

    public Test2Model(IOptions<PositionOptions> options)
    {
        _options = options.Value;
    }
```

```
    public ContentResult OnGet()
    {
        return Content($"Title: {_options.Title} \n" +
                       $"Name: {_options.Name}");
    }
}
```

In the preceding code, changes to the JSON configuration file after the app has started are ***not*** read. To read changes after the app has started, use IOptionsSnapshot.

Using the default configuration, the `appsettings.json` and `appsettings.{Environment}.json` files are enabled with reloadOnChange: true. Changes made to the `appsettings.json` and `appsettings.{Environment}.json` file ***after*** the app starts are read by the JSON configuration provider.

See JSON configuration provider in this document for information on adding additional JSON configuration files.

Combining service collection

Consider the following which registers services and configures options:

C#

```
using ConfigSample.Options;
using Microsoft.Extensions.DependencyInjection.ConfigSample.Options;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();

builder.Services.Configure<PositionOptions>(
    builder.Configuration.GetSection(PositionOptions.Position));
builder.Services.Configure<ColorOptions>(
    builder.Configuration.GetSection(ColorOptions.Color));

builder.Services.AddScoped<IMyDependency, MyDependency>();
builder.Services.AddScoped<IMyDependency2, MyDependency2>();

var app = builder.Build();
```

Related groups of registrations can be moved to an extension method to register services. For example, the configuration services are added to the following class:

C#

```
using ConfigSample.Options;
using Microsoft.Extensions.Configuration;

namespace Microsoft.Extensions.DependencyInjection
{
    public static class MyConfigServiceCollectionExtensions
    {
        public static IServiceCollection AddConfig(
             this IServiceCollection services, IConfiguration config)
        {
            services.Configure<PositionOptions>(
                config.GetSection(PositionOptions.Position));
            services.Configure<ColorOptions>(
                config.GetSection(ColorOptions.Color));

            return services;
        }

        public static IServiceCollection AddMyDependencyGroup(
             this IServiceCollection services)
        {
            services.AddScoped<IMyDependency, MyDependency>();
            services.AddScoped<IMyDependency2, MyDependency2>();

            return services;
        }
    }
}
```

The remaining services are registered in a similar class. The following code uses the new extension methods to register the services:

C#

```
using Microsoft.Extensions.DependencyInjection.ConfigSample.Options;

var builder = WebApplication.CreateBuilder(args);

builder.Services
    .AddConfig(builder.Configuration)
    .AddMyDependencyGroup();

builder.Services.AddRazorPages();

var app = builder.Build();
```

Note: Each `services.Add{GROUP_NAME}` extension method adds and potentially configures services. For example, AddControllersWithViews adds the services MVC controllers with views require, and AddRazorPages adds the services Razor Pages requires.

Security and user secrets

Configuration data guidelines:

- Never store passwords or other sensitive data in configuration provider code or in plain text configuration files. The Secret Manager tool can be used to store secrets in development.
- Don't use production secrets in development or test environments.
- Specify secrets outside of the project so that they can't be accidentally committed to a source code repository.
- Production apps should use the most secure authentication flow available. For more information, see Secure authentication flows.

By default, the user secrets configuration source is registered after the JSON configuration sources. Therefore, user secrets keys take precedence over keys in `appsettings.json` and `appsettings.{Environment}.json`.

For more information on storing passwords or other sensitive data:

- Use multiple environments in ASP.NET Core
- Safe storage of app secrets in development in ASP.NET Core: Includes advice on using environment variables to store sensitive data. The Secret Manager tool uses the File configuration provider to store user secrets in a JSON file on the local system.
- Azure Key Vault safely stores app secrets for ASP.NET Core apps. For more information, see Azure Key Vault configuration provider in ASP.NET Core.

Non-prefixed environment variables

Non-prefixed environment variables are environment variables other than those prefixed by `ASPNETCORE_` or `DOTNET_`. For example, the ASP.NET Core web application templates set `"ASPNETCORE_ENVIRONMENT": "Development"` in `launchSettings.json`. For more information on `ASPNETCORE_` and `DOTNET_` environment variables, see:

- List of highest to lowest priority default configuration sources including non-prefixed, `ASPNETCORE_`-prefixed and `DOTNETCORE_`-prefixed environment variables.
- DOTNET_ environment variables used outside of Microsoft.Extensions.Hosting.

Using the default configuration, the EnvironmentVariablesConfigurationProvider loads configuration from environment variable key-value pairs after reading `appsettings.json`, `appsettings.{Environment}.json`, and user secrets. Therefore, key

values read from the environment override values read from `appsettings.json`, `appsettings.{Environment}.json`, and user secrets.

The `:` separator doesn't work with environment variable hierarchical keys on all platforms. For example, the `:` separator is not supported by Bash. The double underscore, `__`, is:

- Supported by all platforms.
- Automatically replaced by a colon, `:`.

The following commands:

- Set the environment keys and values of the preceding example on Windows.
- Test the settings when using the sample download. The `dotnet run` command must be run in the project directory.

.NET CLI

```
set MyKey="My key from Environment"
set Position__Title=Environment_Editor
set Position__Name=Environment_Rick
dotnet run
```

The preceding environment settings:

- Are only set in processes launched from the command window they were set in.
- Won't be read by browsers launched with Visual Studio.

The following setx commands can be used to set the environment keys and values on Windows. Unlike `set`, `setx` settings are persisted. `/M` sets the variable in the system environment. If the `/M` switch isn't used, a user environment variable is set.

Console

```
setx MyKey "My key from setx Environment" /M
setx Position__Title Environment_Editor /M
setx Position__Name Environment_Rick /M
```

To test that the preceding commands override `appsettings.json` and `appsettings.{Environment}.json`:

- With Visual Studio: Exit and restart Visual Studio.
- With the CLI: Start a new command window and enter `dotnet run`.

Call AddEnvironmentVariables with a string to specify a prefix for environment variables:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();

builder.Configuration.AddEnvironmentVariables(prefix: "MyCustomPrefix_");

var app = builder.Build();
```

In the preceding code:

- `builder.Configuration.AddEnvironmentVariables(prefix: "MyCustomPrefix_")` is added after the default configuration providers. For an example of ordering the configuration providers, see JSON configuration provider.
- Environment variables set with the `MyCustomPrefix_` prefix override the default configuration providers. This includes environment variables without the prefix.

The prefix is stripped off when the configuration key-value pairs are read.

The following commands test the custom prefix:

.NET CLI

```
set MyCustomPrefix_MyKey="My key with MyCustomPrefix_ Environment"
set MyCustomPrefix_Position__Title=Editor_with_customPrefix
set MyCustomPrefix_Position__Name=Environment_Rick_cp
dotnet run
```

The default configuration loads environment variables and command line arguments prefixed with `DOTNET_` and `ASPNETCORE_`. The `DOTNET_` and `ASPNETCORE_` prefixes are used by ASP.NET Core for host and app configuration, but not for user configuration. For more information on host and app configuration, see .NET Generic Host.

On Azure App Service, select **New application setting** on the **Settings** > **Configuration** page. Azure App Service application settings are:

- Encrypted at rest and transmitted over an encrypted channel.
- Exposed as environment variables.

For more information, see Azure Apps: Override app configuration using the Azure Portal.

See Connection string prefixes for information on Azure database connection strings.

Naming of environment variables

Environment variable names reflect the structure of an `appsettings.json` file. Each element in the hierarchy is separated by a double underscore (preferable) or a colon. When the element structure includes an array, the array index should be treated as an additional element name in this path. Consider the following `appsettings.json` file and its equivalent values represented as environment variables.

`appsettings.json`

JSON

```
{
    "SmtpServer": "smtp.example.com",
    "Logging": [
        {
            "Name": "ToEmail",
            "Level": "Critical",
            "Args": {
                "FromAddress": "MySystem@example.com",
                "ToAddress": "SRE@example.com"
            }
        },
        {
            "Name": "ToConsole",
            "Level": "Information"
        }
    ]
}
```

environment variables

Console

```
setx SmtpServer smtp.example.com
setx Logging__0__Name ToEmail
setx Logging__0__Level Critical
setx Logging__0__Args__FromAddress MySystem@example.com
setx Logging__0__Args__ToAddress SRE@example.com
setx Logging__1__Name ToConsole
setx Logging__1__Level Information
```

Environment variables set in generated launchSettings.json

Environment variables set in `launchSettings.json` override those set in the system environment. For example, the ASP.NET Core web templates generate a `launchSettings.json` file that sets the endpoint configuration to:

JSON

```
"applicationUrl": "https://localhost:5001;http://localhost:5000"
```

Configuring the `applicationUrl` sets the `ASPNETCORE_URLS` environment variable and overrides values set in the environment.

Escape environment variables on Linux

On Linux, the value of URL environment variables must be escaped so `systemd` can parse it. Use the linux tool `systemd-escape` which yields `http:--localhost:5001`

Windows Command Prompt

```
groot@terminus:~$ systemd-escape http://localhost:5001
http:--localhost:5001
```

Display environment variables

The following code displays the environment variables and values on application startup, which can be helpful when debugging environment settings:

C#

```
var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

foreach (var c in builder.Configuration.AsEnumerable())
{
    Console.WriteLine(c.Key + " = " + c.Value);
}
```

Command-line

Using the default configuration, the CommandLineConfigurationProvider loads configuration from command-line argument key-value pairs after the following configuration sources:

- `appsettings.json` and `appsettings.{Environment}.json` files.
- App secrets in the Development environment.
- Environment variables.

By default, configuration values set on the command-line override configuration values set with all the other configuration providers.

Command-line arguments

The following command sets keys and values using `=`:

.NET CLI

```
dotnet run MyKey="Using =" Position:Title=Cmd Position:Name=Cmd_Rick
```

The following command sets keys and values using `/`:

.NET CLI

```
dotnet run /MyKey "Using /" /Position:Title=Cmd /Position:Name=Cmd_Rick
```

The following command sets keys and values using `--`:

.NET CLI

```
dotnet run --MyKey "Using --" --Position:Title=Cmd --Position:Name=Cmd_Rick
```

The key value:

- Must follow `=`, or the key must have a prefix of `--` or `/` when the value follows a space.
- Isn't required if `=` is used. For example, `MySetting=`.

Within the same command, don't mix command-line argument key-value pairs that use `=` with key-value pairs that use a space.

Switch mappings

Switch mappings allow **key** name replacement logic. Provide a dictionary of switch replacements to the AddCommandLine method.

When the switch mappings dictionary is used, the dictionary is checked for a key that matches the key provided by a command-line argument. If the command-line key is found in the dictionary, the dictionary value is passed back to set the key-value pair into the app's configuration. A switch mapping is required for any command-line key prefixed with a single dash (`-`).

Switch mappings dictionary key rules:

- Switches must start with `-` or `--`.
- The switch mappings dictionary must not contain duplicate keys.

To use a switch mappings dictionary, pass it into the call to `AddCommandLine`:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();

var switchMappings = new Dictionary<string, string>()
         {
             { "-k1", "key1" },
             { "-k2", "key2" },
             { "--alt3", "key3" },
             { "--alt4", "key4" },
             { "--alt5", "key5" },
             { "--alt6", "key6" },
         };

builder.Configuration.AddCommandLine(args, switchMappings);

var app = builder.Build();
```

Run the following command works to test key replacement:

.NET CLI

```
dotnet run -k1 value1 -k2 value2 --alt3=value2 /alt4=value3 --alt5 value5
/alt6 value6
```

The following code shows the key values for the replaced keys:

C#

```
public class Test3Model : PageModel
{
```

```
    private readonly IConfiguration Config;

    public Test3Model(IConfiguration configuration)
    {
        Config = configuration;
    }

    public ContentResult OnGet()
    {
        return Content(
                $"Key1: '{Config["Key1"]}'\n" +
                $"Key2: '{Config["Key2"]}'\n" +
                $"Key3: '{Config["Key3"]}'\n" +
                $"Key4: '{Config["Key4"]}'\n" +
                $"Key5: '{Config["Key5"]}'\n" +
                $"Key6: '{Config["Key6"]}'");
    }
}
```

For apps that use switch mappings, the call to `CreateDefaultBuilder` shouldn't pass arguments. The `CreateDefaultBuilder` method's `AddCommandLine` call doesn't include mapped switches, and there's no way to pass the switch-mapping dictionary to `CreateDefaultBuilder`. The solution isn't to pass the arguments to `CreateDefaultBuilder` but instead to allow the `ConfigurationBuilder` method's `AddCommandLine` method to process both the arguments and the switch-mapping dictionary.

Set environment and command-line arguments with Visual Studio

Environment and command-line arguments can be set in Visual Studio from the launch profiles dialog:

- In Solution Explorer, right click the project and select **Properties**.
- Select the **Debug** > **General** tab and select **Open debug launch profiles UI**.

Hierarchical configuration data

The Configuration API reads hierarchical configuration data by flattening the hierarchical data with the use of a delimiter in the configuration keys.

The sample download contains the following `appsettings.json` file:

```
JSON
```

```
{
  "Position": {
    "Title": "Editor",
    "Name": "Joe Smith"
  },
  "MyKey": "My appsettings.json Value",
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "Microsoft": "Warning",
      "Microsoft.Hosting.Lifetime": "Information"
    }
  },
  "AllowedHosts": "*"
}
```

The following code from the sample download displays several of the configurations settings:

C#

```
public class TestModel : PageModel
{
    // requires using Microsoft.Extensions.Configuration;
    private readonly IConfiguration Configuration;

    public TestModel(IConfiguration configuration)
    {
        Configuration = configuration;
    }

    public ContentResult OnGet()
    {
        var myKeyValue = Configuration["MyKey"];
        var title = Configuration["Position:Title"];
        var name = Configuration["Position:Name"];
        var defaultLogLevel = Configuration["Logging:LogLevel:Default"];

        return Content($"MyKey value: {myKeyValue} \n" +
                       $"Title: {title} \n" +
                       $"Name: {name} \n" +
                       $"Default Log Level: {defaultLogLevel}");
    }
}
```

The preferred way to read hierarchical configuration data is using the options pattern. For more information, see Bind hierarchical configuration data in this document.

GetSection and GetChildren methods are available to isolate sections and children of a section in the configuration data. These methods are described later in GetSection, GetChildren, and Exists.

Configuration keys and values

> ⚠ **Warning**
>
> This article shows the use of connection strings. With a local database the user doesn't have to be authenticated, but in production, connection strings sometimes include a password to authenticate. A resource owner password credential (ROPC) is a security risk that should be avoided in production databases. Production apps should use the most secure authentication flow available. For more information on authentication for apps deployed to test or production environments, see **Secure authentication flows**.

Configuration keys:

- Are case-insensitive. For example, `ConnectionString` and `connectionstring` are treated as equivalent keys.
- If a key and value is set in more than one configuration provider, the value from the last provider added is used. For more information, see Default configuration.
- Hierarchical keys
  - Within the Configuration API, a colon separator (`:`) works on all platforms.
  - In environment variables, a colon separator may not work on all platforms. A double underscore, `__`, is supported by all platforms and is automatically converted into a colon `:`.
  - In Azure Key Vault, hierarchical keys use `--` as a separator. The Azure Key Vault configuration provider automatically replaces `--` with a `:` when the secrets are loaded into the app's configuration.
- The ConfigurationBinder supports binding arrays to objects using array indices in configuration keys. Array binding is described in the Bind an array to a class section.

Configuration values:

- Are strings.
- Null values can't be stored in configuration or bound to objects.

Configuration providers

The following table shows the configuration providers available to ASP.NET Core apps.

Expand table

Provider	Provides configuration from
Azure Key Vault configuration provider	Azure Key Vault
Azure App configuration provider	Azure App Configuration
Command-line configuration provider	Command-line parameters
Custom configuration provider	Custom source
Environment Variables configuration provider	Environment variables
File configuration provider	INI, JSON, and XML files
Key-per-file configuration provider	Directory files
Memory configuration provider	In-memory collections
User secrets	File in the user profile directory

Configuration sources are read in the order that their configuration providers are specified. Order configuration providers in code to suit the priorities for the underlying configuration sources that the app requires.

A typical sequence of configuration providers is:

1. `appsettings.json`
2. `appsettings.{Environment}.json`
3. User secrets
4. Environment variables using the Environment Variables configuration provider.
5. Command-line arguments using the Command-line configuration provider.

A common practice is to add the Command-line configuration provider last in a series of providers to allow command-line arguments to override configuration set by the other providers.

The preceding sequence of providers is used in the default configuration.

Connection string prefixes

⚠ **Warning**

This article shows the use of connection strings. With a local database the user doesn't have to be authenticated, but in production, connection strings sometimes include a password to authenticate. A resource owner password credential (ROPC) is a security risk that should be avoided in production databases. Production apps should use the most secure authentication flow available. For more information on authentication for apps deployed to test or production environments, see **Secure authentication flows**.

The Configuration API has special processing rules for four connection string environment variables. These connection strings are involved in configuring Azure connection strings for the app environment. Environment variables with the prefixes shown in the table are loaded into the app with the default configuration or when no prefix is supplied to `AddEnvironmentVariables`.

Expand table

Connection string prefix	Provider
`CUSTOMCONNSTR_`	Custom provider
`MYSQLCONNSTR_`	MySQL
`SQLAZURECONNSTR_`	Azure SQL Database
`SQLCONNSTR_`	SQL Server

When an environment variable is discovered and loaded into configuration with any of the four prefixes shown in the table:

- The configuration key is created by removing the environment variable prefix and adding a configuration key section (`ConnectionStrings`).
- A new configuration key-value pair is created that represents the database connection provider (except for `CUSTOMCONNSTR_`, which has no stated provider).

Expand table

Environment variable key	Converted configuration key	Provider configuration entry
`CUSTOMCONNSTR_{KEY}`	`ConnectionStrings:{KEY}`	Configuration entry not created.
`MYSQLCONNSTR_{KEY}`	`ConnectionStrings:{KEY}`	Key: `ConnectionStrings:{KEY}_ProviderName` Value: `MySql.Data.MySqlClient`

Environment variable key	Converted configuration key	Provider configuration entry
`SQLAZURECONNSTR_{KEY}`	`ConnectionStrings:{KEY}`	Key: `ConnectionStrings:{KEY}_ProviderName`: Value: `System.Data.SqlClient`
`SQLCONNSTR_{KEY}`	`ConnectionStrings:{KEY}`	Key: `ConnectionStrings:{KEY}_ProviderName`: Value: `System.Data.SqlClient`

File configuration provider

FileConfigurationProvider is the base class for loading configuration from the file system. The following configuration providers derive from `FileConfigurationProvider`:

- INI configuration provider
- JSON configuration provider
- XML configuration provider

INI configuration provider

The IniConfigurationProvider loads configuration from INI file key-value pairs at runtime.

The following code adds several configuration providers:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Configuration
    .AddIniFile("MyIniConfig.ini", optional: true, reloadOnChange: true)
    .AddIniFile($"MyIniConfig.{builder.Environment.EnvironmentName}.ini",
                optional: true, reloadOnChange: true);

builder.Configuration.AddEnvironmentVariables();
builder.Configuration.AddCommandLine(args);

builder.Services.AddRazorPages();

var app = builder.Build();
```

In the preceding code, settings in the `MyIniConfig.ini` and `MyIniConfig.{Environment}.ini` files are overridden by settings in the:

- Environment variables configuration provider

- Command-line configuration provider.

The sample download contains the following `MyIniConfig.ini` file:

ini

```ini
MyKey="MyIniConfig.ini Value"

[Position]
Title="My INI Config title"
Name="My INI Config name"

[Logging:LogLevel]
Default=Information
Microsoft=Warning
```

The following code from the sample download displays several of the preceding configurations settings:

C#

```
public class TestModel : PageModel
{
    // requires using Microsoft.Extensions.Configuration;
    private readonly IConfiguration Configuration;

    public TestModel(IConfiguration configuration)
    {
        Configuration = configuration;
    }

    public ContentResult OnGet()
    {
        var myKeyValue = Configuration["MyKey"];
        var title = Configuration["Position:Title"];
        var name = Configuration["Position:Name"];
        var defaultLogLevel = Configuration["Logging:LogLevel:Default"];

        return Content($"MyKey value: {myKeyValue} \n" +
                       $"Title: {title} \n" +
                       $"Name: {name} \n" +
                       $"Default Log Level: {defaultLogLevel}");
    }
}
```

JSON configuration provider

The JsonConfigurationProvider loads configuration from JSON file key-value pairs.

Overloads can specify:

- Whether the file is optional.
- Whether the configuration is reloaded if the file changes.

Consider the following code:

```
C#
```

```
using Microsoft.Extensions.DependencyInjection.ConfigSample.Options;

var builder = WebApplication.CreateBuilder(args);

builder.Configuration.AddJsonFile("MyConfig.json",
        optional: true,
        reloadOnChange: true);

builder.Services.AddRazorPages();

var app = builder.Build();
```

The preceding code:

- Configures the JSON configuration provider to load the `MyConfig.json` file with the following options:
  - `optional: true`: The file is optional.
  - `reloadOnChange: true` : The file is reloaded when changes are saved.
- Reads the default configuration providers before the `MyConfig.json` file. Settings in the `MyConfig.json` file override setting in the default configuration providers, including the Environment variables configuration provider and the Command-line configuration provider.

You typically ***don't*** want a custom JSON file overriding values set in the Environment variables configuration provider and the Command-line configuration provider.

XML configuration provider

The XmlConfigurationProvider loads configuration from XML file key-value pairs at runtime.

The following code adds several configuration providers:

```
C#
```

```
var builder = WebApplication.CreateBuilder(args);
```

```
builder.Configuration
    .AddXmlFile("MyXMLFile.xml", optional: true, reloadOnChange: true)
    .AddXmlFile($"MyXMLFile.{builder.Environment.EnvironmentName}.xml",
                optional: true, reloadOnChange: true);

builder.Configuration.AddEnvironmentVariables();
builder.Configuration.AddCommandLine(args);

builder.Services.AddRazorPages();

var app = builder.Build();
```

In the preceding code, settings in the `MyXMLFile.xml` and `MyXMLFile.{Environment}.xml` files are overridden by settings in the:

- Environment variables configuration provider
- Command-line configuration provider.

The sample download contains the following `MyXMLFile.xml` file:

XML

```
<?xml version="1.0" encoding="utf-8" ?>
<configuration>
  <MyKey>MyXMLFile Value</MyKey>
  <Position>
    <Title>Title from  MyXMLFile</Title>
    <Name>Name from MyXMLFile</Name>
  </Position>
  <Logging>
    <LogLevel>
      <Default>Information</Default>
      <Microsoft>Warning</Microsoft>
    </LogLevel>
  </Logging>
</configuration>
```

The following code from the sample download displays several of the preceding configurations settings:

C#

```
public class TestModel : PageModel
{
    // requires using Microsoft.Extensions.Configuration;
    private readonly IConfiguration Configuration;

    public TestModel(IConfiguration configuration)
    {
        Configuration = configuration;
```

```
    }

    public ContentResult OnGet()
    {
        var myKeyValue = Configuration["MyKey"];
        var title = Configuration["Position:Title"];
        var name = Configuration["Position:Name"];
        var defaultLogLevel = Configuration["Logging:LogLevel:Default"];

        return Content($"MyKey value: {myKeyValue} \n" +
                       $"Title: {title} \n" +
                       $"Name: {name} \n" +
                       $"Default Log Level: {defaultLogLevel}");
    }
}
```

Repeating elements that use the same element name work if the `name` attribute is used to distinguish the elements:

XML

```
<?xml version="1.0" encoding="UTF-8"?>
<configuration>
  <section name="section0">
    <key name="key0">value 00</key>
    <key name="key1">value 01</key>
  </section>
  <section name="section1">
    <key name="key0">value 10</key>
    <key name="key1">value 11</key>
  </section>
</configuration>
```

The following code reads the previous configuration file and displays the keys and values:

C#

```
public class IndexModel : PageModel
{
    private readonly IConfiguration Configuration;

    public IndexModel(IConfiguration configuration)
    {
        Configuration = configuration;
    }

    public ContentResult OnGet()
    {
        var key00 = "section:section0:key:key0";
```

```
        var key01 = "section:section0:key:key1";
        var key10 = "section:section1:key:key0";
        var key11 = "section:section1:key:key1";

        var val00 = Configuration[key00];
        var val01 = Configuration[key01];
        var val10 = Configuration[key10];
        var val11 = Configuration[key11];

        return Content($"{key00} value: {val00} \n" +
                       $"{key01} value: {val01} \n" +
                       $"{key10} value: {val10} \n" +
                       $"{key10} value: {val11} \n"
                       );
    }
}
```

Attributes can be used to supply values:

XML

```
<?xml version="1.0" encoding="UTF-8"?>
<configuration>
  <key attribute="value" />
  <section>
    <key attribute="value" />
  </section>
</configuration>
```

The previous configuration file loads the following keys with `value`:

- key:attribute
- section:key:attribute

Key-per-file configuration provider

The KeyPerFileConfigurationProvider uses a directory's files as configuration key-value pairs. The key is the file name. The value contains the file's contents. The Key-per-file configuration provider is used in Docker hosting scenarios.

To activate key-per-file configuration, call the AddKeyPerFile extension method on an instance of ConfigurationBuilder. The `directoryPath` to the files must be an absolute path.

Overloads permit specifying:

- An `Action<KeyPerFileConfigurationSource>` delegate that configures the source.

- Whether the directory is optional and the path to the directory.

The double-underscore (`__`) is used as a configuration key delimiter in file names. For example, the file name `Logging__LogLevel__System` produces the configuration key `Logging:LogLevel:System`.

Call `ConfigureAppConfiguration` when building the host to specify the app's configuration:

C#

```
.ConfigureAppConfiguration((hostingContext, config) =>
{
    var path = Path.Combine(
        Directory.GetCurrentDirectory(), "path/to/files");
    config.AddKeyPerFile(directoryPath: path, optional: true);
})
```

Memory configuration provider

The MemoryConfigurationProvider uses an in-memory collection as configuration key-value pairs.

The following code adds a memory collection to the configuration system:

C#

```
var builder = WebApplication.CreateBuilder(args);

var Dict = new Dictionary<string, string>
        {
           {"MyKey", "Dictionary MyKey Value"},
           {"Position:Title", "Dictionary_Title"},
           {"Position:Name", "Dictionary_Name" },
           {"Logging:LogLevel:Default", "Warning"}
        };

builder.Configuration.AddInMemoryCollection(Dict);
builder.Configuration.AddEnvironmentVariables();
builder.Configuration.AddCommandLine(args);

builder.Services.AddRazorPages();

var app = builder.Build();
```

The following code from the sample download displays the preceding configurations settings:

C#

```
public class TestModel : PageModel
{
    // requires using Microsoft.Extensions.Configuration;
    private readonly IConfiguration Configuration;

    public TestModel(IConfiguration configuration)
    {
        Configuration = configuration;
    }

    public ContentResult OnGet()
    {
        var myKeyValue = Configuration["MyKey"];
        var title = Configuration["Position:Title"];
        var name = Configuration["Position:Name"];
        var defaultLogLevel = Configuration["Logging:LogLevel:Default"];

        return Content($"MyKey value: {myKeyValue} \n" +
                       $"Title: {title} \n" +
                       $"Name: {name} \n" +
                       $"Default Log Level: {defaultLogLevel}");
    }
}
```

In the preceding code, `config.AddInMemoryCollection(Dict)` is added after the default configuration providers. For an example of ordering the configuration providers, see JSON configuration provider.

See Bind an array for another example using `MemoryConfigurationProvider`.

Kestrel endpoint configuration

Kestrel specific endpoint configuration overrides all cross-server endpoint configurations. Cross-server endpoint configurations include:

- UseUrls
- `--urls` on the command line
- The environment variable `ASPNETCORE_URLS`

Consider the following `appsettings.json` file used in an ASP.NET Core web app:

JSON

```
{
  "Kestrel": {
    "Endpoints": {
      "Https": {
        "Url": "https://localhost:9999"
      }
    }
  },
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "Microsoft": "Warning",
      "Microsoft.Hosting.Lifetime": "Information"
    }
  },
  "AllowedHosts": "*"
}
```

When the preceding highlighted markup is used in an ASP.NET Core web app ***and*** the app is launched on the command line with the following cross-server endpoint configuration:

```
dotnet run --urls="https://localhost:7777"
```

Kestrel binds to the endpoint configured specifically for Kestrel in the `appsettings.json` file (`https://localhost:9999`) and not `https://localhost:7777`.

Consider the Kestrel specific endpoint configured as an environment variable:

```
set Kestrel__Endpoints__Https__Url=https://localhost:8888
```

In the preceding environment variable, `Https` is the name of the Kestrel specific endpoint. The preceding `appsettings.json` file also defines a Kestrel specific endpoint named `Https`. By default, environment variables using the Environment Variables configuration provider are read after `appsettings.{Environment}.json`, therefore, the preceding environment variable is used for the `Https` endpoint.

GetValue

ConfigurationBinder.GetValue extracts a single value from configuration with a specified key and converts it to the specified type:

```
C#

public class TestNumModel : PageModel
{
```

```
    private readonly IConfiguration Configuration;

    public TestNumModel(IConfiguration configuration)
    {
        Configuration = configuration;
    }

    public ContentResult OnGet()
    {
        var number = Configuration.GetValue<int>("NumberKey", 99);
        return Content($"{number}");
    }
}
```

In the preceding code, if `NumberKey` isn't found in the configuration, the default value of `99` is used.

GetSection, GetChildren, and Exists

For the examples that follow, consider the following `MySubsection.json` file:

JSON

```
{
  "section0": {
    "key0": "value00",
    "key1": "value01"
  },
  "section1": {
    "key0": "value10",
    "key1": "value11"
  },
  "section2": {
    "subsection0": {
      "key0": "value200",
      "key1": "value201"
    },
    "subsection1": {
      "key0": "value210",
      "key1": "value211"
    }
  }
}
```

The following code adds `MySubsection.json` to the configuration providers:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Configuration
    .AddJsonFile("MySubsection.json",
                 optional: true,
                 reloadOnChange: true);

builder.Services.AddRazorPages();

var app = builder.Build();
```

GetSection

IConfiguration.GetSection returns a configuration subsection with the specified subsection key.

The following code returns values for `section1`:

C#

```
public class TestSectionModel : PageModel
{
    private readonly IConfiguration Config;

    public TestSectionModel(IConfiguration configuration)
    {
        Config = configuration.GetSection("section1");
    }

    public ContentResult OnGet()
    {
        return Content(
                $"section1:key0: '{Config["key0"]}'\n" +
                $"section1:key1: '{Config["key1"]}'");
    }
}
```

The following code returns values for `section2:subsection0`:

C#

```
public class TestSection2Model : PageModel
{
    private readonly IConfiguration Config;

    public TestSection2Model(IConfiguration configuration)
    {
        Config = configuration.GetSection("section2:subsection0");
    }
```

```
    public ContentResult OnGet()
    {
        return Content(
                $"section2:subsection0:key0 '{Config["key0"]}'\n" +
                $"section2:subsection0:key1:'{Config["key1"]}'");
    }
}
```

`GetSection` never returns `null`. If a matching section isn't found, an empty `IConfigurationSection` is returned.

When `GetSection` returns a matching section, Value isn't populated. A Key and Path are returned when the section exists.

GetChildren and Exists

The following code calls IConfiguration.GetChildren and returns values for `section2:subsection0`:

C#

```
public class TestSection4Model : PageModel
{
    private readonly IConfiguration Config;

    public TestSection4Model(IConfiguration configuration)
    {
        Config = configuration;
    }

    public ContentResult OnGet()
    {
        string s = "";
        var selection = Config.GetSection("section2");
        if (!selection.Exists())
        {
            throw new Exception("section2 does not exist.");
        }
        var children = selection.GetChildren();

        foreach (var subSection in children)
        {
            int i = 0;
            var key1 = subSection.Key + ":key" + i++.ToString();
            var key2 = subSection.Key + ":key" + i.ToString();
            s += key1 + " value: " + selection[key1] + "\n";
            s += key2 + " value: " + selection[key2] + "\n";
        }
        return Content(s);
```

```
    }
}
```

The preceding code calls ConfigurationExtensions.Exists to verify the section exists:

Bind an array

The ConfigurationBinder.Bind supports binding arrays to objects using array indices in configuration keys. Any array format that exposes a numeric key segment is capable of array binding to a POCO class array.

Consider `MyArray.json` from the sample download:

JSON

```
{
  "array": {
    "entries": {
      "0": "value00",
      "1": "value10",
      "2": "value20",
      "4": "value40",
      "5": "value50"
    }
  }
}
```

The following code adds `MyArray.json` to the configuration providers:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Configuration
    .AddJsonFile("MyArray.json",
                 optional: true,
                 reloadOnChange: true);

builder.Services.AddRazorPages();

var app = builder.Build();
```

The following code reads the configuration and displays the values:

C#

```
public class ArrayModel : PageModel
{
    private readonly IConfiguration Config;
    public ArrayExample? _array { get; private set; }

    public ArrayModel(IConfiguration config)
    {
        Config = config;
    }

    public ContentResult OnGet()
    {
       _array = Config.GetSection("array").Get<ArrayExample>();
        if (_array == null)
        {
            throw new ArgumentNullException(nameof(_array));
        }
        string s = String.Empty;

        for (int j = 0; j < _array.Entries.Length; j++)
        {
            s += $"Index: {j}  Value:  {_array.Entries[j]} \n";
        }

        return Content(s);
    }
}
```

C#

```
public class ArrayExample
{
    public string[]? Entries { get; set; }
}
```

The preceding code returns the following output:

text

```
Index: 0  Value: value00
Index: 1  Value: value10
Index: 2  Value: value20
Index: 3  Value: value40
Index: 4  Value: value50
```

In the preceding output, Index 3 has value `value40`, corresponding to `"4": "value40",` in `MyArray.json`. The bound array indices are continuous and not bound to the configuration key index. The configuration binder isn't capable of binding null values or creating null entries in bound objects.

Custom configuration provider

The sample app demonstrates how to create a basic configuration provider that reads configuration key-value pairs from a database using Entity Framework (EF).

The provider has the following characteristics:

- The EF in-memory database is used for demonstration purposes. To use a database that requires a connection string, implement a secondary `ConfigurationBuilder` to supply the connection string from another configuration provider.
- The provider reads a database table into configuration at startup. The provider doesn't query the database on a per-key basis.
- Reload-on-change isn't implemented, so updating the database after the app starts has no effect on the app's configuration.

Define an `EFConfigurationValue` entity for storing configuration values in the database.

`Models/EFConfigurationValue.cs`:

C#

```
public class EFConfigurationValue
{
    public string Id { get; set; } = String.Empty;
    public string Value { get; set; } = String.Empty;
}
```

Add an `EFConfigurationContext` to store and access the configured values.

`EFConfigurationProvider/EFConfigurationContext.cs`:

C#

```
public class EFConfigurationContext : DbContext
{
    public EFConfigurationContext(DbContextOptions<EFConfigurationContext>
options) : base(options)
    {
    }

    public DbSet<EFConfigurationValue> Values => Set<EFConfigurationValue>
();
}
```

Create a class that implements IConfigurationSource.

`EFConfigurationProvider/EFConfigurationSource.cs`:

```
C#

public class EFConfigurationSource : IConfigurationSource
{
    private readonly Action<DbContextOptionsBuilder> _optionsAction;

    public EFConfigurationSource(Action<DbContextOptionsBuilder>
optionsAction) => _optionsAction = optionsAction;

    public IConfigurationProvider Build(IConfigurationBuilder builder) =>
new EFConfigurationProvider(_optionsAction);
}
```

Create the custom configuration provider by inheriting from ConfigurationProvider. The configuration provider initializes the database when it's empty. Since configuration keys are case-insensitive, the dictionary used to initialize the database is created with the case-insensitive comparer (StringComparer.OrdinalIgnoreCase).

`EFConfigurationProvider/EFConfigurationProvider.cs`:

```
C#

public class EFConfigurationProvider : ConfigurationProvider
{
    public EFConfigurationProvider(Action<DbContextOptionsBuilder>
optionsAction)
    {
        OptionsAction = optionsAction;
    }

    Action<DbContextOptionsBuilder> OptionsAction { get; }

    public override void Load()
    {
        var builder = new DbContextOptionsBuilder<EFConfigurationContext>();

        OptionsAction(builder);

        using (var dbContext = new EFConfigurationContext(builder.Options))
        {
            if (dbContext == null || dbContext.Values == null)
            {
                throw new Exception("Null DB context");
            }
            dbContext.Database.EnsureCreated();

            Data = !dbContext.Values.Any()
                ? CreateAndSaveDefaultValues(dbContext)
                : dbContext.Values.ToDictionary(c => c.Id, c => c.Value);
```

```
        }
    }

    private static IDictionary<string, string> CreateAndSaveDefaultValues(
        EFConfigurationContext dbContext)
    {
        // Quotes (c)2005 Universal Pictures: Serenity
        // https://www.uphe.com/movies/serenity-2005
        var configValues =
            new Dictionary<string, string>(StringComparer.OrdinalIgnoreCase)
            {
                    { "quote1", "I aim to misbehave." },
                    { "quote2", "I swallowed a bug." },
                    { "quote3", "You can't stop the signal, Mal." }
            };

        if (dbContext == null || dbContext.Values == null)
        {
            throw new Exception("Null DB context");
        }

        dbContext.Values.AddRange(configValues
            .Select(kvp => new EFConfigurationValue
            {
                Id = kvp.Key,
                Value = kvp.Value
            })
            .ToArray());

        dbContext.SaveChanges();

        return configValues;
    }
}
```

An `AddEFConfiguration` extension method permits adding the configuration source to a `ConfigurationBuilder`.

`Extensions/EntityFrameworkExtensions.cs`:

C#

```
public static class EntityFrameworkExtensions
{
    public static IConfigurationBuilder AddEFConfiguration(
                this IConfigurationBuilder builder,
                Action<DbContextOptionsBuilder> optionsAction)
    {
        return builder.Add(new EFConfigurationSource(optionsAction));
    }
}
```

The following code shows how to use the custom `EFConfigurationProvider` in `Program.cs`:

C#

```
//using Microsoft.EntityFrameworkCore;

var builder = WebApplication.CreateBuilder(args);

builder.Configuration.AddEFConfiguration(
    opt => opt.UseInMemoryDatabase("InMemoryDb"));

var app = builder.Build();

app.Run();
```

Access configuration with Dependency Injection (DI)

Configuration can be injected into services using Dependency Injection (DI) by resolving the IConfiguration service:

C#

```
public class Service
{
    private readonly IConfiguration _config;

    public Service(IConfiguration config) =>
        _config = config;

    public void DoSomething()
    {
        var configSettingValue = _config["ConfigSetting"];

        // ...
    }
}
```

For information on how to access values using `IConfiguration`, see GetValue and GetSection, GetChildren, and Exists in this article.

Access configuration in Razor Pages

The following code displays configuration data in a Razor Page:

CSHTML

```
@page
@model Test5Model
@using Microsoft.Extensions.Configuration
@inject IConfiguration Configuration

Configuration value for 'MyKey': @Configuration["MyKey"]
```

In the following code, `MyOptions` is added to the service container with Configure and bound to configuration:

C#

```
using SampleApp.Models;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();

builder.Services.Configure<MyOptions>(
    builder.Configuration.GetSection("MyOptions"));

var app = builder.Build();
```

The following markup uses the @inject Razor directive to resolve and display the options values:

CSHTML

```
@page
@model SampleApp.Pages.Test3Model
@using Microsoft.Extensions.Options
@using SampleApp.Models
@inject IOptions<MyOptions> optionsAccessor

<p><b>Option1:</b> @optionsAccessor.Value.Option1</p>
<p><b>Option2:</b> @optionsAccessor.Value.Option2</p>
```

Access configuration in a MVC view file

The following code displays configuration data in a MVC view:

CSHTML

```
@using Microsoft.Extensions.Configuration
@inject IConfiguration Configuration

Configuration value for 'MyKey': @Configuration["MyKey"]
```

Access configuration in `Program.cs`

The following code accesses configuration in the `Program.cs` file.

C#

```
var builder = WebApplication.CreateBuilder(args);

var key1 = builder.Configuration.GetValue<string>("KeyOne");

var app = builder.Build();

app.MapGet("/", () => "Hello World!");

var key2 = app.Configuration.GetValue<int>("KeyTwo");
var key3 = app.Configuration.GetValue<bool>("KeyThree");

app.Logger.LogInformation("KeyOne: {KeyOne}", key1);
app.Logger.LogInformation("KeyTwo: {KeyTwo}", key2);
app.Logger.LogInformation("KeyThree: {KeyThree}", key3);

app.Run();
```

In `appsettings.json` for the preceding example:

JSON

```
{
  ...
  "KeyOne": "Key One Value",
  "KeyTwo": 1999,
  "KeyThree": true
}
```

Configure options with a delegate

Options configured in a delegate override values set in the configuration providers.

In the following code, an IConfigureOptions<TOptions> service is added to the service container. It uses a delegate to configure values for `MyOptions`:

C#

```
using SampleApp.Models;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();

builder.Services.Configure<MyOptions>(myOptions =>
{
    myOptions.Option1 = "Value configured in delegate";
    myOptions.Option2 = 500;
});

var app = builder.Build();
```

The following code displays the options values:

C#

```
public class Test2Model : PageModel
{
    private readonly IOptions<MyOptions> _optionsDelegate;

    public Test2Model(IOptions<MyOptions> optionsDelegate )
    {
        _optionsDelegate = optionsDelegate;
    }

    public ContentResult OnGet()
    {
        return Content($"Option1: {_optionsDelegate.Value.Option1} \n" +
                       $"Option2: {_optionsDelegate.Value.Option2}");
    }
}
```

In the preceding example, the values of `Option1` and `Option2` are specified in `appsettings.json` and then overridden by the configured delegate.

Host versus app configuration

Before the app is configured and started, a *host* is configured and launched. The host is responsible for app startup and lifetime management. Both the app and the host are configured using the configuration providers described in this topic. Host configuration key-value pairs are also included in the app's configuration. For more information on how the configuration providers are used when the host is built and how configuration sources affect host configuration, see ASP.NET Core fundamentals overview.

Default host configuration

For details on the default configuration when using the Web Host, see the ASP.NET Core 2.2 version of this topic.

- Host configuration is provided from:
  - Environment variables prefixed with `DOTNET_` (for example, `DOTNET_ENVIRONMENT`) using the Environment Variables configuration provider. The prefix (`DOTNET_`) is stripped when the configuration key-value pairs are loaded.
  - Command-line arguments using the Command-line configuration provider.
- Web Host default configuration is established (`ConfigureWebHostDefaults`):
  - Kestrel is used as the web server and configured using the app's configuration providers.
  - Add Host Filtering Middleware.
  - Add Forwarded Headers Middleware if the `ASPNETCORE_FORWARDEDHEADERS_ENABLED` environment variable is set to `true`.
  - Enable IIS integration.

Other configuration

This topic only pertains to *app configuration*. Other aspects of running and hosting ASP.NET Core apps are configured using configuration files not covered in this topic:

- `launch.json`/`launchSettings.json` are tooling configuration files for the Development environment, described:
  - In Use multiple environments in ASP.NET Core.
  - Across the documentation set where the files are used to configure ASP.NET Core apps for Development scenarios.
- `web.config` is a server configuration file, described in the following topics:
  - Host ASP.NET Core on Windows with IIS
  - ASP.NET Core Module (ANCM) for IIS

Environment variables set in `launchSettings.json` override those set in the system environment.

For more information on migrating app configuration from earlier versions of ASP.NET, see Update from ASP.NET to ASP.NET Core.

Add configuration from an external assembly

An IHostingStartup implementation allows adding enhancements to an app at startup from an external assembly outside of the app's `Startup` class. For more information, see Use hosting startup assemblies in ASP.NET Core.

Configuration-binding source generator

The Configuration-binding source generator provides AOT and trim-friendly configuration. For more information, see Configuration-binding source generator.

Options pattern in ASP.NET Core

Article • 10/18/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

By Rick Anderson.

The options pattern uses classes to provide strongly typed access to groups of related settings. When configuration settings are isolated by scenario into separate classes, the app adheres to two important software engineering principles:

- Encapsulation:
  - Classes that depend on configuration settings depend only on the configuration settings that they use.
- Separation of Concerns:
  - Settings for different parts of the app aren't dependent or coupled to one another.

Options also provide a mechanism to validate configuration data. For more information, see the Options validation section.

This article provides information on the options pattern in ASP.NET Core. For information on using the options pattern in console apps, see Options pattern in .NET.

Bind hierarchical configuration

The preferred way to read related configuration values is using the options pattern. For example, to read the following configuration values:

JSON

```
"Position": {
  "Title": "Editor",
  "Name": "Joe Smith"
}
```

Create the following `PositionOptions` class:

C#

```
public class PositionOptions
{
    public const string Position = "Position";

    public string Title { get; set; } = String.Empty;
    public string Name { get; set; } = String.Empty;
}
```

An options class:

- Must be non-abstract.
- Has public read-write properties of the type that have corresponding items in config are bound.
- Has its read-write properties bound to matching entries in configuration.
- Does ***not*** have its fields bound. In the preceding code, `Position` is not bound. The `Position` field is used so the string `"Position"` doesn't need to be hard coded in the app when binding the class to a configuration provider.

The following code:

- Calls ConfigurationBinder.Bind to bind the `PositionOptions` class to the `Position` section.
- Displays the `Position` configuration data.

C#

```
public class Test22Model : PageModel
{
    private readonly IConfiguration Configuration;

    public Test22Model(IConfiguration configuration)
    {
        Configuration = configuration;
    }

    public ContentResult OnGet()
    {
        var positionOptions = new PositionOptions();

Configuration.GetSection(PositionOptions.Position).Bind(positionOptions);

        return Content($"Title: {positionOptions.Title} \n" +
                       $"Name: {positionOptions.Name}");
```

```
    }
}
```

In the preceding code, by default, changes to the JSON configuration file after the app has started are read.

ConfigurationBinder.Get<T> binds and returns the specified type. `ConfigurationBinder.Get<T>` may be more convenient than using `ConfigurationBinder.Bind`. The following code shows how to use `ConfigurationBinder.Get<T>` with the `PositionOptions` class:

C#

```
public class Test21Model : PageModel
{
    private readonly IConfiguration Configuration;
    public PositionOptions? positionOptions { get; private set; }

    public Test21Model(IConfiguration configuration)
    {
        Configuration = configuration;
    }

    public ContentResult OnGet()
    {
        positionOptions = Configuration.GetSection(PositionOptions.Position)
                                                    .Get<PositionOptions>
();

        return Content($"Title: {positionOptions.Title} \n" +
                       $"Name: {positionOptions.Name}");
    }
}
```

In the preceding code, by default, changes to the JSON configuration file after the app has started are read.

Bind also allows the concretion of an abstract class. Consider the following code which uses the abstract class `SomethingWithAName`:

C#

```
namespace ConfigSample.Options;

public abstract class SomethingWithAName
{
    public abstract string? Name { get; set; }
}
```

```
public class NameTitleOptions(int age) : SomethingWithAName
{
    public const string NameTitle = "NameTitle";

    public override string? Name { get; set; }
    public string Title { get; set; } = string.Empty;

    public int Age { get; set; } = age;
}
```

The following code displays the `NameTitleOptions` configuration values:

C#

```
public class Test33Model : PageModel
{
    private readonly IConfiguration Configuration;

    public Test33Model(IConfiguration configuration)
    {
        Configuration = configuration;
    }

    public ContentResult OnGet()
    {
        var nameTitleOptions = new NameTitleOptions(22);

Configuration.GetSection(NameTitleOptions.NameTitle).Bind(nameTitleOptions);

        return Content($"Title: {nameTitleOptions.Title} \n" +
                       $"Name: {nameTitleOptions.Name}  \n" +
                       $"Age: {nameTitleOptions.Age}"
                       );
    }
}
```

Calls to `Bind` are less strict than calls to `Get<>`:

- `Bind` allows the concretion of an abstract.
- `Get<>` has to create an instance itself.

The Options Pattern

An alternative approach when using the ***options pattern*** is to bind the `Position` section and add it to the dependency injection service container. In the following code, `PositionOptions` is added to the service container with Configure and bound to configuration:

C#

```
using ConfigSample.Options;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();

builder.Services.Configure<PositionOptions>(
    builder.Configuration.GetSection(PositionOptions.Position));

var app = builder.Build();
```

Using the preceding code, the following code reads the position options:

C#

```
public class Test2Model : PageModel
{
    private readonly PositionOptions _options;

    public Test2Model(IOptions<PositionOptions> options)
    {
        _options = options.Value;
    }

    public ContentResult OnGet()
    {
        return Content($"Title: {_options.Title} \n" +
                       $"Name: {_options.Name}");
    }
}
```

In the preceding code, changes to the JSON configuration file after the app has started are ***not*** read. To read changes after the app has started, use IOptionsSnapshot.

Options interfaces

IOptions<TOptions>:

- Does ***not*** support:
  - Reading of configuration data after the app has started.
  - Named options
- Is registered as a Singleton and can be injected into any service lifetime.

IOptionsSnapshot<TOptions>:

- Is useful in scenarios where options should be recomputed on every request. For more information, see Use IOptionsSnapshot to read updated data.
- Is registered as Scoped and therefore can't be injected into a Singleton service.
- Supports named options

IOptionsMonitor<TOptions>:

- Is used to retrieve options and manage options notifications for `TOptions` instances.
- Is registered as a Singleton and can be injected into any service lifetime.
- Supports:
  - Change notifications
  - named options
  - Reloadable configuration
  - Selective options invalidation (IOptionsMonitorCache<TOptions>)

Post-configuration scenarios enable setting or changing options after all IConfigureOptions<TOptions> configuration occurs.

IOptionsFactory<TOptions> is responsible for creating new options instances. It has a single Create method. The default implementation takes all registered IConfigureOptions<TOptions> and IPostConfigureOptions<TOptions> and runs all the configurations first, followed by the post-configuration. It distinguishes between IConfigureNamedOptions<TOptions> and IConfigureOptions<TOptions> and only calls the appropriate interface.

IOptionsMonitorCache<TOptions> is used by IOptionsMonitor<TOptions> to cache `TOptions` instances. The IOptionsMonitorCache<TOptions> invalidates options instances in the monitor so that the value is recomputed (TryRemove). Values can be manually introduced with TryAdd. The Clear method is used when all named instances should be recreated on demand.

Use IOptionsSnapshot to read updated data

Using IOptionsSnapshot<TOptions>:

- Options are computed once per request when accessed and cached for the lifetime of the request.
- May incur a significant performance penalty because it's a Scoped service and is recomputed per request. For more information, see this GitHub issue and Improve the performance of configuration binding.

- Changes to the configuration are read after the app starts when using configuration providers that support reading updated configuration values.

The difference between `IOptionsMonitor` and `IOptionsSnapshot` is that:

- `IOptionsMonitor` is a Singleton service that retrieves current option values at any time, which is especially useful in singleton dependencies.
- `IOptionsSnapshot` is a Scoped service and provides a snapshot of the options at the time the `IOptionsSnapshot<T>` object is constructed. Options snapshots are designed for use with transient and scoped dependencies.

The following code uses IOptionsSnapshot<TOptions>.

C#

```
public class TestSnapModel : PageModel
{
    private readonly MyOptions _snapshotOptions;

    public TestSnapModel(IOptionsSnapshot<MyOptions>
snapshotOptionsAccessor)
    {
        _snapshotOptions = snapshotOptionsAccessor.Value;
    }

    public ContentResult OnGet()
    {
        return Content($"Option1: {_snapshotOptions.Option1} \n" +
                       $"Option2: {_snapshotOptions.Option2}");
    }
}
```

The following code registers a configuration instance which `MyOptions` binds against:

C#

```
using SampleApp.Models;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();

builder.Services.Configure<MyOptions>(
    builder.Configuration.GetSection("MyOptions"));

var app = builder.Build();
```

In the preceding code, changes to the JSON configuration file after the app has started are read.

IOptionsMonitor

The following code registers a configuration instance which `MyOptions` binds against.

C#

```
using SampleApp.Models;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();

builder.Services.Configure<MyOptions>(
    builder.Configuration.GetSection("MyOptions"));

var app = builder.Build();
```

The following example uses IOptionsMonitor<TOptions>:

C#

```
public class TestMonitorModel : PageModel
{
    private readonly IOptionsMonitor<MyOptions> _optionsDelegate;

    public TestMonitorModel(IOptionsMonitor<MyOptions> optionsDelegate )
    {
        _optionsDelegate = optionsDelegate;
    }

    public ContentResult OnGet()
    {
        return Content($"Option1: {_optionsDelegate.CurrentValue.Option1}
\n" +
                       $"Option2: {_optionsDelegate.CurrentValue.Option2}");
    }
}
```

In the preceding code, by default, changes to the JSON configuration file after the app has started are read.

Named options support using IConfigureNamedOptions

Named options:

- Are useful when multiple configuration sections bind to the same properties.
- Are case sensitive.

Consider the following `appsettings.json` file:

JSON

```
{
  "TopItem": {
    "Month": {
      "Name": "Green Widget",
      "Model": "GW46"
    },
    "Year": {
      "Name": "Orange Gadget",
      "Model": "OG35"
    }
  }
}
```

Rather than creating two classes to bind `TopItem:Month` and `TopItem:Year`, the following class is used for each section:

C#

```
public class TopItemSettings
{
    public const string Month = "Month";
    public const string Year = "Year";

    public string Name { get; set; } = string.Empty;
    public string Model { get; set; } = string.Empty;
}
```

The following code configures the named options:

C#

```
using SampleApp.Models;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();

builder.Services.Configure<TopItemSettings>(TopItemSettings.Month,
    builder.Configuration.GetSection("TopItem:Month"));
builder.Services.Configure<TopItemSettings>(TopItemSettings.Year,
    builder.Configuration.GetSection("TopItem:Year"));
```

```
var app = builder.Build();
```

The following code displays the named options:

C#

```
public class TestNOModel : PageModel
{
    private readonly TopItemSettings _monthTopItem;
    private readonly TopItemSettings _yearTopItem;

    public TestNOModel(IOptionsSnapshot<TopItemSettings>
namedOptionsAccessor)
    {
        _monthTopItem = namedOptionsAccessor.Get(TopItemSettings.Month);
        _yearTopItem = namedOptionsAccessor.Get(TopItemSettings.Year);
    }

    public ContentResult OnGet()
    {
        return Content($"Month:Name {_monthTopItem.Name} \n" +
                       $"Month:Model {_monthTopItem.Model} \n\n" +
                       $"Year:Name {_yearTopItem.Name} \n" +
                       $"Year:Model {_yearTopItem.Model} \n"    );
    }
}
```

All options are named instances. IConfigureOptions<TOptions> instances are treated as targeting the `Options.DefaultName` instance, which is `string.Empty`. IConfigureNamedOptions<TOptions> also implements IConfigureOptions<TOptions>. The default implementation of the IOptionsFactory<TOptions> has logic to use each appropriately. The `null` named option is used to target all of the named instances instead of a specific named instance. ConfigureAll and PostConfigureAll use this convention.

OptionsBuilder API

OptionsBuilder<TOptions> is used to configure `TOptions` instances. `OptionsBuilder` streamlines creating named options as it's only a single parameter to the initial `AddOptions<TOptions>(string optionsName)` call instead of appearing in all of the subsequent calls. Options validation and the `ConfigureOptions` overloads that accept service dependencies are only available via `OptionsBuilder`.

`OptionsBuilder` is used in the Options validation section.

See Use AddOptions to configure custom repository for information adding a custom repository.

Use DI services to configure options

Services can be accessed from dependency injection while configuring options in two ways:

- Pass a configuration delegate to Configure on OptionsBuilder<TOptions>. `OptionsBuilder<TOptions>` provides overloads of Configure that allow use of up to five services to configure options:

  C#

  ```
  builder.Services.AddOptions<MyOptions>("optionalName")
      .Configure<Service1, Service2, Service3, Service4, Service5>(
          (o, s, s2, s3, s4, s5) =>
              o.Property = DoSomethingWith(s, s2, s3, s4, s5));
  ```

- Create a type that implements IConfigureOptions<TOptions> or IConfigureNamedOptions<TOptions> and register the type as a service.

We recommend passing a configuration delegate to Configure, since creating a service is more complex. Creating a type is equivalent to what the framework does when calling Configure. Calling Configure registers a transient generic IConfigureNamedOptions<TOptions>, which has a constructor that accepts the generic service types specified.

Options validation

Options validation enables option values to be validated.

Consider the following `appsettings.json` file:

JSON

```
{
  "MyConfig": {
    "Key1": "My Key One",
    "Key2": 10,
    "Key3": 32
  }
}
```

The following class is used to bind to the `"MyConfig"` configuration section and applies a couple of `DataAnnotations` rules:

C#

```
public class MyConfigOptions
{
    public const string MyConfig = "MyConfig";

    [RegularExpression(@"^[a-zA-Z''-'\s]{1,40}$")]
    public string Key1 { get; set; }
    [Range(0, 1000,
        ErrorMessage = "Value for {0} must be between {1} and {2}.")]
    public int Key2 { get; set; }
    public int Key3 { get; set; }
}
```

The following code:

- Calls AddOptions to get an OptionsBuilder<TOptions> that binds to the `MyConfigOptions` class.
- Calls ValidateDataAnnotations to enable validation using `DataAnnotations`.

C#

```
using OptionsValidationSample.Configuration;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddControllersWithViews();

builder.Services.AddOptions<MyConfigOptions>()

.Bind(builder.Configuration.GetSection(MyConfigOptions.MyConfig))
            .ValidateDataAnnotations();

var app = builder.Build();
```

The `ValidateDataAnnotations` extension method is defined in the Microsoft.Extensions.Options.DataAnnotations NuGet package. For web apps that use the `Microsoft.NET.Sdk.Web` SDK, this package is referenced implicitly from the shared framework.

The following code displays the configuration values or the validation errors:

C#

```
public class HomeController : Controller
{
    private readonly ILogger<HomeController> _logger;
    private readonly IOptions<MyConfigOptions> _config;

    public HomeController(IOptions<MyConfigOptions> config,
                          ILogger<HomeController> logger)
    {
        _config = config;
        _logger = logger;

        try
        {
            var configValue = _config.Value;

        }
        catch (OptionsValidationException ex)
        {
            foreach (var failure in ex.Failures)
            {
                _logger.LogError(failure);
            }
        }
    }

    public ContentResult Index()
    {
        string msg;
        try
        {
            msg = $"Key1: {_config.Value.Key1} \n" +
                  $"Key2: {_config.Value.Key2} \n" +
                  $"Key3: {_config.Value.Key3}";
        }
        catch (OptionsValidationException optValEx)
        {
            return Content(optValEx.Message);
        }
        return Content(msg);
    }
```

The following code applies a more complex validation rule using a delegate:

C#

```
using OptionsValidationSample.Configuration;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddControllersWithViews();

builder.Services.AddOptions<MyConfigOptions>()
```

```
.Bind(builder.Configuration.GetSection(MyConfigOptions.MyConfig))
            .ValidateDataAnnotations()
        .Validate(config =>
        {
            if (config.Key2 != 0)
            {
                return config.Key3 > config.Key2;
            }

            return true;
        }, "Key3 must be > than Key2.");   // Failure message.

var app = builder.Build();
```

`IValidateOptions<TOptions>` and `IValidatableObject`

The following class implements IValidateOptions<TOptions>:

C#

```
public class MyConfigValidation : IValidateOptions<MyConfigOptions>
{
    public MyConfigOptions _config { get; private set; }

    public  MyConfigValidation(IConfiguration config)
    {
        _config = config.GetSection(MyConfigOptions.MyConfig)
            .Get<MyConfigOptions>();
    }

    public ValidateOptionsResult Validate(string name, MyConfigOptions
options)
    {
        string? vor = null;
        var rx = new Regex(@"^[a-zA-Z''-'\s]{1,40}$");
        var match = rx.Match(options.Key1!);

        if (string.IsNullOrEmpty(match.Value))
        {
            vor = $"{options.Key1} doesn't match RegEx \n";
        }

        if ( options.Key2 < 0 || options.Key2 > 1000)
        {
            vor = $"{options.Key2} doesn't match Range 0 - 1000 \n";
        }

        if (_config.Key2 != default)
        {
            if(_config.Key3 <= _config.Key2)
            {
```

```
                vor +=  "Key3 must be > than Key2.";
            }
        }

        if (vor != null)
        {
            return ValidateOptionsResult.Fail(vor);
        }

        return ValidateOptionsResult.Success;
    }
}
```

`IValidateOptions` enables moving the validation code out of `Program.cs` and into a class.

Using the preceding code, validation is enabled in `Program.cs` with the following code:

C#

```
using Microsoft.Extensions.Options;
using OptionsValidationSample.Configuration;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddControllersWithViews();

builder.Services.Configure<MyConfigOptions>
(builder.Configuration.GetSection(
                                        MyConfigOptions.MyConfig));

builder.Services.AddSingleton<IValidateOptions
                              <MyConfigOptions>, MyConfigValidation>();

var app = builder.Build();
```

Options validation also supports IValidatableObject. To perform class-level validation of a class within the class itself:

- Implement the `IValidatableObject` interface and its Validate method within the class.
- Call ValidateDataAnnotations in `Program.cs`.

`ValidateOnStart`

Options validation runs the first time a `TOption` instance is created. That means, for instance, when first access to IOptionsSnapshot<TOptions>.Value occurs in a request pipeline or when IOptionsMonitor<TOptions>.Get(string) is called on settings present.

After settings are reloaded, validation runs again. The ASP.NET Core runtime uses OptionsCache<TOptions> to cache the options instance once it is created.

To run options validation eagerly, when the app starts, call ValidateOnStart<TOptions>(OptionsBuilder<TOptions>)in `Program.cs`:

C#

```
builder.Services.AddOptions<MyConfigOptions>()
    .Bind(builder.Configuration.GetSection(MyConfigOptions.MyConfig))
    .ValidateDataAnnotations()
    .ValidateOnStart();
```

Options post-configuration

Set post-configuration with IPostConfigureOptions<TOptions>. Post-configuration runs after all IConfigureOptions<TOptions> configuration occurs:

C#

```
using OptionsValidationSample.Configuration;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddControllersWithViews();

builder.Services.AddOptions<MyConfigOptions>()

.Bind(builder.Configuration.GetSection(MyConfigOptions.MyConfig));

builder.Services.PostConfigure<MyConfigOptions>(myOptions =>
{
    myOptions.Key1 = "post_configured_key1_value";
});
```

PostConfigure is available to post-configure named options:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();

builder.Services.Configure<TopItemSettings>(TopItemSettings.Month,
    builder.Configuration.GetSection("TopItem:Month"));
builder.Services.Configure<TopItemSettings>(TopItemSettings.Year,
    builder.Configuration.GetSection("TopItem:Year"));
```

```
builder.Services.PostConfigure<TopItemSettings>("Month", myOptions =>
{
    myOptions.Name = "post_configured_name_value";
    myOptions.Model = "post_configured_model_value";
});

var app = builder.Build();
```

Use PostConfigureAll to post-configure all configuration instances:

C#

```
using OptionsValidationSample.Configuration;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddControllersWithViews();

builder.Services.AddOptions<MyConfigOptions>()

.Bind(builder.Configuration.GetSection(MyConfigOptions.MyConfig));

builder.Services.PostConfigureAll<MyConfigOptions>(myOptions =>
{
    myOptions.Key1 = "post_configured_key1_value";
});
```

Access options in `Program.cs`

To access IOptions<TOptions> or IOptionsMonitor<TOptions> in `Program.cs`, call GetRequiredService on WebApplication.Services:

C#

```
var app = builder.Build();

var option1 = app.Services.GetRequiredService<IOptionsMonitor<MyOptions>>()
    .CurrentValue.Option1;
```

Use multiple environments in ASP.NET Core

Article • 09/18/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

By Rick Anderson and Kirk Larkin

ASP.NET Core configures app behavior based on the runtime environment using an environment variable.

For Blazor environments guidance, which adds to or supersedes the guidance in this article, see ASP.NET Core Blazor environments.

Environments

To determine the runtime environment, ASP.NET Core reads from the following environment variables:

1. DOTNET_ENVIRONMENT
2. `ASPNETCORE_ENVIRONMENT` when the WebApplication.CreateBuilder method is called. The default ASP.NET Core web app templates call `WebApplication.CreateBuilder`. The `DOTNET_ENVIRONMENT` value overrides `ASPNETCORE_ENVIRONMENT` when `WebApplicationBuilder` is used. For other hosts, such as `ConfigureWebHostDefaults` and `WebHost.CreateDefaultBuilder`, `ASPNETCORE_ENVIRONMENT` has higher precedence.

`IHostEnvironment.EnvironmentName` can be set to any value, but the following values are provided by the framework:

- Development: The launchSettings.json file sets `ASPNETCORE_ENVIRONMENT` to `Development` on the local machine.
- Staging

- Production: The default if `DOTNET_ENVIRONMENT` and `ASPNETCORE_ENVIRONMENT` have not been set.

The following code:

- Is similar to the code generated by the ASP.NET Core templates.
- Enables the Developer Exception Page when `ASPNETCORE_ENVIRONMENT` is set to `Development`. This is done automatically by the WebApplication.CreateBuilder method.
- Calls UseExceptionHandler when the value of `ASPNETCORE_ENVIRONMENT` is anything other than `Development`.
- Provides an IWebHostEnvironment instance in the Environment property of `WebApplication`.

C#

```
var builder = WebApplication.CreateBuilder(args);

// Add services to the container.
builder.Services.AddRazorPages();

var app = builder.Build();

// Configure the HTTP request pipeline.
if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    // The default HSTS value is 30 days. You may want to change this for
production scenarios, see https://aka.ms/aspnetcore-hsts.
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseRouting();

app.UseAuthorization();

app.MapRazorPages();

app.Run();
```

The Environment Tag Helper uses the value of IHostEnvironment.EnvironmentName to include or exclude markup in the element:

CSHTML

```
<environment include="Development">
    <div>Environment is Development</div>
</environment>
<environment exclude="Development">
    <div>Environment is NOT Development</div>
</environment>
<environment include="Staging,Development,Staging_2">
    <div>Environment is: Staging, Development or Staging_2</div>
</environment>
```

The About page from the sample code includes the preceding markup and displays the value of `IWebHostEnvironment.EnvironmentName`.

On Windows and macOS, environment variables and values aren't case-sensitive. Linux environment variables and values are case-sensitive by default.

Create EnvironmentsSample

The sample code used in this article is based on a Razor Pages project named *EnvironmentsSample*.

The following .NET CLI commands create and run a web app named *EnvironmentsSample*:

Bash

```
dotnet new webapp -o EnvironmentsSample
cd EnvironmentsSample
dotnet run --verbosity normal
```

When the app runs, it displays output similar to the following:

Bash

```
info: Microsoft.Hosting.Lifetime[14]
      Now listening on: https://localhost:7152
info: Microsoft.Hosting.Lifetime[14]
      Now listening on: http://localhost:5105
info: Microsoft.Hosting.Lifetime[0]
      Application started. Press Ctrl+C to shut down.
info: Microsoft.Hosting.Lifetime[0]
      Hosting environment: Development
info: Microsoft.Hosting.Lifetime[0]
      Content root path: C:\Path\To\EnvironmentsSample
```

Set environment on the command line

Use the `--environment` flag to set the environment. For example:

.NET CLI

```
dotnet run --environment Production
```

The preceding command sets the environment to `Production` and displays output similar to the following in the command window:

Bash

```
info: Microsoft.Hosting.Lifetime[14]
      Now listening on: https://localhost:7262
info: Microsoft.Hosting.Lifetime[14]
      Now listening on: http://localhost:5005
info: Microsoft.Hosting.Lifetime[0]
      Application started. Press Ctrl+C to shut down.
info: Microsoft.Hosting.Lifetime[0]
      Hosting environment: Production
info: Microsoft.Hosting.Lifetime[0]
      Content root path: C:\Path\To\EnvironmentsSample
```

Development and launchSettings.json

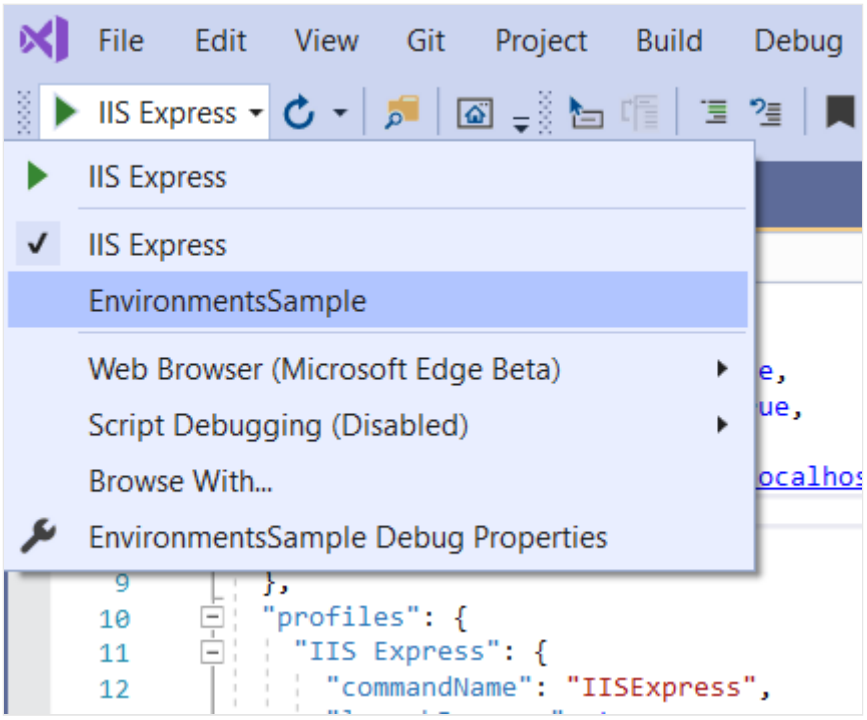
The development environment can enable features that shouldn't be exposed in production. For example, the ASP.NET Core project templates enable the Developer Exception Page in the development environment. Because of the performance cost, scope validation and dependency validation only happens in development.

The environment for local machine development can be set in the *Properties\launchSettings.json* file of the project. Environment values set in `launchSettings.json` override values set in the system environment.

The `launchSettings.json` file:

- Is only used on the local development machine.
- Is not deployed.
- Contains profile settings.

The following JSON shows the `launchSettings.json` file for an ASP.NET Core web project named *EnvironmentsSample* created with Visual Studio or `dotnet new`:

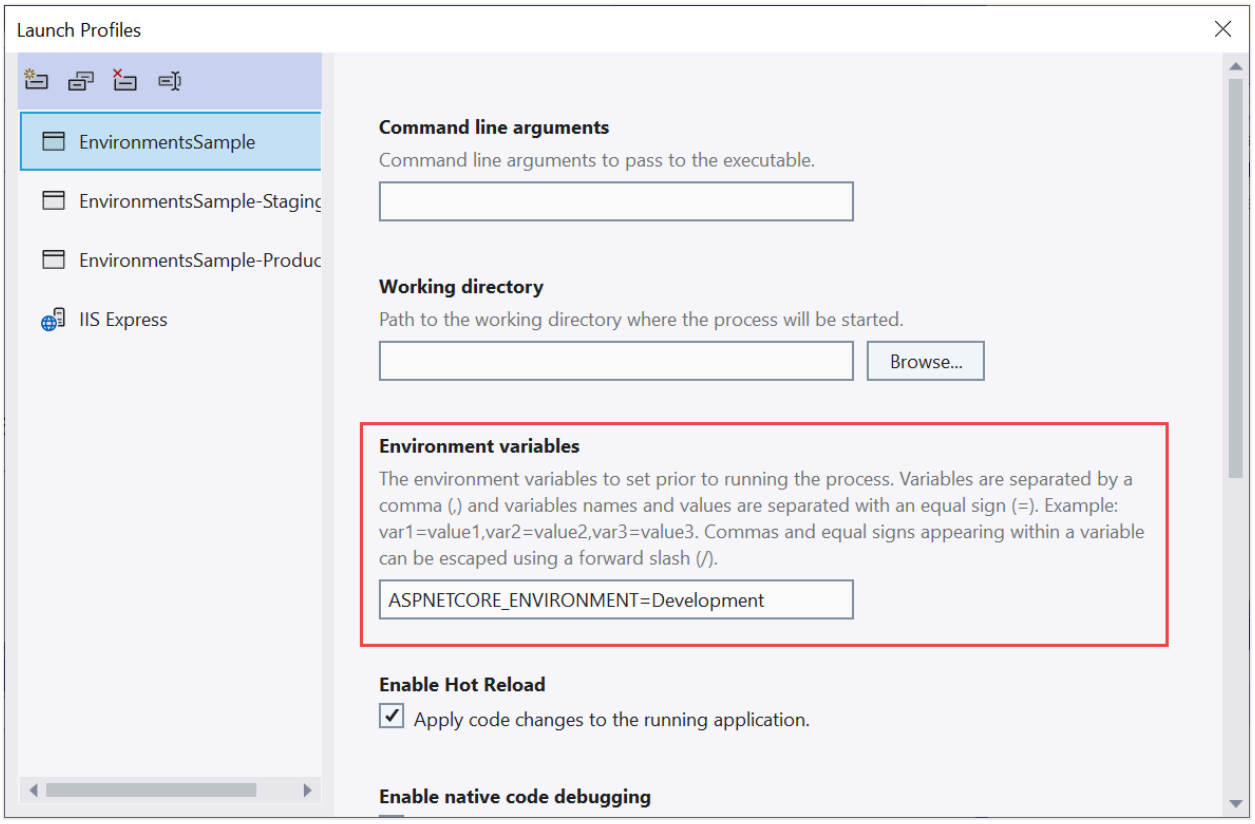


JSON

```
{
  "iisSettings": {
    "windowsAuthentication": false,
    "anonymousAuthentication": true,
    "iisExpress": {
      "applicationUrl": "http://localhost:59481",
      "sslPort": 44308
    }
  },
  "profiles": {
    "EnvironmentsSample": {
      "commandName": "Project",
      "dotnetRunMessages": true,
      "launchBrowser": true,
      "applicationUrl": "https://localhost:7152;http://localhost:5105",
      "environmentVariables": {
        "ASPNETCORE_ENVIRONMENT": "Development"
      }
    },
    "IIS Express": {
      "commandName": "IISExpress",
      "launchBrowser": true,
      "environmentVariables": {
        "ASPNETCORE_ENVIRONMENT": "Development"
      }
    }
  }
}
```

The preceding JSON contains two profiles:

- `EnvironmentsSample`: The profile name is the project name. As the first profile listed, this profile is used by default. The `"commandName"` key has the value `"Project"`, therefore, the Kestrel web server is launched.
- `IIS Express`: The `"commandName"` key has the value `"IISExpress"`, therefore, IISExpress is the web server.



You can set the launch profile to the project or any other profile included in `launchSettings.json`. For example, in the image below, selecting the project name launches the Kestrel web server.

The value of `commandName` can specify the web server to launch. `commandName` can be any one of the following:

- `IISExpress` : Launches IIS Express.
- `IIS` : No web server launched. IIS is expected to be available.
- `Project` : Launches Kestrel.

The Visual Studio 2022 project properties **Debug / General** tab provides an **Open debug launch profiles UI** link. This link opens a **Launch Profiles** dialog that lets you edit the environment variable settings in the `launchSettings.json` file. You can also open the **Launch Profiles** dialog from the **Debug** menu by selecting **<project name> Debug Properties**. Changes made to project profiles may not take effect until the web server is restarted. Kestrel must be restarted before it can detect changes made to its environment.

The following `launchSettings.json` file contains multiple profiles:

JSON

```
{
  "iisSettings": {
    "windowsAuthentication": false,
    "anonymousAuthentication": true,
    "iisExpress": {
      "applicationUrl": "http://localhost:59481",
      "sslPort": 44308
    }
  },
  "profiles": {
    "EnvironmentsSample": {
      "commandName": "Project",
      "dotnetRunMessages": true,
      "launchBrowser": true,
      "applicationUrl": "https://localhost:7152;http://localhost:5105",
      "environmentVariables": {
        "ASPNETCORE_ENVIRONMENT": "Development"
      }
    },
    "EnvironmentsSample-Staging": {
      "commandName": "Project",
      "dotnetRunMessages": true,
      "launchBrowser": true,
      "applicationUrl": "https://localhost:7152;http://localhost:5105",
      "environmentVariables": {
        "ASPNETCORE_ENVIRONMENT": "Staging",
        "ASPNETCORE_DETAILEDERRORS": "1",
```

```
        "ASPNETCORE_SHUTDOWNTIMEOUTSECONDS": "3"
      }
    },
    "EnvironmentsSample-Production": {
      "commandName": "Project",
      "dotnetRunMessages": true,
      "launchBrowser": true,
      "applicationUrl": "https://localhost:7152;http://localhost:5105",
      "environmentVariables": {
        "ASPNETCORE_ENVIRONMENT": "Production"
      }
    },
    "IIS Express": {
      "commandName": "IISExpress",
      "launchBrowser": true,
      "environmentVariables": {
        "ASPNETCORE_ENVIRONMENT": "Development"
      }
    }
  }
}
```

Profiles can be selected:

- From the Visual Studio UI.
- Using the dotnet run CLI command with the `--launch-profile` option set to the profile's name. *This approach only supports Kestrel profiles.*

  .NET CLI

  ```
  dotnet run --launch-profile "EnvironmentsSample"
  ```

> **⚠ Warning**
>
> `launchSettings.json` shouldn't store secrets. The Secret Manager tool can be used to store secrets for local development.

When using Visual Studio Code, environment variables can be set in the `.vscode/launch.json` file. The following example sets several environment variables for Host configuration values:

JSON

```
{
    "version": "0.2.0",
    "configurations": [
```

```
        {
            "name": ".NET Core Launch (web)",
            "type": "coreclr",
            // Configuration ommitted for brevity.
            "env": {
                "ASPNETCORE_ENVIRONMENT": "Development",
                "ASPNETCORE_URLS": "https://localhost:5001",
                "ASPNETCORE_DETAILEDERRORS": "1",
                "ASPNETCORE_SHUTDOWNTIMEOUTSECONDS": "3"
            },
            // Configuration ommitted for brevity.
```

The `.vscode/launch.json` file is used only by Visual Studio Code.

Production

The production environment should be configured to maximize security, performance, and application robustness. Some common settings that differ from development include:

- Caching.
- Client-side resources are bundled, minified, and potentially served from a CDN.
- Diagnostic error pages disabled.
- Friendly error pages enabled.
- Production logging and monitoring enabled. For example, using Application Insights.

Set the environment by setting an environment variable

It's often useful to set a specific environment for testing with an environment variable or platform setting. If the environment isn't set, it defaults to `Production`, which disables most debugging features. The method for setting the environment depends on the operating system.

When the host is built, the last environment setting read by the app determines the app's environment. The app's environment can't be changed while the app is running.

The About page from the sample code displays the value of `IWebHostEnvironment.EnvironmentName`.

Azure App Service

Production is the default value if `DOTNET_ENVIRONMENT` and `ASPNETCORE_ENVIRONMENT` have not been set. Apps deployed to Azure are `Production` by default.

To set the environment in an Azure App Service app by using the portal:

1. Select the app from the **App Services** page.
2. In the **Settings** group, select **Environment variables**.
3. In the **App settings** tab, select **+ Add**.
4. In the **Add/Edit application setting** window, provide `ASPNETCORE_ENVIRONMENT` for the **Name**. For **Value**, provide the environment (for example, `Staging`).
5. Select the **Deployment slot setting** checkbox if you wish the environment setting to remain with the current slot when deployment slots are swapped. For more information, see Set up staging environments in Azure App Service in the Azure documentation.
6. Select **OK** to close the **Add/Edit application setting** dialog.
7. Select **Save** at the top of the **Configuration** page.

Azure App Service automatically restarts the app after an app setting is added, changed, or deleted in the Azure portal.

Windows - Set environment variable for a process

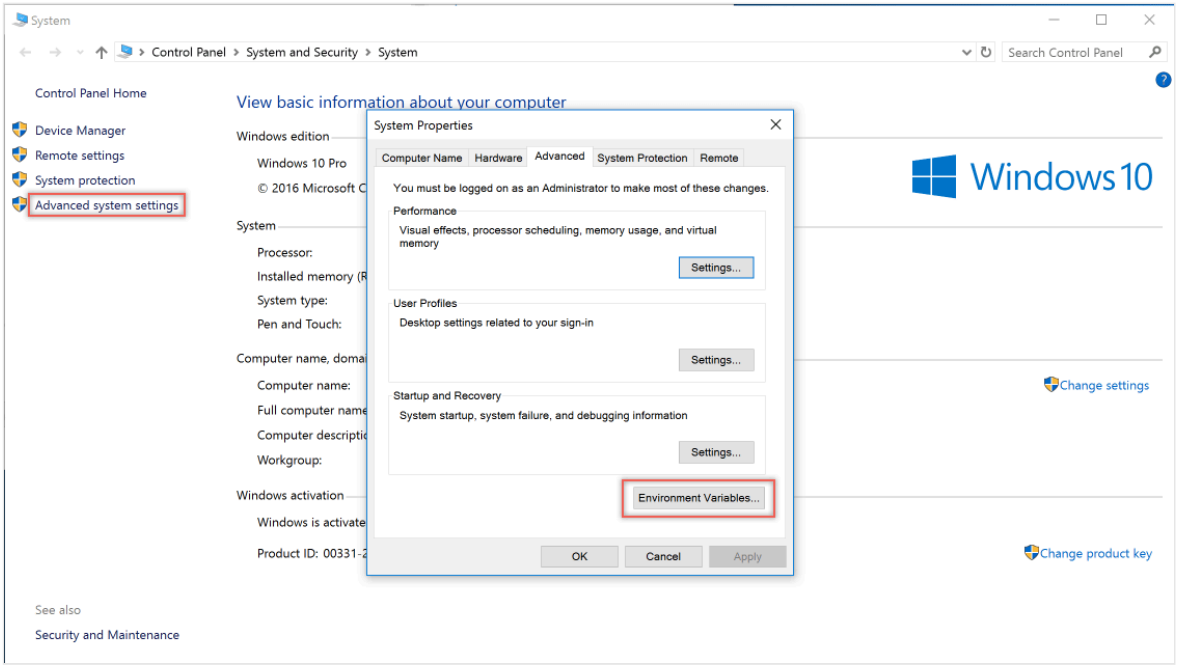
Environment values in `launchSettings.json` override values set in the system environment.

To set the `ASPNETCORE_ENVIRONMENT` for the current session when the app is started using dotnet run, use the following commands at a command prompt or in PowerShell:

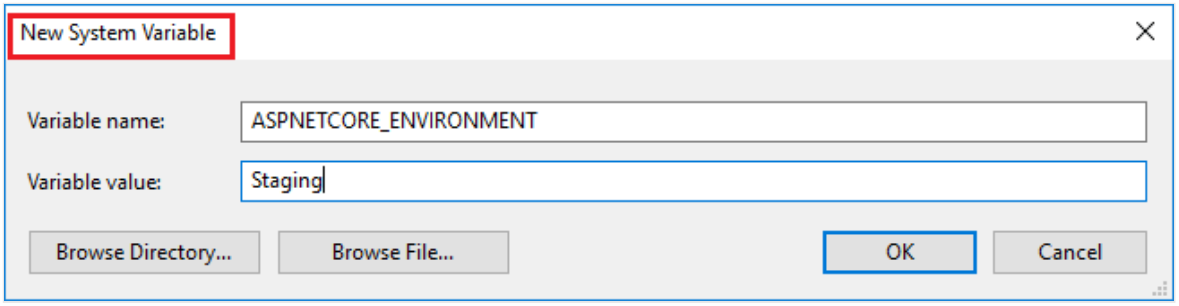
Console

```
set ASPNETCORE_ENVIRONMENT=Staging
dotnet run --no-launch-profile
```

PowerShell



```
$Env:ASPNETCORE_ENVIRONMENT = "Staging"
dotnet run --no-launch-profile
```



Windows - Set environment variable globally

The preceding commands set `ASPNETCORE_ENVIRONMENT` only for processes launched from that command window.

To set the value globally in Windows, use either of the following approaches:

- Open the **Control Panel** > **System** > **Advanced system settings** and add or edit the `ASPNETCORE_ENVIRONMENT` value:

- Open an administrative command prompt and use the `setx` command or open an administrative PowerShell command prompt and use `[Environment]::SetEnvironmentVariable`:

  - Console

    ```
    setx ASPNETCORE_ENVIRONMENT Staging /M
    ```

    The `/M` switch sets the environment variable at the system level. If the `/M` switch isn't used, the environment variable is set for the user account.

  - PowerShell

    ```
    [Environment]::SetEnvironmentVariable("ASPNETCORE_ENVIRONMENT",
    "Staging", "Machine")
    ```

The `Machine` option sets the environment variable at the system level. If the option value is changed to `User`, the environment variable is set for the user account.

When the `ASPNETCORE_ENVIRONMENT` environment variable is set globally, it takes effect for `dotnet run` in any command window opened after the value is set. Environment values in `launchSettings.json` override values set in the system environment.

Windows - Use web.config

To set the `ASPNETCORE_ENVIRONMENT` environment variable with `web.config`, see the *Set environment variables* section of web.config file.

Windows - IIS deployments

Include the `<EnvironmentName>` property in the publish profile (.pubxml) or project file. This approach sets the environment in *web.config* when the project is published:

XML

```
<PropertyGroup>
  <EnvironmentName>Development</EnvironmentName>
</PropertyGroup>
```

To set the `ASPNETCORE_ENVIRONMENT` environment variable for an app running in an isolated Application Pool (supported on IIS 10.0 or later), see the *AppCmd.exe command* section of Environment Variables <environmentVariables>. When the `ASPNETCORE_ENVIRONMENT` environment variable is set for an app pool, its value overrides a setting at the system level.

When hosting an app in IIS and adding or changing the `ASPNETCORE_ENVIRONMENT` environment variable, use one of the following approaches to have the new value picked up by apps:

- Execute `net stop was /y` followed by `net start w3svc` from a command prompt.
- Restart the server.

macOS

Setting the current environment for macOS can be performed in-line when running the app:

Bash

```
ASPNETCORE_ENVIRONMENT=Staging dotnet run
```

Alternatively, set the environment with `export` prior to running the app:

Bash

```
export ASPNETCORE_ENVIRONMENT=Staging
```

Machine-level environment variables are set in the *.bashrc* or *.bash_profile* file. Edit the file using any text editor. Add the following statement:

Bash

```
export ASPNETCORE_ENVIRONMENT=Staging
```

Linux

For Linux distributions, use the `export` command at a command prompt for session-based variable settings and the *bash_profile* file for machine-level environment settings.

Set the environment in code

To set the environment in code, use WebApplicationOptions.EnvironmentName when creating WebApplicationBuilder, as shown in the following example:

C#

```
var builder = WebApplication.CreateBuilder(new WebApplicationOptions
{
    EnvironmentName = Environments.Staging
});

// Add services to the container.
builder.Services.AddRazorPages();

var app = builder.Build();

// Configure the HTTP request pipeline.
if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    // The default HSTS value is 30 days. You may want to change this for
production scenarios, see https://aka.ms/aspnetcore-hsts.
```

```
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseRouting();

app.UseAuthorization();

app.MapRazorPages();

app.Run();
```

Configuration by environment

To load configuration by environment, see Configuration in ASP.NET Core.

Configure services and middleware by environment

Use WebApplicationBuilder.Environment or WebApplication.Environment to conditionally add services or middleware depending on the current environment. The project template includes an example of code that adds middleware only when the current environment isn't Development:

C#

```
var builder = WebApplication.CreateBuilder(args);

// Add services to the container.
builder.Services.AddRazorPages();

var app = builder.Build();

// Configure the HTTP request pipeline.
if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    // The default HSTS value is 30 days. You may want to change this for
production scenarios, see https://aka.ms/aspnetcore-hsts.
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseRouting();
```

```
app.UseAuthorization();

app.MapRazorPages();

app.Run();
```

The highlighted code checks the current environment while building the request pipeline. To check the current environment while configuring services, use `builder.Environment` instead of `app.Environment`.

Logging in .NET Core and ASP.NET Core

Article • 09/18/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

By Kirk Larkin, Juergen Gutsch, and Rick Anderson

This article describes logging in .NET as it applies to ASP.NET Core apps. For detailed information on logging in .NET, see Logging in .NET.

For Blazor logging guidance, which adds to or supersedes the guidance in this node, see ASP.NET Core Blazor logging.

Logging providers

Logging providers store logs, except for the `Console` provider which displays logs. For example, the Azure Application Insights provider stores logs in Azure Application Insights. Multiple providers can be enabled.

The default ASP.NET Core web app templates call WebApplication.CreateBuilder, which adds the following logging providers:

- Console
- Debug
- EventSource
- EventLog: Windows only

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();

var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
```

```
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseRouting();

app.UseAuthorization();

app.MapRazorPages();

app.Run();
```

The preceding code shows the `Program.cs` file created with the ASP.NET Core web app templates. The next several sections provide samples based on the ASP.NET Core web app templates.

The following code overrides the default set of logging providers added by `WebApplication.CreateBuilder`:

C#

```
var builder = WebApplication.CreateBuilder(args);
builder.Logging.ClearProviders();
builder.Logging.AddConsole();

builder.Services.AddRazorPages();

var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseRouting();

app.UseAuthorization();

app.MapRazorPages();

app.Run();
```

Alternatively, the preceding logging code can be written as follows:

C#

```
var builder = WebApplication.CreateBuilder();
builder.Host.ConfigureLogging(logging =>
{
    logging.ClearProviders();
    logging.AddConsole();
});
```

For additional providers, see:

- Built-in logging providers
- Third-party logging providers.

Create logs

To create logs, use an ILogger<TCategoryName> object from dependency injection (DI).

The following example:

- Creates a logger, `ILogger<AboutModel>`, which uses a log *category* of the fully qualified name of the type `AboutModel`. The log category is a string that is associated with each log.
- Calls LogInformation to log at the Information level. The Log *level* indicates the severity of the logged event.

C#

```
public class AboutModel : PageModel
{
    private readonly ILogger _logger;

    public AboutModel(ILogger<AboutModel> logger)
    {
        _logger = logger;
    }

    public void OnGet()
    {
        _logger.LogInformation("About page visited at {DT}",
            DateTime.UtcNow.ToLongTimeString());
    }
}
```

Levels and categories are explained in more detail later in this document.

For information on Blazor, see ASP.NET Core Blazor logging.

Configure logging

Logging configuration is commonly provided by the `Logging` section of `appsettings.{ENVIRONMENT}.json` files, where the `{ENVIRONMENT}` placeholder is the environment. The following `appsettings.Development.json` file is generated by the ASP.NET Core web app templates:

JSON

```
{
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "Microsoft.AspNetCore": "Warning"
    }
  }
}
```

In the preceding JSON:

- The `"Default"` and `"Microsoft.AspNetCore"` categories are specified.
- The `"Microsoft.AspNetCore"` category applies to all categories that start with `"Microsoft.AspNetCore"`. For example, this setting applies to the `"Microsoft.AspNetCore.Routing.EndpointMiddleware"` category.
- The `"Microsoft.AspNetCore"` category logs at log level `Warning` and higher.
- A specific log provider is not specified, so `LogLevel` applies to all the enabled logging providers except for the Windows EventLog.

The `Logging` property can have LogLevel and log provider properties. The `LogLevel` specifies the minimum level to log for selected categories. In the preceding JSON, `Information` and `Warning` log levels are specified. `LogLevel` indicates the severity of the log and ranges from 0 to 6:

`Trace` = 0, `Debug` = 1, `Information` = 2, `Warning` = 3, `Error` = 4, `Critical` = 5, and `None` = 6.

When a `LogLevel` is specified, logging is enabled for messages at the specified level and higher. In the preceding JSON, the `Default` category is logged for `Information` and higher. For example, `Information`, `Warning`, `Error`, and `Critical` messages are logged. If no `LogLevel` is specified, logging defaults to the `Information` level. For more information, see Log levels.

A provider property can specify a `LogLevel` property. `LogLevel` under a provider specifies levels to log for that provider, and overrides the non-provider log settings. Consider the following `appsettings.json` file:

JSON

```
{
  "Logging": {
    "LogLevel": { // All providers, LogLevel applies to all the enabled
providers.
      "Default": "Error", // Default logging, Error and higher.
      "Microsoft": "Warning" // All Microsoft* categories, Warning and
higher.
    },
    "Debug": { // Debug provider.
      "LogLevel": {
        "Default": "Information", // Overrides preceding LogLevel:Default
setting.
        "Microsoft.Hosting": "Trace" // Debug:Microsoft.Hosting category.
      }
    },
    "EventSource": { // EventSource provider
      "LogLevel": {
        "Default": "Warning" // All categories of EventSource provider.
      }
    }
  }
}
```

Settings in `Logging.{PROVIDER NAME}.LogLevel` override settings in `Logging.LogLevel`, where the `{PROVIDER NAME}` placeholder is the provider name. In the preceding JSON, the `Debug` provider's default log level is set to `Information`:

`Logging:Debug:LogLevel:Default:Information`

The preceding setting specifies the `Information` log level for every `Logging:Debug:` category except `Microsoft.Hosting`. When a specific category is listed, the specific category overrides the default category. In the preceding JSON, the `Logging:Debug:LogLevel` categories `"Microsoft.Hosting"` and `"Default"` override the settings in `Logging:LogLevel`.

The minimum log level can be specified for any of:

- Specific providers: For example, `Logging:EventSource:LogLevel:Default:Information`
- Specific categories: For example, `Logging:LogLevel:Microsoft:Warning`
- All providers and all categories: `Logging:LogLevel:Default:Warning`

Any logs below the minimum level are ***not***:

- Passed to the provider.
- Logged or displayed.

To suppress all logs, specify LogLevel.None. `LogLevel.None` has a value of 6, which is higher than `LogLevel.Critical` (5).

If a provider supports log scopes, `IncludeScopes` indicates whether they're enabled. For more information, see log scopes.

The following `appsettings.json` file contains all the providers enabled by default:

JSON

```
{
  "Logging": {
    "LogLevel": { // No provider, LogLevel applies to all the enabled
providers.
      "Default": "Error",
      "Microsoft": "Warning",
      "Microsoft.Hosting.Lifetime": "Warning"
    },
    "Debug": { // Debug provider.
      "LogLevel": {
        "Default": "Information" // Overrides preceding LogLevel:Default
setting.
      }
    },
    "Console": {
      "IncludeScopes": true,
      "LogLevel": {
        "Microsoft.AspNetCore.Mvc.Razor.Internal": "Warning",
        "Microsoft.AspNetCore.Mvc.Razor.Razor": "Debug",
        "Microsoft.AspNetCore.Mvc.Razor": "Error",
        "Default": "Information"
      }
    },
    "EventSource": {
      "LogLevel": {
        "Microsoft": "Information"
      }
    },
    "EventLog": {
      "LogLevel": {
        "Microsoft": "Information"
      }
    },
    "AzureAppServicesFile": {
      "IncludeScopes": true,
      "LogLevel": {
        "Default": "Warning"
```

```
      }
    },
    "AzureAppServicesBlob": {
      "IncludeScopes": true,
      "LogLevel": {
        "Microsoft": "Information"
      }
    },
    "ApplicationInsights": {
      "LogLevel": {
        "Default": "Information"
      }
    }
  }
}
```

In the preceding sample:

- The categories and levels aren't suggested values. The sample is provided to show all of the default providers.
- Settings in `Logging.{PROVIDER NAME}.LogLevel` override settings in `Logging.LogLevel`, where the `{PROVIDER NAME}` placeholder is the provider name. For example, the level in `Debug.LogLevel.Default` overrides the level in `LogLevel.Default`.
- Each default provider *alias* is used. Each provider defines an *alias* that can be used in configuration in place of the fully qualified type name. The built-in providers aliases are:
  - `Console`
  - `Debug`
  - `EventSource`
  - `EventLog`
  - `AzureAppServicesFile`
  - `AzureAppServicesBlob`
  - `ApplicationInsights`

Log in `Program.cs`

The following example calls Builder.WebApplication.Logger in `Program.cs` and logs informational messages:

C#

```
var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();
```

```
app.Logger.LogInformation("Adding Routes");
app.MapGet("/", () => "Hello World!");
app.Logger.LogInformation("Starting the app");
app.Run();
```

The following example calls AddConsole in `Program.cs` and logs the `/Test` endpoint:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Logging.AddConsole();

var app = builder.Build();

app.MapGet("/", () => "Hello World!");

app.MapGet("/Test", async (ILogger<Program> logger, HttpResponse response)
=>
{
    logger.LogInformation("Testing logging in Program.cs");
    await response.WriteAsync("Testing");
});

app.Run();
```

The following example calls AddSimpleConsole in `Program.cs`, disables color output, and logs the `/Test` endpoint:

C#

```
using Microsoft.Extensions.Logging.Console;

var builder = WebApplication.CreateBuilder(args);

builder.Logging.AddSimpleConsole(i => i.ColorBehavior =
LoggerColorBehavior.Disabled);

var app = builder.Build();

app.MapGet("/", () => "Hello World!");

app.MapGet("/Test", async (ILogger<Program> logger, HttpResponse response)
=>
{
    logger.LogInformation("Testing logging in Program.cs");
    await response.WriteAsync("Testing");
});

app.Run();
```

Set log level by command line, environment variables, and other configuration

Log level can be set by any of the configuration providers.

The `:` separator doesn't work with environment variable hierarchical keys on all platforms. For example, the `:` separator is not supported by Bash. The double underscore, `__`, is:

- Supported by all platforms.
- Automatically replaced by a colon, `:`.

The following commands:

- Set the environment key `Logging:LogLevel:Microsoft` to a value of `Information` on Windows.
- Test the settings when using an app created with the ASP.NET Core web application templates. The `dotnet run` command must be run in the project directory after using `set`.

.NET CLI

```
set Logging__LogLevel__Microsoft=Information
dotnet run
```

The preceding environment setting:

- Is only set in processes launched from the command window they were set in.
- Isn't read by browsers launched with Visual Studio.

The following setx command also sets the environment key and value on Windows. Unlike `set`, `setx` settings are persisted. The `/M` switch sets the variable in the system environment. If `/M` isn't used, a user environment variable is set.

Console

```
setx Logging__LogLevel__Microsoft Information /M
```

Consider the following `appsettings.json` file:

JSON

```
"Logging": {
  "Console": {
    "LogLevel": {
      "Microsoft.Hosting.Lifetime": "Trace"
    }
  }
}
```

The following command sets the preceding configuration in the environment:

Console

```
setx Logging__Console__LogLevel__Microsoft.Hosting.Lifetime Trace /M
```

> **Note**
>
> When configuring environment variables with names that contain `.` (periods) in macOS and Linux, consider the "Exporting a variable with a dot (.) in it" question on **Stack Exchange** and its corresponding accepted answer.

On Azure App Service, select **New application setting** on the **Settings** > **Configuration** page. Azure App Service application settings are:

- Encrypted at rest and transmitted over an encrypted channel.
- Exposed as environment variables.

For more information, see Azure Apps: Override app configuration using the Azure portal.

For more information on setting ASP.NET Core configuration values using environment variables, see environment variables. For information on using other configuration sources, including the command line, Azure Key Vault, Azure App Configuration, other file formats, and more, see Configuration in ASP.NET Core.

How filtering rules are applied

When an ILogger<TCategoryName> object is created, the ILoggerFactory object selects a single rule per provider to apply to that logger. All messages written by an `ILogger` instance are filtered based on the selected rules. The most specific rule for each provider and category pair is selected from the available rules.

The following algorithm is used for each provider when an `ILogger` is created for a given category:

- Select all rules that match the provider or its alias. If no match is found, select all rules with an empty provider.
- From the result of the preceding step, select rules with longest matching category prefix. If no match is found, select all rules that don't specify a category.
- If multiple rules are selected, take the **last** one.
- If no rules are selected, use `MinimumLevel`.

Logging output from dotnet run and Visual Studio

Logs created with the default logging providers are displayed:

- In Visual Studio
  - In the Debug output window when debugging.
  - In the ASP.NET Core Web Server window.
- In the console window when the app is run with `dotnet run`.

Logs that begin with "Microsoft" categories are from .NET. .NET and application code use the same logging API and providers.

Log category

When an `ILogger` object is created, a *category* is specified. That category is included with each log message created by that instance of `ILogger`. The category string is arbitrary, but the convention is to use the fully qualified class name. For example, in a controller the name might be `"TodoApi.Controllers.TodoController"`. The ASP.NET Core web apps use `ILogger<T>` to automatically get an `ILogger` instance that uses the fully qualified type name of `T` as the category:

C#

```
public class PrivacyModel : PageModel
{
    private readonly ILogger<PrivacyModel> _logger;

    public PrivacyModel(ILogger<PrivacyModel> logger)
    {
        _logger = logger;
    }
```

```
    public void OnGet()
    {
        _logger.LogInformation("GET Pages.PrivacyModel called.");
    }
}
```

If further categorization is desired, the convention is to use a hierarchical name by appending a subcategory to the fully qualified class name, and explicitly specify the category using `ILoggerFactory.CreateLogger`:

C#

```
public class ContactModel : PageModel
{
    private readonly ILogger _logger;

    public ContactModel(ILoggerFactory logger)
    {
        _logger =
logger.CreateLogger("TodoApi.Pages.ContactModel.MyCategory");
    }

    public void OnGet()
    {
        _logger.LogInformation("GET Pages.ContactModel called.");
    }
```

Calling `CreateLogger` with a fixed name can be useful when used in multiple methods so the events can be organized by category.

`ILogger<T>` is equivalent to calling `CreateLogger` with the fully qualified type name of `T`.

Log level

The following table lists the LogLevel values, the convenience `Log{LogLevel}` extension method, and the suggested usage:

Expand table

LogLevel	Value	Method	Description
Trace	0	LogTrace	Contain the most detailed messages. These messages may contain sensitive app data. These messages are disabled by default and should ***not*** be enabled in production.

LogLevel	Value	Method	Description
Debug	1	LogDebug	For debugging and development. Use with caution in production due to the high volume.
Information	2	LogInformation	Tracks the general flow of the app. May have long-term value.
Warning	3	LogWarning	For abnormal or unexpected events. Typically includes errors or conditions that don't cause the app to fail.
Error	4	LogError	For errors and exceptions that cannot be handled. These messages indicate a failure in the current operation or request, not an app-wide failure.
Critical	5	LogCritical	For failures that require immediate attention. Examples: data loss scenarios, out of disk space.
None	6		Specifies that a logging category shouldn't write messages.

In the previous table, the `LogLevel` is listed from lowest to highest severity.

The Log method's first parameter, LogLevel, indicates the severity of the log. Rather than calling `Log(LogLevel, ...)`, most developers call the Log{LOG LEVEL} extension methods, where the `{LOG LEVEL}` placeholder is the log level. For example, the following two logging calls are functionally equivalent and produce the same log:

C#

```
[HttpGet]
public IActionResult Test1(int id)
{
    var routeInfo = ControllerContext.ToCtxString(id);

    _logger.Log(LogLevel.Information, MyLogEvents.TestItem, routeInfo);
    _logger.LogInformation(MyLogEvents.TestItem, routeInfo);

    return ControllerContext.MyDisplayRouteInfo();
}
```

`MyLogEvents.TestItem` is the event ID. `MyLogEvents` is part of the sample app and is displayed in the Log event ID section.

MyDisplayRouteInfo and ToCtxString are provided by the Rick.Docs.Samples.RouteInfo NuGet package. The methods display `Controller` and `Razor Page` route information.

The following code creates `Information` and `Warning` logs:

C#

```
[HttpGet("{id}")]
public async Task<ActionResult<TodoItemDTO>> GetTodoItem(long id)
{
    _logger.LogInformation(MyLogEvents.GetItem, "Getting item {Id}", id);

    var todoItem = await _context.TodoItems.FindAsync(id);

    if (todoItem == null)
    {
        _logger.LogWarning(MyLogEvents.GetItemNotFound, "Get({Id}) NOT
FOUND", id);
        return NotFound();
    }

    return ItemToDTO(todoItem);
}
```

In the preceding code, the first `Log{LOG LEVEL}` parameter, `MyLogEvents.GetItem`, is the Log event ID. The second parameter is a message template with placeholders for argument values provided by the remaining method parameters. The method parameters are explained in the message template section later in this document.

Call the appropriate `Log{LOG LEVEL}` method to control how much log output is written to a particular storage medium. For example:

- In production:
  - Logging at the `Trace`, `Debug`, or `Information` levels produces a high-volume of detailed log messages. To control costs and not exceed data storage limits, log `Trace`, `Debug`, or `Information` level messages to a high-volume, low-cost data store. Consider limiting `Trace`, `Debug`, or `Information` to specific categories.
  - Logging at `Warning` through `Critical` levels should produce few log messages.
    - Costs and storage limits usually aren't a concern.
    - Few logs allow more flexibility in data store choices.
- In development:
  - Set to `Warning`.
  - Add `Trace`, `Debug`, or `Information` messages when troubleshooting. To limit output, set `Trace`, `Debug`, or `Information` only for the categories under investigation.

ASP.NET Core writes logs for framework events. For example, consider the log output for:

- A Razor Pages app created with the ASP.NET Core templates.
- Logging set to `Logging:Console:LogLevel:Microsoft:Information`.
- Navigation to the Privacy page:

Console

```
info: Microsoft.AspNetCore.Hosting.Diagnostics[1]
      Request starting HTTP/2 GET https://localhost:5001/Privacy
info: Microsoft.AspNetCore.Routing.EndpointMiddleware[0]
      Executing endpoint '/Privacy'
info:
Microsoft.AspNetCore.Mvc.RazorPages.Infrastructure.PageActionInvoker[3]
      Route matched with {page = "/Privacy"}. Executing page /Privacy
info:
Microsoft.AspNetCore.Mvc.RazorPages.Infrastructure.PageActionInvoker[101]
      Executing handler method DefaultRP.Pages.PrivacyModel.OnGet -
ModelState is Valid
info:
Microsoft.AspNetCore.Mvc.RazorPages.Infrastructure.PageActionInvoker[102]
      Executed handler method OnGet, returned result .
info:
Microsoft.AspNetCore.Mvc.RazorPages.Infrastructure.PageActionInvoker[103]
      Executing an implicit handler method - ModelState is Valid
info:
Microsoft.AspNetCore.Mvc.RazorPages.Infrastructure.PageActionInvoker[104]
      Executed an implicit handler method, returned result
Microsoft.AspNetCore.Mvc.RazorPages.PageResult.
info:
Microsoft.AspNetCore.Mvc.RazorPages.Infrastructure.PageActionInvoker[4]
      Executed page /Privacy in 74.5188ms
info: Microsoft.AspNetCore.Routing.EndpointMiddleware[1]
      Executed endpoint '/Privacy'
info: Microsoft.AspNetCore.Hosting.Diagnostics[2]
      Request finished in 149.3023ms 200 text/html; charset=utf-8
```

The following JSON sets `Logging:Console:LogLevel:Microsoft:Information`:

JSON

```
{
  "Logging": {      // Default, all providers.
    "LogLevel": {
      "Microsoft": "Warning"
    },
    "Console": { // Console provider.
      "LogLevel": {
        "Microsoft": "Information"
      }
    }
  }
}
```

Log event ID

Each log can specify an *event ID*. The sample app uses the `MyLogEvents` class to define event IDs:

C#

```
public class MyLogEvents
{
    public const int GenerateItems = 1000;
    public const int ListItems     = 1001;
    public const int GetItem       = 1002;
    public const int InsertItem    = 1003;
    public const int UpdateItem    = 1004;
    public const int DeleteItem    = 1005;

    public const int TestItem      = 3000;

    public const int GetItemNotFound    = 4000;
    public const int UpdateItemNotFound = 4001;
}
```

C#

```
[HttpGet("{id}")]
public async Task<ActionResult<TodoItemDTO>> GetTodoItem(long id)
{
    _logger.LogInformation(MyLogEvents.GetItem, "Getting item {Id}", id);

    var todoItem = await _context.TodoItems.FindAsync(id);

    if (todoItem == null)
    {
        _logger.LogWarning(MyLogEvents.GetItemNotFound, "Get({Id}) NOT
FOUND", id);
        return NotFound();
    }

    return ItemToDTO(todoItem);
}
```

An event ID associates a set of events. For example, all logs related to displaying a list of items on a page might be 1001.

The logging provider may store the event ID in an ID field, in the logging message, or not at all. The Debug provider doesn't show event IDs. The console provider shows event IDs in brackets after the category:

Console

```
info: TodoApi.Controllers.TodoItemsController[1002]
      Getting item 1
warn: TodoApi.Controllers.TodoItemsController[4000]
      Get(1) NOT FOUND
```

Some logging providers store the event ID in a field, which allows for filtering on the ID.

Log message template

Each log API uses a message template. The message template can contain placeholders for which arguments are provided. Use names for the placeholders, not numbers.

C#

```
[HttpGet("{id}")]
public async Task<ActionResult<TodoItemDTO>> GetTodoItem(long id)
{
    _logger.LogInformation(MyLogEvents.GetItem, "Getting item {Id}", id);

    var todoItem = await _context.TodoItems.FindAsync(id);

    if (todoItem == null)
    {
        _logger.LogWarning(MyLogEvents.GetItemNotFound, "Get({Id}) NOT
FOUND", id);
        return NotFound();
    }

    return ItemToDTO(todoItem);
}
```

The *order of the parameters*, not their placeholder names, determines which parameters are used to provide placeholder values in log messages. In the following code, the parameter names are out of sequence in the placeholders of the message template:

C#

```
var apples = 1;
var pears = 2;
var bananas = 3;

_logger.LogInformation("Parameters: {Pears}, {Bananas}, {Apples}", apples,
pears, bananas);
```

However, the parameters are assigned to the placeholders in the order: `apples`, `pears`, `bananas`. The log message reflects the *order of the parameters*:

text

```
Parameters: 1, 2, 3
```

This approach allows logging providers to implement semantic or structured logging. The arguments themselves are passed to the logging system, not just the formatted message template. This enables logging providers to store the parameter values as fields. For example, consider the following logger method:

C#

```
_logger.LogInformation("Getting item {Id} at {RequestTime}", id,
DateTime.Now);
```

For example, when logging to Azure Table Storage:

- Each Azure Table entity can have `ID` and `RequestTime` properties.
- Tables with properties simplify queries on logged data. For example, a query can find all logs within a particular `RequestTime` range without having to parse the time out of the text message.

Log exceptions

The logger methods have overloads that take an exception parameter:

C#

```
[HttpGet("{id}")]
public IActionResult TestExp(int id)
{
    var routeInfo = ControllerContext.ToCtxString(id);
    _logger.LogInformation(MyLogEvents.TestItem, routeInfo);

    try
    {
        if (id == 3)
        {
            throw new Exception("Test exception");
        }
    }
    catch (Exception ex)
    {
        _logger.LogWarning(MyLogEvents.GetItemNotFound, ex, "TestExp({Id})",
id);
        return NotFound();
    }
```

```
    return ControllerContext.MyDisplayRouteInfo();
}
```

MyDisplayRouteInfo and ToCtxString are provided by the Rick.Docs.Samples.RouteInfo NuGet package. The methods display `Controller` and `Razor Page` route information.

Exception logging is provider-specific.

Default log level

If the default log level is not set, the default log level value is `Information`.

For example, consider the following web app:

- Created with the ASP.NET web app templates.
- `appsettings.json` and `appsettings.Development.json` deleted or renamed.

With the preceding setup, navigating to the privacy or home page produces many `Trace`, `Debug`, and `Information` messages with `Microsoft` in the category name.

The following code sets the default log level when the default log level is not set in configuration:

C#

```
var builder = WebApplication.CreateBuilder();
builder.Logging.SetMinimumLevel(LogLevel.Warning);
```

Generally, log levels should be specified in configuration and not code.

Filter function

A filter function is invoked for all providers and categories that don't have rules assigned to them by configuration or code:

C#

```
var builder = WebApplication.CreateBuilder();
builder.Logging.AddFilter((provider, category, logLevel) =>
{
    if (provider.Contains("ConsoleLoggerProvider")
        && category.Contains("Controller")
        && logLevel >= LogLevel.Information)
    {
```

```
            return true;
        }
        else if (provider.Contains("ConsoleLoggerProvider")
            && category.Contains("Microsoft")
            && logLevel >= LogLevel.Information)
        {
            return true;
        }
        else
        {
            return false;
        }
    });
```

The preceding code displays console logs when the category contains `Controller` or `Microsoft` and the log level is `Information` or higher.

Generally, log levels should be specified in configuration and not code.

ASP.NET Core categories

The following table contains some categories used by ASP.NET Core.

Expand table

Category	Notes
`Microsoft.AspNetCore`	General ASP.NET Core diagnostics.
`Microsoft.AspNetCore.DataProtection`	Which keys were considered, found, and used.
`Microsoft.AspNetCore.HostFiltering`	Hosts allowed.
`Microsoft.AspNetCore.Hosting`	How long HTTP requests took to complete and what time they started. Which hosting startup assemblies were loaded.
`Microsoft.AspNetCore.Mvc`	MVC and Razor diagnostics. Model binding, filter execution, view compilation, action selection.
`Microsoft.AspNetCore.Routing`	Route matching information.
`Microsoft.AspNetCore.Server`	Connection start, stop, and keep alive responses. HTTPS certificate information.
`Microsoft.AspNetCore.StaticFiles`	Files served.

To view more categories in the console window, set `appsettings.Development.json` to the following:

JSON

```
{
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "Microsoft": "Trace",
      "Microsoft.Hosting.Lifetime": "Information"
    }
  }
}
```

For a list of Entity Framework categories, see EF Message categories.

Log scopes

A *scope* can group a set of logical operations. This grouping can be used to attach the same data to each log that's created as part of a set. For example, every log created as part of processing a transaction can include the transaction ID.

A scope:

- Is an IDisposable type that's returned by the BeginScope method.
- Lasts until it's disposed.

The following providers support scopes:

- `Console`
- AzureAppServicesFile and AzureAppServicesBlob

Use a scope by wrapping logger calls in a `using` block:

C#

```
[HttpGet("{id}")]
public async Task<ActionResult<TodoItemDTO>> GetTodoItem(long id)
{
    TodoItem todoItem;
    var transactionId = Guid.NewGuid().ToString();
    using (_logger.BeginScope(new List<KeyValuePair<string, object>>
        {
            new KeyValuePair<string, object>("TransactionId",
transactionId),
        }))
    {
```

```
        _logger.LogInformation(MyLogEvents.GetItem, "Getting item {Id}",
id);

        todoItem = await _context.TodoItems.FindAsync(id);

        if (todoItem == null)
        {
            _logger.LogWarning(MyLogEvents.GetItemNotFound,
                "Get({Id}) NOT FOUND", id);
            return NotFound();
        }
    }

    return ItemToDTO(todoItem);
}
```

Built-in logging providers

ASP.NET Core includes the following logging providers as part of the shared framework:

- Console
- Debug
- EventSource
- EventLog

The following logging providers are shipped by Microsoft, but not as part of the shared framework. They must be installed as additional nuget.

- AzureAppServicesFile and AzureAppServicesBlob
- ApplicationInsights

ASP.NET Core doesn't include a logging provider for writing logs to files. To write logs to files from an ASP.NET Core app, consider using a third-party logging provider.

For information on `stdout` and debug logging with the ASP.NET Core Module, see Troubleshoot ASP.NET Core on Azure App Service and IIS and ASP.NET Core Module (ANCM) for IIS.

Console

The `Console` provider logs output to the console. For more information on viewing `Console` logs in development, see Logging output from dotnet run and Visual Studio.

Debug

The `Debug` provider writes log output by using the System.Diagnostics.Debug class. Calls to `System.Diagnostics.Debug.WriteLine` write to the `Debug` provider.

On Linux, the `Debug` provider log location is distribution-dependent and may be one of the following:

- `/var/log/message`
- `/var/log/syslog`

Event Source

The `EventSource` provider writes to a cross-platform event source with the name `Microsoft-Extensions-Logging`. On Windows, the provider uses ETW.

dotnet-trace tooling

The dotnet-trace tool is a cross-platform CLI global tool that enables the collection of .NET Core traces of a running process. The tool collects Microsoft.Extensions.Logging.EventSource provider data using a LoggingEventSource.

For installation instructions, see dotnet-trace.

Use the `dotnet-trace` tooling to collect a trace from an app:

1. Run the app with the `dotnet run` command.

2. Determine the process identifier (PID) of the .NET Core app:

   .NET CLI

   ```
   dotnet-trace ps
   ```

   Find the PID for the process that has the same name as the app's assembly.

3. Execute the `dotnet-trace` command.

   General command syntax:

   .NET CLI

   ```
   dotnet-trace collect -p {PID}
       --providers Microsoft-Extensions-Logging:{Keyword}:{Provider Level}
           :FilterSpecs=\"
               {Logger Category 1}:{Category Level 1};
               {Logger Category 2}:{Category Level 2};
   ```

```
            ...
            {Logger Category N}:{Category Level N}\"
```

When using a PowerShell command shell, enclose the `--providers` value in single quotes (`'`):

.NET CLI

```
dotnet-trace collect -p {PID}
    --providers 'Microsoft-Extensions-Logging:{Keyword}:{Provider
Level}
        :FilterSpecs=\"
            {Logger Category 1}:{Category Level 1};
            {Logger Category 2}:{Category Level 2};
            ...
            {Logger Category N}:{Category Level N}\"'
```

On non-Windows platforms, add the `-f speedscope` option to change the format of the output trace file to `speedscope`.

The following table defines the Keyword:

Expand table

Keyword	Description
1	Log meta events about the `LoggingEventSource`. Doesn't log events from `ILogger`.
2	Turns on the `Message` event when `ILogger.Log()` is called. Provides information in a programmatic (not formatted) way.
4	Turns on the `FormatMessage` event when `ILogger.Log()` is called. Provides the formatted string version of the information.
8	Turns on the `MessageJson` event when `ILogger.Log()` is called. Provides a JSON representation of the arguments.

The following table lists the provider levels:

Expand table

Provider Level	Description
0	`LogAlways`
1	`Critical`

Provider Level	Description
2	`Error`
3	`Warning`
4	`Informational`
5	`Verbose`

The parsing for a category level can be either a string or a number:

Expand table

Category named value	Numeric value
`Trace`	0
`Debug`	1
`Information`	2
`Warning`	3
`Error`	4
`Critical`	5

The provider level and category level:

- Are in reverse order.
- The string constants aren't all identical.

If no `FilterSpecs` are specified then the `EventSourceLogger` implementation attempts to convert the provider level to a category level and applies it to all categories.

Expand table

Provider Level	Category Level
`Verbose` (5)	`Debug` (1)
`Informational` (4)	`Information` (2)
`Warning` (3)	`Warning` (3)
`Error` (2)	`Error` (4)

Provider Level	Category Level
`Critical` (1)	`Critical` (5)

If `FilterSpecs` are provided, any category that is included in the list uses the category level encoded there, all other categories are filtered out.

The following examples assume:

- An app is running and calling `logger.LogDebug("12345")`.
- The process ID (PID) has been set via `set PID=12345`, where `12345` is the actual PID.

Consider the following command:

.NET CLI

```
dotnet-trace collect -p %PID% --providers Microsoft-Extensions-
Logging:4:5
```

The preceding command:

- Captures debug messages.
- Doesn't apply a `FilterSpecs`.
- Specifies level 5 which maps category Debug.

Consider the following command:

.NET CLI

```
dotnet-trace collect -p %PID%  --providers Microsoft-Extensions-
Logging:4:5:\"FilterSpecs=*:5\"
```

The preceding command:

- Doesn't capture debug messages because the category level 5 is `Critical`.
- Provides a `FilterSpecs`.

The following command captures debug messages because category level 1 specifies `Debug`.

.NET CLI

```
dotnet-trace collect -p %PID%  --providers Microsoft-Extensions-
Logging:4:5:\"FilterSpecs=*:1\"
```

The following command captures debug messages because category specifies `Debug`.

.NET CLI

```
dotnet-trace collect -p %PID%  --providers Microsoft-Extensions-
Logging:4:5:\"FilterSpecs=*:Debug\"
```

`FilterSpecs` entries for `{Logger Category}` and `{Category Level}` represent additional log filtering conditions. Separate `FilterSpecs` entries with the `;` semicolon character.

Example using a Windows command shell:

.NET CLI

```
dotnet-trace collect -p %PID% --providers Microsoft-Extensions-
Logging:4:2:FilterSpecs=\"Microsoft.AspNetCore.Hosting*:4\"
```

The preceding command activates:

- The Event Source logger to produce formatted strings (`4`) for errors (`2`).
- `Microsoft.AspNetCore.Hosting` logging at the `Informational` logging level (`4`).

4. Stop the `dotnet-trace` tooling by pressing the Enter key or `Ctrl`+`C`.

   The trace is saved with the name `trace.nettrace` in the folder where the `dotnet-trace` command is executed.

5. Open the trace with Perfview. Open the `trace.nettrace` file and explore the trace events.

If the app doesn't build the host with WebApplication.CreateBuilder, add the Event Source provider to the app's logging configuration.

For more information, see:

- Trace for performance analysis utility (dotnet-trace) (.NET Core documentation)
- Trace for performance analysis utility (dotnet-trace) (dotnet/diagnostics GitHub repository documentation)
- LoggingEventSource
- EventLevel
- Perfview: Useful for viewing Event Source traces.

Perfview

Use the PerfView utility to collect and view logs. There are other tools for viewing ETW logs, but PerfView provides the best experience for working with the ETW events emitted by ASP.NET Core.

To configure PerfView for collecting events logged by this provider, add the string `*Microsoft-Extensions-Logging` to the **Additional Providers** list. Don't miss the `*` at the start of the string.

Windows EventLog

The `EventLog` provider sends log output to the Windows Event Log. Unlike the other providers, the `EventLog` provider does ***not*** inherit the default non-provider settings. If `EventLog` log settings aren't specified, they default to LogLevel.Warning.

To log events lower than LogLevel.Warning, explicitly set the log level. The following example sets the Event Log default log level to LogLevel.Information:

JSON

```
"Logging": {
  "EventLog": {
    "LogLevel": {
      "Default": "Information"
    }
  }
}
```

AddEventLog overloads can pass in EventLogSettings. If `null` or not specified, the following default settings are used:

- `LogName`: "Application"
- `SourceName`: ".NET Runtime"
- `MachineName`: The local machine name is used.

The following code changes the `SourceName` from the default value of `".NET Runtime"` to `MyLogs`:

C#

```
var builder = WebApplication.CreateBuilder();
builder.Logging.AddEventLog(eventLogSettings =>
{
```

```
    eventLogSettings.SourceName = "MyLogs";
});
```

Azure App Service

The Microsoft.Extensions.Logging.AzureAppServices provider package writes logs to text files in an Azure App Service app's file system and to blob storage in an Azure Storage account.

The provider package isn't included in the shared framework. To use the provider, add the provider package to the project.

To configure provider settings, use AzureFileLoggerOptions and AzureBlobLoggerOptions, as shown in the following example:

C#

```
using Microsoft.Extensions.Logging.AzureAppServices;

var builder = WebApplication.CreateBuilder();
builder.Logging.AddAzureWebAppDiagnostics();
builder.Services.Configure<AzureFileLoggerOptions>(options =>
{
    options.FileName = "azure-diagnostics-";
    options.FileSizeLimit = 50 * 1024;
    options.RetainedFileCountLimit = 5;
});
builder.Services.Configure<AzureBlobLoggerOptions>(options =>
{
    options.BlobName = "log.txt";
});
```

When deployed to Azure App Service, the app uses the settings in the App Service logs section of the **App Service** page of the Azure portal. When the following settings are updated, the changes take effect immediately without requiring a restart or redeployment of the app.

- **Application Logging (Filesystem)**
- **Application Logging (Blob)**

The default location for log files is in the `D:\\home\\LogFiles\\Application` folder, and the default file name is `diagnostics-yyyymmdd.txt`. The default file size limit is 10 MB, and the default maximum number of files retained is 2. The default blob name is `{app-name}{timestamp}/yyyy/mm/dd/hh/{guid}-applicationLog.txt`.

This provider only logs when the project runs in the Azure environment.

Azure log streaming

Azure log streaming supports viewing log activity in real time from:

- The app server
- The web server
- Failed request tracing

To configure Azure log streaming:

- Navigate to the **App Service logs** page from the app's portal page.
- Set **Application Logging (Filesystem)** to **On**.
- Choose the log **Level**. This setting only applies to Azure log streaming.

Navigate to the **Log Stream** page to view logs. The logged messages are logged with the `ILogger` interface.

Azure Application Insights

The Microsoft.Extensions.Logging.ApplicationInsights provider package writes logs to Azure Application Insights. Application Insights is a service that monitors a web app and provides tools for querying and analyzing the telemetry data. If you use this provider, you can query and analyze your logs by using the Application Insights tools.

The logging provider is included as a dependency of Microsoft.ApplicationInsights.AspNetCore, which is the package that provides all available telemetry for ASP.NET Core. If you use this package, you don't have to install the provider package.

The Microsoft.ApplicationInsights.Web package is for ASP.NET 4.x, not ASP.NET Core.

For more information, see the following resources:

- Application Insights overview
- Application Insights for ASP.NET Core applications: Start here if you want to implement the full range of Application Insights telemetry along with logging.
- ApplicationInsightsLoggerProvider for .NET Core ILogger logs: Start here if you want to implement the logging provider without the rest of Application Insights telemetry.
- Application Insights logging adapters
- Install, configure, and initialize the Application Insights SDK interactive tutorial.

Third-party logging providers

Third-party logging frameworks that work with ASP.NET Core:

- elmah.io (GitHub repo)
- Gelf (GitHub repo)
- JSNLog (GitHub repo)
- KissLog.net (GitHub repo)
- Log4Net (GitHub repo)
- NLog (GitHub repo)
- PLogger (GitHub repo)
- Sentry (GitHub repo)
- Serilog (GitHub repo)
- Stackdriver (Github repo)

Some third-party frameworks can perform semantic logging, also known as structured logging.

Using a third-party framework is similar to using one of the built-in providers:

1. Add a NuGet package to your project.
2. Call an `ILoggerFactory` extension method provided by the logging framework.

For more information, see each provider's documentation. Third-party logging providers aren't supported by Microsoft.

No asynchronous logger methods

Logging should be so fast that it isn't worth the performance cost of asynchronous code. If a logging data store is slow, don't write to it directly. Consider writing the log messages to a fast store initially, then moving them to the slow store later. For example, when logging to SQL Server, don't do so directly in a `Log` method, since the `Log` methods are synchronous. Instead, synchronously add log messages to an in-memory queue and have a background worker pull the messages out of the queue to do the asynchronous work of pushing data to SQL Server. For more information, see Guidance on how to log to a message queue for slow data stores (dotnet/AspNetCore.Docs #11801).

Change log levels in a running app

The Logging API doesn't include a scenario to change log levels while an app is running. However, some configuration providers are capable of reloading configuration, which takes immediate effect on logging configuration. For example, the File Configuration Provider, reloads logging configuration by default. If configuration is changed in code

while an app is running, the app can call IConfigurationRoot.Reload to update the app's logging configuration.

ILogger and ILoggerFactory

The ILogger<TCategoryName> and ILoggerFactory interfaces and implementations are included in the .NET Core SDK. They are also available in the following NuGet packages:

- The interfaces are in Microsoft.Extensions.Logging.Abstractions.
- The default implementations are in Microsoft.Extensions.Logging.

Apply log filter rules in code

The preferred approach for setting log filter rules is by using Configuration.

The following example shows how to register filter rules in code:

C#

```
using Microsoft.Extensions.Logging.Console;
using Microsoft.Extensions.Logging.Debug;

var builder = WebApplication.CreateBuilder();
builder.Logging.AddFilter("System", LogLevel.Debug);
builder.Logging.AddFilter<DebugLoggerProvider>("Microsoft",
LogLevel.Information);
builder.Logging.AddFilter<ConsoleLoggerProvider>("Microsoft",
LogLevel.Trace);
```

`logging.AddFilter("System", LogLevel.Debug)` specifies the `System` category and log level `Debug`. The filter is applied to all providers because a specific provider was not configured.

`AddFilter<DebugLoggerProvider>("Microsoft", LogLevel.Information)` specifies:

- The `Debug` logging provider.
- Log level `Information` and higher.
- All categories starting with `"Microsoft"`.

Automatically log scope with `SpanId`, `TraceId`, `ParentId`, `Baggage`, and `Tags`.

The logging libraries implicitly create a scope object with `SpanId`, `TraceId`, `ParentId`, `Baggage`, and `Tags`. This behavior is configured via ActivityTrackingOptions.

```C#
var builder = WebApplication.CreateBuilder(args);

builder.Logging.AddSimpleConsole(options =>
{
    options.IncludeScopes = true;
});

builder.Logging.Configure(options =>
{
    options.ActivityTrackingOptions = ActivityTrackingOptions.SpanId
                                      | ActivityTrackingOptions.TraceId
                                      | ActivityTrackingOptions.ParentId
                                      | ActivityTrackingOptions.Baggage
                                      | ActivityTrackingOptions.Tags;
});
var app = builder.Build();

app.MapGet("/", () => "Hello World!");

app.Run();
```

If the `traceparent` http request header is set, the `ParentId` in the log scope shows the W3C `parent-id` from in-bound `traceparent` header and the `SpanId` in the log scope shows the updated `parent-id` for the next out-bound step/span. For more information, see Mutating the traceparent Field.

Create a custom logger

To create a custom logger, see Implement a custom logging provider in .NET.

HTTP logging in ASP.NET Core

Article • 06/17/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

HTTP logging is a middleware that logs information about incoming HTTP requests and HTTP responses. HTTP logging provides logs of:

- HTTP request information
- Common properties
- Headers
- Body
- HTTP response information

HTTP logging can:

- Log all requests and responses or only requests and responses that meet certain criteria.
- Select which parts of the request and response are logged.
- Allow you to redact sensitive information from the logs.

HTTP logging ***can reduce the performance of an app***, especially when logging the request and response bodies. Consider the performance impact when selecting fields to log. Test the performance impact of the selected logging properties.

> **⚠ Warning**
>
> HTTP logging can potentially log personally identifiable information (PII). Consider the risk and avoid logging sensitive information.

Enable HTTP logging

HTTP logging is enabled by calling AddHttpLogging and UseHttpLogging, as shown in the following example:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddHttpLogging(o => { });

var app = builder.Build();

app.UseHttpLogging();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
}
app.UseStaticFiles();

app.MapGet("/", () => "Hello World!");

app.Run();
```

The empty lambda in the preceding example of calling `AddHttpLogging` adds the middleware with the default configuration. By default, HTTP logging logs common properties such as path, status-code, and headers for requests and responses.

Add the following line to the `appsettings.Development.json` file at the `"LogLevel": {` level so the HTTP logs are displayed:

JSON

```
 "Microsoft.AspNetCore.HttpLogging.HttpLoggingMiddleware": "Information"
```

With the default configuration, a request and response is logged as a pair of messages similar to the following example:

Output

```
info: Microsoft.AspNetCore.HttpLogging.HttpLoggingMiddleware[1]
      Request:
      Protocol: HTTP/2
      Method: GET
      Scheme: https
      PathBase:
      Path: /
      Accept:
text/html,application/xhtml+xml,application/xml;q=0.9,image/webp,image/apng,
*/*;q=0.8,application/signed-exchange;v=b3;q=0.7
      Host: localhost:52941
      User-Agent: Mozilla/5.0 (Windows NT 10.0; Win64; x64)
AppleWebKit/537.36 (KHTML, like Gecko) Chrome/118.0.0.0 Safari/537.36
```

```
Edg/118.0.2088.61
      Accept-Encoding: gzip, deflate, br
      Accept-Language: en-US,en;q=0.9
      Upgrade-Insecure-Requests: [Redacted]
      sec-ch-ua: [Redacted]
      sec-ch-ua-mobile: [Redacted]
      sec-ch-ua-platform: [Redacted]
      sec-fetch-site: [Redacted]
      sec-fetch-mode: [Redacted]
      sec-fetch-user: [Redacted]
      sec-fetch-dest: [Redacted]
info: Microsoft.AspNetCore.HttpLogging.HttpLoggingMiddleware[2]
      Response:
      StatusCode: 200
      Content-Type: text/plain; charset=utf-8
      Date: Tue, 24 Oct 2023 02:03:53 GMT
      Server: Kestrel
```

HTTP logging options

To configure global options for the HTTP logging middleware, call AddHttpLogging in `Program.cs`, using the lambda to configure HttpLoggingOptions.

C#

```
using Microsoft.AspNetCore.HttpLogging;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddHttpLogging(logging =>
{
    logging.LoggingFields = HttpLoggingFields.All;
    logging.RequestHeaders.Add("sec-ch-ua");
    logging.ResponseHeaders.Add("MyResponseHeader");
    logging.MediaTypeOptions.AddText("application/javascript");
    logging.RequestBodyLogLimit = 4096;
    logging.ResponseBodyLogLimit = 4096;
    logging.CombineLogs = true;
});

var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
}

app.UseStaticFiles();

app.UseHttpLogging();
```

```
app.Use(async (context, next) =>
{
    context.Response.Headers["MyResponseHeader"] =
        new string[] { "My Response Header Value" };

    await next();
});

app.MapGet("/", () => "Hello World!");

app.Run();
```

> ⓘ Note
>
> In the preceding sample and following samples, `UseHttpLogging` is called after `UseStaticFiles`, so HTTP logging is not enabled for static files. To enable static file HTTP logging, call `UseHttpLogging` before `UseStaticFiles`.

`LoggingFields`

HttpLoggingOptions.LoggingFields is an enum flag that configures specific parts of the request and response to log. `HttpLoggingOptions.LoggingFields` defaults to RequestPropertiesAndHeaders | ResponsePropertiesAndHeaders.

`RequestHeaders` and `ResponseHeaders`

RequestHeaders and ResponseHeaders are sets of HTTP headers that are logged. Header values are only logged for header names that are in these collections. The following code adds `sec-ch-ua` to the RequestHeaders, so the value of the `sec-ch-ua` header is logged. And it adds `MyResponseHeader` to the ResponseHeaders, so the value of the `MyResponseHeader` header is logged. If these lines are removed, the values of these headers are `[Redacted]`.

C#

```
using Microsoft.AspNetCore.HttpLogging;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddHttpLogging(logging =>
{
    logging.LoggingFields = HttpLoggingFields.All;
    logging.RequestHeaders.Add("sec-ch-ua");
    logging.ResponseHeaders.Add("MyResponseHeader");
```

```
    logging.MediaTypeOptions.AddText("application/javascript");
    logging.RequestBodyLogLimit = 4096;
    logging.ResponseBodyLogLimit = 4096;
    logging.CombineLogs = true;
});

var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
}

app.UseStaticFiles();

app.UseHttpLogging();

app.Use(async (context, next) =>
{
    context.Response.Headers["MyResponseHeader"] =
        new string[] { "My Response Header Value" };

    await next();
});

app.MapGet("/", () => "Hello World!");

app.Run();
```

`MediaTypeOptions`

MediaTypeOptions provides configuration for selecting which encoding to use for a specific media type.

C#

```
using Microsoft.AspNetCore.HttpLogging;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddHttpLogging(logging =>
{
    logging.LoggingFields = HttpLoggingFields.All;
    logging.RequestHeaders.Add("sec-ch-ua");
    logging.ResponseHeaders.Add("MyResponseHeader");
    logging.MediaTypeOptions.AddText("application/javascript");
    logging.RequestBodyLogLimit = 4096;
    logging.ResponseBodyLogLimit = 4096;
    logging.CombineLogs = true;
});

var app = builder.Build();
```

```
if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
}

app.UseStaticFiles();

app.UseHttpLogging();

app.Use(async (context, next) =>
{
    context.Response.Headers["MyResponseHeader"] =
        new string[] { "My Response Header Value" };

    await next();
});

app.MapGet("/", () => "Hello World!");

app.Run();
```

This approach can also be used to enable logging for data that isn't logged by default (for example, form data, which might have a media type such as `application/x-www-form-urlencoded` or `multipart/form-data`).

`MediaTypeOptions` methods

- AddText
- AddBinary
- Clear

`RequestBodyLogLimit` and `ResponseBodyLogLimit`

- RequestBodyLogLimit
- ResponseBodyLogLimit

C#

```
using Microsoft.AspNetCore.HttpLogging;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddHttpLogging(logging =>
{
    logging.LoggingFields = HttpLoggingFields.All;
    logging.RequestHeaders.Add("sec-ch-ua");
    logging.ResponseHeaders.Add("MyResponseHeader");
```

```
    logging.MediaTypeOptions.AddText("application/javascript");
    logging.RequestBodyLogLimit = 4096;
    logging.ResponseBodyLogLimit = 4096;
    logging.CombineLogs = true;
});

var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
}

app.UseStaticFiles();

app.UseHttpLogging();

app.Use(async (context, next) =>
{
    context.Response.Headers["MyResponseHeader"] =
        new string[] { "My Response Header Value" };

    await next();
});

app.MapGet("/", () => "Hello World!");

app.Run();
```

`CombineLogs`

Setting CombineLogs to `true` configures the middleware to consolidate all of its enabled logs for a request and response into one log at the end. This includes the request, request body, response, response body, and duration.

C#

```
using Microsoft.AspNetCore.HttpLogging;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddHttpLogging(logging =>
{
    logging.LoggingFields = HttpLoggingFields.All;
    logging.RequestHeaders.Add("sec-ch-ua");
    logging.ResponseHeaders.Add("MyResponseHeader");
    logging.MediaTypeOptions.AddText("application/javascript");
    logging.RequestBodyLogLimit = 4096;
    logging.ResponseBodyLogLimit = 4096;
    logging.CombineLogs = true;
});
```

```
var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
}

app.UseStaticFiles();

app.UseHttpLogging();

app.Use(async (context, next) =>
{
    context.Response.Headers["MyResponseHeader"] =
        new string[] { "My Response Header Value" };

    await next();
});

app.MapGet("/", () => "Hello World!");

app.Run();
```

Endpoint-specific configuration

For endpoint-specific configuration in minimal API apps, a WithHttpLogging extension method is available. The following example shows how to configure HTTP logging for one endpoint:

C#

```
app.MapGet("/response", () => "Hello World! (logging response)")
    .WithHttpLogging(HttpLoggingFields.ResponsePropertiesAndHeaders);
```

For endpoint-specific configuration in apps that use controllers, the [HttpLogging] attribute is available. The attribute can also be used in minimal API apps, as shown in the following example:

C#

```
app.MapGet("/duration", [HttpLogging(loggingFields:
HttpLoggingFields.Duration)]
    () => "Hello World! (logging duration)");
```

`IHttpLoggingInterceptor`

IHttpLoggingInterceptor is the interface for a service that can be implemented to handle per-request and per-response callbacks for customizing what details get logged. Any endpoint-specific log settings are applied first and can then be overridden in these callbacks. An implementation can:

- Inspect a request or response.
- Enable or disable any HttpLoggingFields.
- Adjust how much of the request or response body is logged.
- Add custom fields to the logs.

Register an `IHttpLoggingInterceptor` implementation by calling AddHttpLoggingInterceptor<T> in `Program.cs`. If multiple `IHttpLoggingInterceptor` instances are registered, they're run in the order registered.

The following example shows how to register an `IHttpLoggingInterceptor` implementation:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddHttpLogging(logging =>
{
    logging.LoggingFields = HttpLoggingFields.Duration;
});
builder.Services.AddHttpLoggingInterceptor<SampleHttpLoggingInterceptor>();
```

The following example is an `IHttpLoggingInterceptor` implementation that:

- Inspects the request method and disables logging for POST requests.
- For non-POST requests:
  - Redacts request path, request headers, and response headers.
  - Adds custom fields and field values to the request and response logs.

C#

```
using Microsoft.AspNetCore.HttpLogging;

namespace HttpLoggingSample;

internal sealed class SampleHttpLoggingInterceptor : IHttpLoggingInterceptor
{
    public ValueTask OnRequestAsync(HttpLoggingInterceptorContext
logContext)
    {
        if (logContext.HttpContext.Request.Method == "POST")
        {
```

```
            // Don't log anything if the request is a POST.
            logContext.LoggingFields = HttpLoggingFields.None;
        }

        // Don't enrich if we're not going to log any part of the request.
        if (!logContext.IsAnyEnabled(HttpLoggingFields.Request))
        {
            return default;
        }

        if (logContext.TryDisable(HttpLoggingFields.RequestPath))
        {
            RedactPath(logContext);
        }

        if (logContext.TryDisable(HttpLoggingFields.RequestHeaders))
        {
            RedactRequestHeaders(logContext);
        }

        EnrichRequest(logContext);

        return default;
    }

    public ValueTask OnResponseAsync(HttpLoggingInterceptorContext
logContext)
    {
        // Don't enrich if we're not going to log any part of the response
        if (!logContext.IsAnyEnabled(HttpLoggingFields.Response))
        {
            return default;
        }

        if (logContext.TryDisable(HttpLoggingFields.ResponseHeaders))
        {
            RedactResponseHeaders(logContext);
        }

        EnrichResponse(logContext);

        return default;
    }

    private void RedactPath(HttpLoggingInterceptorContext logContext)
    {
        logContext.AddParameter(nameof(logContext.HttpContext.Request.Path),
"RedactedPath");
    }

    private void RedactRequestHeaders(HttpLoggingInterceptorContext
logContext)
    {
        foreach (var header in logContext.HttpContext.Request.Headers)
        {
```

```
            logContext.AddParameter(header.Key, "RedactedHeader");
        }
    }

    private void EnrichRequest(HttpLoggingInterceptorContext logContext)
    {
        logContext.AddParameter("RequestEnrichment", "Stuff");
    }

    private void RedactResponseHeaders(HttpLoggingInterceptorContext
logContext)
    {
        foreach (var header in logContext.HttpContext.Response.Headers)
        {
            logContext.AddParameter(header.Key, "RedactedHeader");
        }
    }

    private void EnrichResponse(HttpLoggingInterceptorContext logContext)
    {
        logContext.AddParameter("ResponseEnrichment", "Stuff");
    }
}
```

With this interceptor, a POST request doesn't generate any logs even if HTTP logging is configured to log `HttpLoggingFields.All`. A GET request generates logs similar to the following example:

Output

```
info: Microsoft.AspNetCore.HttpLogging.HttpLoggingMiddleware[1]
      Request:
      Path: RedactedPath
      Accept: RedactedHeader
      Host: RedactedHeader
      User-Agent: RedactedHeader
      Accept-Encoding: RedactedHeader
      Accept-Language: RedactedHeader
      Upgrade-Insecure-Requests: RedactedHeader
      sec-ch-ua: RedactedHeader
      sec-ch-ua-mobile: RedactedHeader
      sec-ch-ua-platform: RedactedHeader
      sec-fetch-site: RedactedHeader
      sec-fetch-mode: RedactedHeader
      sec-fetch-user: RedactedHeader
      sec-fetch-dest: RedactedHeader
      RequestEnrichment: Stuff
      Protocol: HTTP/2
      Method: GET
      Scheme: https
info: Microsoft.AspNetCore.HttpLogging.HttpLoggingMiddleware[2]
```

```
      Response:
      Content-Type: RedactedHeader
      MyResponseHeader: RedactedHeader
      ResponseEnrichment: Stuff
      StatusCode: 200
info: Microsoft.AspNetCore.HttpLogging.HttpLoggingMiddleware[4]
      ResponseBody: Hello World!
info: Microsoft.AspNetCore.HttpLogging.HttpLoggingMiddleware[8]
      Duration: 2.2778ms
```

Logging configuration order of precedence

The following list shows the order of precedence for logging configuration:

1. Global configuration from HttpLoggingOptions, set by calling AddHttpLogging.
2. Endpoint-specific configuration from the [HttpLogging] attribute or the WithHttpLogging extension method overrides global configuration.
3. IHttpLoggingInterceptor is called with the results and can further modify the configuration per request.

W3CLogger in ASP.NET Core

Article • 07/26/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

W3CLogger is a middleware that writes log files in the W3C standard format. The logs contain information about HTTP requests and HTTP responses. W3CLogger provides logs of:

- HTTP request information
- Common properties
- Headers
- HTTP response information
- Metadata about the request/response pair (date/time started, time taken)

W3CLogger is valuable in several scenarios to:

- Record information about incoming requests and responses.
- Filter which parts of the request and response are logged.
- Filter which headers to log.

W3CLogger ***can reduce the performance of an app***. Consider the performance impact when selecting fields to log - the performance reduction will increase as you log more properties. Test the performance impact of the selected logging properties.

> **⚠ Warning**
>
> W3CLogger can potentially log personally identifiable information (PII). Consider the risk and avoid logging sensitive information. By default, fields that could contain PII aren't logged.

Enable W3CLogger

Enable W3CLogger with UseW3CLogging, which adds the W3CLogger middleware:

C#

```
var app = builder.Build();

app.UseW3CLogging();

app.UseRouting();
```

By default, W3CLogger logs common properties such as path, status-code, date, time, and protocol. All information about a single request/response pair is written to the same line.

```
#Version: 1.0
#Start-Date: 2021-09-29 22:18:28
#Fields: date time c-ip s-computername s-ip s-port cs-method cs-uri-stem cs-uri-query sc-status time-taken cs-version cs-host cs(User-Agent) cs(Referer)
2021-09-29 22:18:28 ::1 DESKTOP-LH3TLTA ::1 5000 GET / - 200 59.9171 HTTP/1.1 localhost:5000 Mozilla/5.0+(Windows+NT+10.0;+WOW64)+AppleWebKit/537.36+(KHTML,+like+Gecko)+Chrome/93.0.4577.82+Safari/537.36 -
2021-09-29 22:18:28 ::1 DESKTOP-LH3TLTA ::1 5000 GET / - 200 0.1802 HTTP/1.1 localhost:5000 Mozilla/5.0+(Windows+NT+10.0;+WOW64)+AppleWebKit/537.36+(KHTML,+like+Gecko)+Chrome/93.0.4577.82+Safari/537.36 -
2021-09-29 22:18:30 ::1 DESKTOP-LH3TLTA ::1 5000 GET / - 200 0.0966 HTTP/1.1 localhost:5000 Mozilla/5.0+(Windows+NT+10.0;+WOW64)+AppleWebKit/537.36+(KHTML,+like+Gecko)+Chrome/93.0.4577.82+Safari/537.36 -
```

W3CLogger options

To configure the W3CLogger middleware, call AddW3CLogging in `Program.cs`:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddW3CLogging(logging =>
{
    // Log all W3C fields
    logging.LoggingFields = W3CLoggingFields.All;

    logging.AdditionalRequestHeaders.Add("x-forwarded-for");
    logging.AdditionalRequestHeaders.Add("x-client-ssl-protocol");
    logging.FileSizeLimit = 5 * 1024 * 1024;
    logging.RetainedFileCountLimit = 2;
    logging.FileName = "MyLogFile";
    logging.LogDirectory = @"C:\logs";
```

```
    logging.FlushInterval = TimeSpan.FromSeconds(2);
});
```

`LoggingFields`

W3CLoggerOptions.LoggingFields is a bit flag enumeration that configures specific parts of the request and response to log, and other information about the connection. `LoggingFields` defaults to include all possible fields except `UserName` and `Cookie`. For a complete list of available fields, see W3CLoggingFields.

Health checks in ASP.NET Core

Article • 07/23/2024

By Glenn Condron and Juergen Gutsch

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

ASP.NET Core offers Health Checks Middleware and libraries for reporting the health of app infrastructure components.

Health checks are exposed by an app as HTTP endpoints. Health check endpoints can be configured for various real-time monitoring scenarios:

- Health probes can be used by container orchestrators and load balancers to check an app's status. For example, a container orchestrator may respond to a failing health check by halting a rolling deployment or restarting a container. A load balancer might react to an unhealthy app by routing traffic away from the failing instance to a healthy instance.
- Use of memory, disk, and other physical server resources can be monitored for healthy status.
- Health checks can test an app's dependencies, such as databases and external service endpoints, to confirm availability and normal functioning.

Health checks are typically used with an external monitoring service or container orchestrator to check the status of an app. Before adding health checks to an app, decide on which monitoring system to use. The monitoring system dictates what types of health checks to create and how to configure their endpoints.

Basic health probe

For many apps, a basic health probe configuration that reports the app's availability to process requests (*liveness*) is sufficient to discover the status of the app.

The basic configuration registers health check services and calls the Health Checks Middleware to respond at a URL endpoint with a health response. By default, no specific

health checks are registered to test any particular dependency or subsystem. The app is considered healthy if it can respond at the health endpoint URL. The default response writer writes HealthStatus as a plaintext response to the client. The `HealthStatus` is HealthStatus.Healthy, HealthStatus.Degraded, or HealthStatus.Unhealthy.

Register health check services with AddHealthChecks in `Program.cs`. Create a health check endpoint by calling MapHealthChecks.

The following example creates a health check endpoint at `/healthz`:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddHealthChecks();

var app = builder.Build();

app.MapHealthChecks("/healthz");

app.Run();
```

Docker `HEALTHCHECK`

Docker offers a built-in `HEALTHCHECK` directive that can be used to check the status of an app that uses the basic health check configuration:

Dockerfile

```
HEALTHCHECK CMD curl --fail http://localhost:5000/healthz || exit
```

The preceding example uses `curl` to make an HTTP request to the health check endpoint at `/healthz`. `curl` isn't included in the .NET Linux container images, but it can be added by installing the required package in the Dockerfile. Containers that use images based on Alpine Linux can use the included `wget` in place of `curl`.

Create health checks

Health checks are created by implementing the IHealthCheck interface. The CheckHealthAsync method returns a HealthCheckResult that indicates the health as `Healthy`, `Degraded`, or `Unhealthy`. The result is written as a plaintext response with a configurable status code. Configuration is described in the Health check options section. HealthCheckResult can also return optional key-value pairs.

The following example demonstrates the layout of a health check:

C#

```
public class SampleHealthCheck : IHealthCheck
{
    public Task<HealthCheckResult> CheckHealthAsync(
        HealthCheckContext context, CancellationToken cancellationToken =
default)
    {
        var isHealthy = true;

        // ...

        if (isHealthy)
        {
            return Task.FromResult(
                HealthCheckResult.Healthy("A healthy result."));
        }

        return Task.FromResult(
            new HealthCheckResult(
                context.Registration.FailureStatus, "An unhealthy
result."));
    }
}
```

The health check's logic is placed in the CheckHealthAsync method. The preceding example sets a dummy variable, `isHealthy`, to `true`. If the value of `isHealthy` is set to `false`, the HealthCheckRegistration.FailureStatus status is returned.

If CheckHealthAsync throws an exception during the check, a new HealthReportEntry is returned with its HealthReportEntry.Status set to the FailureStatus. This status is defined by AddCheck (see the Register health check services section) and includes the inner exception that caused the check failure. The Description is set to the exception's message.

Register health check services

To register a health check service, call AddCheck in `Program.cs`:

C#

```
builder.Services.AddHealthChecks()
    .AddCheck<SampleHealthCheck>("Sample");
```

The AddCheck overload shown in the following example sets the failure status (HealthStatus) to report when the health check reports a failure. If the failure status is set to `null` (default), HealthStatus.Unhealthy is reported. This overload is a useful scenario for library authors, where the failure status indicated by the library is enforced by the app when a health check failure occurs if the health check implementation honors the setting.

Tags can be used to filter health checks. Tags are described in the Filter health checks section.

C#

```
builder.Services.AddHealthChecks()
    .AddCheck<SampleHealthCheck>(
        "Sample",
        failureStatus: HealthStatus.Degraded,
        tags: new[] { "sample" });
```

AddCheck can also execute a lambda function. In the following example, the health check always returns a healthy result:

C#

```
builder.Services.AddHealthChecks()
    .AddCheck("Sample", () => HealthCheckResult.Healthy("A healthy
result."));
```

Call AddTypeActivatedCheck to pass arguments to a health check implementation. In the following example, a type-activated health check accepts an integer and a string in its constructor:

C#

```
public class SampleHealthCheckWithArgs : IHealthCheck
{
    private readonly int _arg1;
    private readonly string _arg2;

    public SampleHealthCheckWithArgs(int arg1, string arg2)
        => (_arg1, _arg2) = (arg1, arg2);

    public Task<HealthCheckResult> CheckHealthAsync(
        HealthCheckContext context, CancellationToken cancellationToken =
default)
    {
        // ...
```

```
        return Task.FromResult(HealthCheckResult.Healthy("A healthy
result."));
    }
}
```

To register the preceding health check, call `AddTypeActivatedCheck` with the integer and string passed as arguments:

C#

```
builder.Services.AddHealthChecks()
    .AddTypeActivatedCheck<SampleHealthCheckWithArgs>(
        "Sample",
        failureStatus: HealthStatus.Degraded,
        tags: new[] { "sample" },
        args: new object[] { 1, "Arg" });
```

Use Health Checks Routing

In `Program.cs`, call `MapHealthChecks` on the endpoint builder with the endpoint URL or relative path:

C#

```
app.MapHealthChecks("/healthz");
```

Require host

Call `RequireHost` to specify one or more permitted hosts for the health check endpoint. Hosts should be Unicode rather than punycode and may include a port. If a collection isn't supplied, any host is accepted:

C#

```
app.MapHealthChecks("/healthz")
    .RequireHost("www.contoso.com:5001");
```

To restrict the health check endpoint to respond only on a specific port, specify a port in the call to `RequireHost`. This approach is typically used in a container environment to expose a port for monitoring services:

C#

```
app.MapHealthChecks("/healthz")
    .RequireHost("*:5001");
```

> ⚠ **Warning**
>
> API that relies on the Host header, such as HttpRequest.Host and RequireHost, are subject to potential spoofing by clients.
>
> To prevent host and port spoofing, use one of the following approaches:
>
> - Use HttpContext.Connection (ConnectionInfo.LocalPort) where the ports are checked.
> - Employ Host filtering.

To prevent unauthorized clients from spoofing the port, call RequireAuthorization:

C#

```
app.MapHealthChecks("/healthz")
    .RequireHost("*:5001")
    .RequireAuthorization();
```

For more information, see Host matching in routes with RequireHost.

Require authorization

Call RequireAuthorization to run Authorization Middleware on the health check request endpoint. A `RequireAuthorization` overload accepts one or more authorization policies. If a policy isn't provided, the default authorization policy is used:

C#

```
app.MapHealthChecks("/healthz")
    .RequireAuthorization();
```

Enable Cross-Origin Requests (CORS)

Although running health checks manually from a browser isn't a common scenario, CORS Middleware can be enabled by calling RequireCors on the health checks endpoints. The RequireCors overload accepts a CORS policy builder delegate

(`CorsPolicyBuilder`) or a policy name. For more information, see Enable Cross-Origin Requests (CORS) in ASP.NET Core.

Health check options

HealthCheckOptions provide an opportunity to customize health check behavior:

- Filter health checks
- Customize the HTTP status code
- Suppress cache headers
- Customize output

Filter health checks

By default, the Health Checks Middleware runs all registered health checks. To run a subset of health checks, provide a function that returns a boolean to the Predicate option.

The following example filters the health checks so that only those tagged with `sample` run:

C#

```
app.MapHealthChecks("/healthz", new HealthCheckOptions
{
    Predicate = healthCheck => healthCheck.Tags.Contains("sample")
});
```

Customize the HTTP status code

Use ResultStatusCodes to customize the mapping of health status to HTTP status codes. The following StatusCodes assignments are the default values used by the middleware. Change the status code values to meet your requirements:

C#

```
app.MapHealthChecks("/healthz", new HealthCheckOptions
{
    ResultStatusCodes =
    {
        [HealthStatus.Healthy] = StatusCodes.Status200OK,
        [HealthStatus.Degraded] = StatusCodes.Status200OK,
        [HealthStatus.Unhealthy] = StatusCodes.Status503ServiceUnavailable
```

```
    }
});
```

Suppress cache headers

AllowCachingResponses controls whether the Health Checks Middleware adds HTTP headers to a probe response to prevent response caching. If the value is `false` (default), the middleware sets or overrides the `Cache-Control`, `Expires`, and `Pragma` headers to prevent response caching. If the value is `true`, the middleware doesn't modify the cache headers of the response:

C#

```
app.MapHealthChecks("/healthz", new HealthCheckOptions
{
    AllowCachingResponses = true
});
```

Customize output

To customize the output of a health checks report, set the HealthCheckOptions.ResponseWriter property to a delegate that writes the response:

C#

```
app.MapHealthChecks("/healthz", new HealthCheckOptions
{
    ResponseWriter = WriteResponse
});
```

The default delegate writes a minimal plaintext response with the string value of HealthReport.Status. The following custom delegate outputs a custom JSON response using System.Text.Json:

C#

```
private static Task WriteResponse(HttpContext context, HealthReport
healthReport)
{
    context.Response.ContentType = "application/json; charset=utf-8";

    var options = new JsonWriterOptions { Indented = true };

    using var memoryStream = new MemoryStream();
    using (var jsonWriter = new Utf8JsonWriter(memoryStream, options))
```

```
    {
        jsonWriter.WriteStartObject();
        jsonWriter.WriteString("status", healthReport.Status.ToString());
        jsonWriter.WriteStartObject("results");

        foreach (var healthReportEntry in healthReport.Entries)
        {
            jsonWriter.WriteStartObject(healthReportEntry.Key);
            jsonWriter.WriteString("status",
                healthReportEntry.Value.Status.ToString());
            jsonWriter.WriteString("description",
                healthReportEntry.Value.Description);
            jsonWriter.WriteStartObject("data");

            foreach (var item in healthReportEntry.Value.Data)
            {
                jsonWriter.WritePropertyName(item.Key);

                JsonSerializer.Serialize(jsonWriter, item.Value,
                    item.Value?.GetType() ?? typeof(object));
            }

            jsonWriter.WriteEndObject();
            jsonWriter.WriteEndObject();
        }

        jsonWriter.WriteEndObject();
        jsonWriter.WriteEndObject();
    }

    return context.Response.WriteAsync(
        Encoding.UTF8.GetString(memoryStream.ToArray()));
}
```

The health checks API doesn't provide built-in support for complex JSON return formats because the format is specific to your choice of monitoring system. Customize the response in the preceding examples as needed. For more information on JSON serialization with `System.Text.Json`, see How to serialize and deserialize JSON in .NET.

Database probe

A health check can specify a database query to run as a boolean test to indicate if the database is responding normally.

AspNetCore.Diagnostics.HealthChecks, a health check library for ASP.NET Core apps, includes a health check that runs against a SQL Server database. `AspNetCore.Diagnostics.HealthChecks` executes a `SELECT 1` query against the database to confirm the connection to the database is healthy.

> ⚠ **Warning**
>
> When checking a database connection with a query, choose a query that returns quickly. The query approach runs the risk of overloading the database and degrading its performance. In most cases, running a test query isn't necessary. Merely making a successful connection to the database is sufficient. If you find it necessary to run a query, choose a simple SELECT query, such as `SELECT 1`.

To use this SQL Server health check, include a package reference to the AspNetCore.HealthChecks.SqlServer NuGet package. The following example registers the SQL Server health check:

C#

```
var conStr = builder.Configuration.GetConnectionString("DefaultConnection");
if (string.IsNullOrEmpty(conStr))
{
    throw new InvalidOperationException(
                        "Could not find a connection string named
'DefaultConnection'.");
}
builder.Services.AddHealthChecks()
    .AddSqlServer(conStr);
```

> ⓘ **Note**
>
> AspNetCore.Diagnostics.HealthChecks isn't maintained or supported by Microsoft.

Entity Framework Core DbContext probe

The `DbContext` check confirms that the app can communicate with the database configured for an EF Core `DbContext`. The `DbContext` check is supported in apps that:

- Use Entity Framework (EF) Core.
- Include a package reference to the Microsoft.Extensions.Diagnostics.HealthChecks.EntityFrameworkCore NuGet package.

AddDbContextCheck registers a health check for a DbContext. The `DbContext` is supplied to the method as the `TContext`. An overload is available to configure the failure

status, tags, and a custom test query.

By default:

- The `DbContextHealthCheck` calls EF Core's `CanConnectAsync` method. You can customize what operation is run when checking health using `AddDbContextCheck` method overloads.
- The name of the health check is the name of the `TContext` type.

The following example registers a `DbContext` and an associated `DbContextHealthCheck`:

C#

```
builder.Services.AddDbContext<SampleDbContext>(options =>
    options.UseSqlServer(
        builder.Configuration.GetConnectionString("DefaultConnection")));

builder.Services.AddHealthChecks()
    .AddDbContextCheck<SampleDbContext>();
```

Separate readiness and liveness probes

In some hosting scenarios, a pair of health checks is used to distinguish two app states:

- *Readiness* indicates if the app is running normally but isn't ready to receive requests.
- *Liveness* indicates if an app has crashed and must be restarted.

Consider the following example: An app must download a large configuration file before it's ready to process requests. We don't want the app to be restarted if the initial download fails because the app can retry downloading the file several times. We use a *liveness probe* to describe the liveness of the process, no other checks are run. We also want to prevent requests from being sent to the app before the configuration file download has succeeded. We use a *readiness probe* to indicate a "not ready" state until the download succeeds and the app is ready to receive requests.

The following background task simulates a startup process that takes roughly 15 seconds. Once it completes, the task sets the `StartupHealthCheck.StartupCompleted` property to true:

C#

```
public class StartupBackgroundService : BackgroundService
{
    private readonly StartupHealthCheck _healthCheck;
```

```
    public StartupBackgroundService(StartupHealthCheck healthCheck)
        => _healthCheck = healthCheck;

    protected override async Task ExecuteAsync(CancellationToken
stoppingToken)
    {
        // Simulate the effect of a long-running task.
        await Task.Delay(TimeSpan.FromSeconds(15), stoppingToken);

        _healthCheck.StartupCompleted = true;
    }
}
```

The `StartupHealthCheck` reports the completion of the long-running startup task and exposes the `StartupCompleted` property that gets set by the background service:

C#

```
public class StartupHealthCheck : IHealthCheck
{
    private volatile bool _isReady;

    public bool StartupCompleted
    {
        get => _isReady;
        set => _isReady = value;
    }

    public Task<HealthCheckResult> CheckHealthAsync(
        HealthCheckContext context, CancellationToken cancellationToken =
default)
    {
        if (StartupCompleted)
        {
            return Task.FromResult(HealthCheckResult.Healthy("The startup
task has completed."));
        }

        return Task.FromResult(HealthCheckResult.Unhealthy("That startup
task is still running."));
    }
}
```

The health check is registered with AddCheck in `Program.cs` along with the hosted service. Because the hosted service must set the property on the health check, the health check is also registered in the service container as a singleton:

C#

```
builder.Services.AddHostedService<StartupBackgroundService>();
builder.Services.AddSingleton<StartupHealthCheck>();

builder.Services.AddHealthChecks()
    .AddCheck<StartupHealthCheck>(
        "Startup",
        tags: new[] { "ready" });
```

To create two different health check endpoints, call `MapHealthChecks` twice:

C#

```
app.MapHealthChecks("/healthz/ready", new HealthCheckOptions
{
    Predicate = healthCheck => healthCheck.Tags.Contains("ready")
});

app.MapHealthChecks("/healthz/live", new HealthCheckOptions
{
    Predicate = _ => false
});
```

The preceding example creates the following health check endpoints:

- `/healthz/ready` for the readiness check. The readiness check filters health checks to those tagged with `ready`.
- `/healthz/live` for the liveness check. The liveness check filters out all health checks by returning `false` in the HealthCheckOptions.Predicate delegate. For more information on filtering health checks, see Filter health checks in this article.

Before the startup task completes, the `/healthz/ready` endpoint reports an `Unhealthy` status. Once the startup task completes, this endpoint reports a `Healthy` status. The `/healthz/live` endpoint excludes all checks and reports a `Healthy` status for all calls.

Kubernetes example

Using separate readiness and liveness checks is useful in an environment such as Kubernetes. In Kubernetes, an app might be required to run time-consuming startup work before accepting requests, such as a test of the underlying database availability. Using separate checks allows the orchestrator to distinguish whether the app is functioning but not yet ready or if the app has failed to start. For more information on readiness and liveness probes in Kubernetes, see Configure Liveness and Readiness Probes in the Kubernetes documentation.

The following example demonstrates a Kubernetes readiness probe configuration:

YAML

```yaml
spec:
  template:
  spec:
    readinessProbe:
      # an http probe
      httpGet:
        path: /healthz/ready
        port: 80
      # length of time to wait for a pod to initialize
      # after pod startup, before applying health checking
      initialDelaySeconds: 30
      timeoutSeconds: 1
    ports:
      - containerPort: 80
```

Distribute a health check library

To distribute a health check as a library:

1. Write a health check that implements the IHealthCheck interface as a standalone class. The class can rely on dependency injection (DI), type activation, and named options to access configuration data.

2. Write an extension method with parameters that the consuming app calls in its `Program.cs` method. Consider the following example health check, which accepts `arg1` and `arg2` as constructor parameters:

   C#

   ```
   public SampleHealthCheckWithArgs(int arg1, string arg2)
       => (_arg1, _arg2) = (arg1, arg2);
   ```

   The preceding signature indicates that the health check requires custom data to process the health check probe logic. The data is provided to the delegate used to create the health check instance when the health check is registered with an extension method. In the following example, the caller specifies:

   - `arg1`: An integer data point for the health check.
   - `arg2`: A string argument for the health check.
   - `name`: An optional health check name. If `null`, a default value is used.

- `failureStatus`: An optional HealthStatus, which is reported for a failure status. If `null`, HealthStatus.Unhealthy is used.
- `tags`: An optional `IEnumerable<string>` collection of tags.

C#

```
public static class SampleHealthCheckBuilderExtensions
{
    private const string DefaultName = "Sample";

    public static IHealthChecksBuilder AddSampleHealthCheck(
        this IHealthChecksBuilder healthChecksBuilder,
        int arg1,
        string arg2,
        string? name = null,
        HealthStatus? failureStatus = null,
        IEnumerable<string>? tags = default)
    {
        return healthChecksBuilder.Add(
            new HealthCheckRegistration(
                name ?? DefaultName,
                _ => new SampleHealthCheckWithArgs(arg1, arg2),
                failureStatus,
                tags));
    }
}
```

Health Check Publisher

When an IHealthCheckPublisher is added to the service container, the health check system periodically executes your health checks and calls PublishAsync with the result. This process is useful in a push-based health monitoring system scenario that expects each process to call the monitoring system periodically to determine health.

HealthCheckPublisherOptions allow you to set the:

- Delay: The initial delay applied after the app starts before executing IHealthCheckPublisher instances. The delay is applied once at startup and doesn't apply to later iterations. The default value is five seconds.
- Period: The period of IHealthCheckPublisher execution. The default value is 30 seconds.
- Predicate: If Predicate is `null` (default), the health check publisher service runs all registered health checks. To run a subset of health checks, provide a function that filters the set of checks. The predicate is evaluated each period.
- Timeout: The timeout for executing the health checks for all IHealthCheckPublisher instances. Use InfiniteTimeSpan to execute without a timeout. The default value is

30 seconds.

The following example demonstrates the layout of a health publisher:

C#

```
public class SampleHealthCheckPublisher : IHealthCheckPublisher
{
    public Task PublishAsync(HealthReport report, CancellationToken
cancellationToken)
    {
        if (report.Status == HealthStatus.Healthy)
        {
            // ...
        }
        else
        {
            // ...
        }

        return Task.CompletedTask;
    }
}
```

The HealthCheckPublisherOptions class provides properties for configuring the behavior of the health check publisher.

The following example registers a health check publisher as a singleton and configures HealthCheckPublisherOptions:

C#

```
builder.Services.Configure<HealthCheckPublisherOptions>(options =>
{
    options.Delay = TimeSpan.FromSeconds(2);
    options.Predicate = healthCheck => healthCheck.Tags.Contains("sample");
});

builder.Services.AddSingleton<IHealthCheckPublisher,
SampleHealthCheckPublisher>();
```

AspNetCore.Diagnostics.HealthChecks :

- Includes publishers for several systems, including Application Insights.
- Is ***not*** maintained or supported by Microsoft.

Individual Healthchecks

Delay and Period can be set on each HealthCheckRegistration individually. This is useful when you want to run some health checks at a different rate than the period set in HealthCheckPublisherOptions.

The following code sets the `Delay` and `Period` for the `SampleHealthCheck1`:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddHealthChecks()
    .Add(new HealthCheckRegistration(
        name: "SampleHealthCheck1",
        instance: new SampleHealthCheck(),
        failureStatus: null,
        tags: null,
        timeout: default)
    {
        Delay = TimeSpan.FromSeconds(40),
        Period = TimeSpan.FromSeconds(30)
    });

var app = builder.Build();

app.MapHealthChecks("/healthz");

app.Run();
```

Dependency Injection and Health Checks

It's possible to use dependency injection to consume an instance of a specific `Type` inside a Health Check class. Dependency injection can be useful to inject options or a global configuration to a Health Check. Using dependency injection is ***not*** a common scenario to configure Health Checks. Usually, each Health Check is quite specific to the actual test and is configured using `IHealthChecksBuilder` extension methods.

The following example shows a sample Health Check that retrieves a configuration object via dependency injection:

C#

```
public class SampleHealthCheckWithDI : IHealthCheck
{
    private readonly SampleHealthCheckWithDiConfig _config;

    public SampleHealthCheckWithDI(SampleHealthCheckWithDiConfig config)
        => _config = config;
```

```
    public Task<HealthCheckResult> CheckHealthAsync(
        HealthCheckContext context, CancellationToken cancellationToken =
default)
    {
        var isHealthy = true;

        // use _config ...

        if (isHealthy)
        {
            return Task.FromResult(
                HealthCheckResult.Healthy("A healthy result."));
        }

        return Task.FromResult(
            new HealthCheckResult(
                context.Registration.FailureStatus, "An unhealthy
result."));
    }
}
```

The `SampleHealthCheckWithDiConfig` and the Health check needs to be added to the service container :

C#

```
builder.Services.AddSingleton<SampleHealthCheckWithDiConfig>(new
SampleHealthCheckWithDiConfig
{
    BaseUriToCheck = new Uri("https://sample.contoso.com/api/")
});
builder.Services.AddHealthChecks()
    .AddCheck<SampleHealthCheckWithDI>(
        "With Dependency Injection",
        tags: new[] { "inject" });
```

UseHealthChecks vs. MapHealthChecks

There are two ways to make health checks accessible to callers:

- UseHealthChecks registers middleware for handling health checks requests in the middleware pipeline.
- MapHealthChecks registers a health checks endpoint. The endpoint is matched and executed along with other endpoints in the app.

The advantage of using `MapHealthChecks` over `UseHealthChecks` is the ability to use endpoint aware middleware, such as authorization, and to have greater fine-grained control over the matching policy. The primary advantage of using `UseHealthChecks` over

`MapHealthChecks` is controlling exactly where health checks runs in the middleware pipeline.

UseHealthChecks:

- Terminates the pipeline when a request matches the health check endpoint. Short-circuiting is often desirable because it avoids unnecessary work, such as logging and other middleware.
- Is primarily used for configuring the health check middleware in the pipeline.
- Can match any path on a port with a `null` or empty `PathString`. Allows performing a health check on any request made to the specified port.
- Source code

MapHealthChecks allows:

- Terminating the pipeline when a request matches the health check endpoint, by calling ShortCircuit. For example, `app.MapHealthChecks("/healthz").ShortCircuit();`. For more information, see Short-circuit middleware after routing.
- Mapping specific routes or endpoints for health checks.
- Customization of the URL or path where the health check endpoint is accessible.
- Mapping multiple health check endpoints with different routes or configurations. Multiple endpoint support:
  - Enables separate endpoints for different types of health checks or components.
  - Is used to differentiate between different aspects of the app's health or apply specific configurations to subsets of health checks.
- Source code

ASP.NET Core metrics

Article • 08/14/2024

Metrics are numerical measurements reported over time. They're typically used to monitor the health of an app and generate alerts. For example, a web service might track how many:

- Requests it received per second.
- Milliseconds it took to respond.
- Responses sent an error.

These metrics can be reported to a monitoring system at regular intervals. Dashboards can be setup to view metrics and alerts created to notify people of problems. If the web service is intended to respond to requests within 400 ms and starts responding in 600 ms, the monitoring system can notify the operations staff that the app response is slower than normal.

> **Tip**
>
> See **ASP.NET Core metrics** for a comprehensive list of all instruments together with their attributes.

Using metrics

There are two parts to using metrics in a .NET app:

- **Instrumentation:** Code in .NET libraries takes measurements and associates these measurements with a metric name. .NET and ASP.NET Core include many built-in metrics.
- **Collection:** A .NET app configures named metrics to be transmitted from the app for external storage and analysis. Some tools may perform configuration outside the app using configuration files or a UI tool.

Instrumented code can record numeric measurements, but the measurements need to be aggregated, transmitted, and stored to create useful metrics for monitoring. The process of aggregating, transmitting, and storing data is called collection. This tutorial shows several examples of collecting metrics:

- Populating metrics in Grafana with OpenTelemetry and Prometheus.
- Viewing metrics in real time with dotnet-counters

Measurements can also be associated with key-value pairs called tags that allow data to be categorized for analysis. For more information, see Multi-dimensional metrics.

Create the starter app

Create a new ASP.NET Core app with the following command:

.NET CLI

```
dotnet new web -o WebMetric
cd WebMetric
dotnet add package OpenTelemetry.Exporter.Prometheus.AspNetCore --prerelease
dotnet add package OpenTelemetry.Extensions.Hosting
```

Replace the contents of `Program.cs` with the following code:

C#

```
using OpenTelemetry.Metrics;

var builder = WebApplication.CreateBuilder(args);
builder.Services.AddOpenTelemetry()
    .WithMetrics(builder =>
    {
        builder.AddPrometheusExporter();

        builder.AddMeter("Microsoft.AspNetCore.Hosting",
                         "Microsoft.AspNetCore.Server.Kestrel");
        builder.AddView("http.server.request.duration",
            new ExplicitBucketHistogramConfiguration
            {
                Boundaries = new double[] { 0, 0.005, 0.01, 0.025, 0.05,
                       0.075, 0.1, 0.25, 0.5, 0.75, 1, 2.5, 5, 7.5, 10 }
            });
    });
var app = builder.Build();

app.MapPrometheusScrapingEndpoint();

app.MapGet("/", () => "Hello OpenTelemetry! ticks:"
                    + DateTime.Now.Ticks.ToString()[^3..]);

app.Run();
```

View metrics with dotnet-counters

dotnet-counters is a command-line tool that can view live metrics for .NET Core apps on demand. It doesn't require setup, making it useful for ad-hoc investigations or verifying that metric instrumentation is working. It works with both System.Diagnostics.Metrics based APIs and EventCounters.

If the dotnet-counters tool isn't installed, run the following command:

.NET CLI

```
dotnet tool update -g dotnet-counters
```

While the test app is running, launch dotnet-counters. The following command shows an example of `dotnet-counters` monitoring all metrics from the Microsoft.AspNetCore.Hosting meter.

.NET CLI

```
dotnet-counters monitor -n WebMetric --counters Microsoft.AspNetCore.Hosting
```

Output similar to the following is displayed:

.NET CLI

```
Press p to pause, r to resume, q to quit.
    Status: Running

[Microsoft.AspNetCore.Hosting]
    http-server-current-requests
        host=localhost,method=GET,port=5045,scheme=http                    0
    http-server-request-duration (s)
        host=localhost,method=GET,port=5045,protocol=HTTP/1.1,ro
0.001
        host=localhost,method=GET,port=5045,protocol=HTTP/1.1,ro
0.001
        host=localhost,method=GET,port=5045,protocol=HTTP/1.1,ro
0.001
        host=localhost,method=GET,port=5045,protocol=HTTP/1.1,ro           0
        host=localhost,method=GET,port=5045,protocol=HTTP/1.1,ro           0
        host=localhost,method=GET,port=5045,protocol=HTTP/1.1,ro           0
```

For more information, see dotnet-counters.

Enrich the ASP.NET Core request metric

ASP.NET Core has many built-in metrics. The `http.server.request.duration` metric:

- Records the duration of HTTP requests on the server.
- Captures request information in tags, such as the matched route and response status code.

The `http.server.request.duration` metric supports tag enrichment using IHttpMetricsTagsFeature. Enrichment is when a library or app adds its own tags to a metric. This is useful if an app wants to add a custom categorization to dashboards or alerts built with metrics.

C#

```
using Microsoft.AspNetCore.Http.Features;

var builder = WebApplication.CreateBuilder();
var app = builder.Build();

app.Use(async (context, next) =>
{
    var tagsFeature = context.Features.Get<IHttpMetricsTagsFeature>();
    if (tagsFeature != null)
    {
        var source = context.Request.Query["utm_medium"].ToString() switch
        {
            "" => "none",
            "social" => "social",
            "email" => "email",
            "organic" => "organic",
            _ => "other"
        };
        tagsFeature.Tags.Add(new KeyValuePair<string, object?>("mkt_medium",
source));
    }

    await next.Invoke();
});

app.MapGet("/", () => "Hello World!");

app.Run();
```

The proceeding example:

- Adds middleware to enrich the ASP.NET Core request metric.
- Gets the IHttpMetricsTagsFeature from the `HttpContext`. The feature is only present on the context if someone is listening to the metric. Verify `IHttpMetricsTagsFeature` is not `null` before using it.
- Adds a custom tag containing the request's marketing source to the http.server.request.duration metric.

- The tag has the name `mkt_medium` and a value based on the utm_medium query string value. The `utm_medium` value is resolved to a known range of values.
- The tag allows requests to be categorized by marketing medium type, which could be useful when analyzing web app traffic.

> **Note**
>
> Follow the **multi-dimensional metrics** best practices when enriching with custom tags. Too many tags, or tags with an unbound range cause a large combination of tags. Collection tools have a limit on how many combinations they support for a counter and may start filtering results out to avoid excessive memory usage.

Create custom metrics

Metrics are created using APIs in the System.Diagnostics.Metrics namespace. See Create custom metrics for information on creating custom metrics.

Creating metrics in ASP.NET Core apps with `IMeterFactory`

We recommended creating Meter instances in ASP.NET Core apps with IMeterFactory.

ASP.NET Core registers IMeterFactory in dependency injection (DI) by default. The meter factory integrates metrics with DI, making isolating and collecting metrics easy. `IMeterFactory` is especially useful for testing. It allows for multiple tests to run side-by-side and only collecting metrics values that are recorded in a test.

To use `IMeterFactory` in an app, create a type that uses `IMeterFactory` to create the app's custom metrics:

C#

```
public class ContosoMetrics
{
    private readonly Counter<int> _productSoldCounter;

    public ContosoMetrics(IMeterFactory meterFactory)
    {
        var meter = meterFactory.Create("Contoso.Web");
        _productSoldCounter = meter.CreateCounter<int>
("contoso.product.sold");
    }
```

```
    public void ProductSold(string productName, int quantity)
    {
        _productSoldCounter.Add(quantity,
            new KeyValuePair<string, object?>("contoso.product.name",
productName));
    }
}
```

Register the metrics type with DI in `Program.cs`:

C#

```
var builder = WebApplication.CreateBuilder(args);
builder.Services.AddSingleton<ContosoMetrics>();
```

Inject the metrics type and record values where needed. Because the metrics type is registered in DI it can be use with MVC controllers, minimal APIs, or any other type that is created by DI:

C#

```
app.MapPost("/complete-sale", (SaleModel model, ContosoMetrics metrics) =>
{
    // ... business logic such as saving the sale to a database ...

    metrics.ProductSold(model.ProductName, model.QuantitySold);
});
```

To monitor the "Contoso.Web" meter, use the following dotnet-counters command.

.NET CLI

```
dotnet-counters monitor -n WebMetric --counters Contoso.Web
```

Output similar to the following is displayed:

.NET CLI

```
Press p to pause, r to resume, q to quit.
    Status: Running

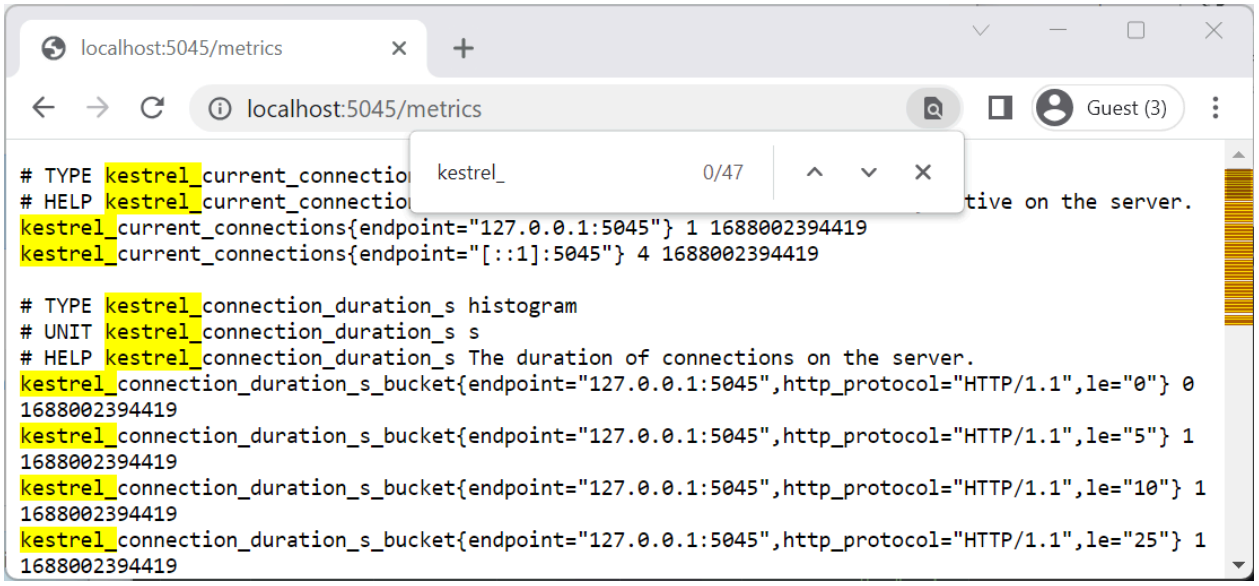
[Contoso.Web]
    contoso.product.sold (Count / 1 sec)
        contoso.product.name=Eggs            12
        contoso.product.name=Milk            0
```

View metrics in Grafana with OpenTelemetry and Prometheus

Overview

OpenTelemetry:

- Is a vendor-neutral open-source project supported by the Cloud Native Computing Foundation.
- Standardizes generating and collecting telemetry for cloud-native software.
- Works with .NET using the .NET metric APIs.
- Is endorsed by Azure Monitor and many APM vendors.



This tutorial shows one of the integrations available for OpenTelemetry metrics using the OSS Prometheus and Grafana projects. The metrics data flow:

1. The ASP.NET Core metric APIs record measurements from the example app.
2. The OpenTelemetry .NET library running in the app aggregates the measurements.
3. The Prometheus exporter library makes the aggregated data available via an HTTP metrics endpoint. 'Exporter' is what OpenTelemetry calls the libraries that transmit telemetry to vendor-specific backends.
4. A Prometheus server:
    - Polls the metrics endpoint
    - Reads the data
    - Stores the data in a database for long-term persistence. Prometheus refers to reading and storing data as *scraping* an endpoint.
    - Can run on a different machine
5. The Grafana server:
    - Queries the data stored in Prometheus and displays it on a web-based monitoring dashboard.
    - Can run on a different machine.

View metrics from sample app

Navigate to the sample app. The browser displays `Hello OpenTelemetry! ticks: <3digits>` where `3digits` are the last 3 digits of the current DateTime.Ticks.

Append `/metrics` to the URL to view the metrics endpoint. The browser displays the metrics being collected:

Set up and configure Prometheus

Follow the Prometheus first steps to set up a Prometheus server and confirm it's working.

Modify the *prometheus.yml* configuration file so that Prometheus scrapes the metrics endpoint that the example app is exposing. Add the following highlighted text in the `scrape_configs` section:

YAML

```yaml
# my global config
global:
  scrape_interval: 15s # Set the scrape interval to every 15 seconds.
Default is every 1 minute.
  evaluation_interval: 15s # Evaluate rules every 15 seconds. The default is
every 1 minute.
  # scrape_timeout is set to the global default (10s).

# Alertmanager configuration
alerting:
  alertmanagers:
    - static_configs:
        - targets:
          # - alertmanager:9093

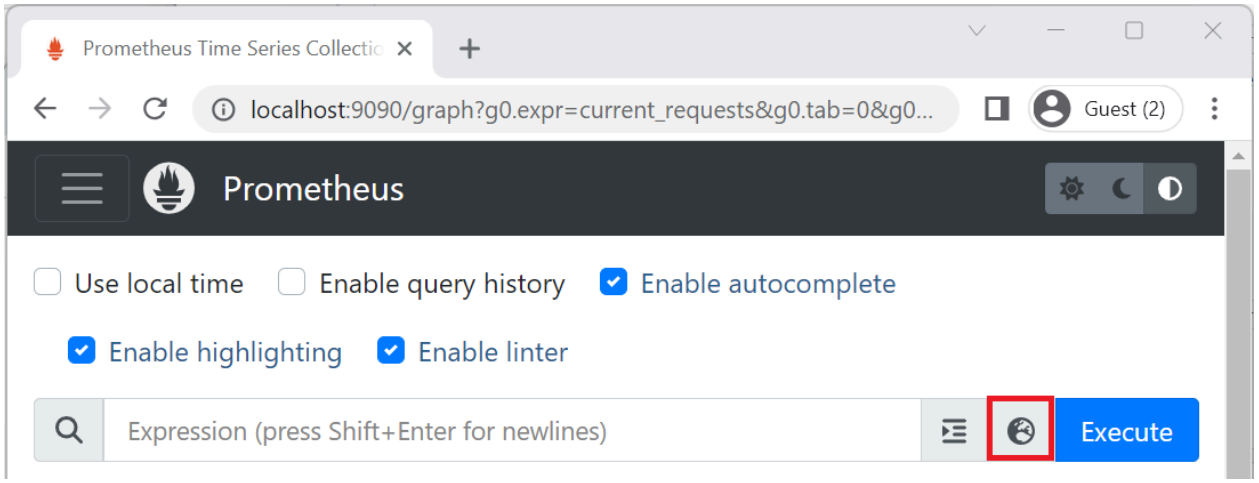
# Load rules once and periodically evaluate them according to the global
'evaluation_interval'.
rule_files:
  # - "first_rules.yml"
  # - "second_rules.yml"
```

```
# A scrape configuration containing exactly one endpoint to scrape:
# Here it's Prometheus itself.
scrape_configs:
  # The job name is added as a label `job=<job_name>` to any timeseries
scraped from this config.
  - job_name: "prometheus"

    # metrics_path defaults to '/metrics'
    # scheme defaults to 'http'.

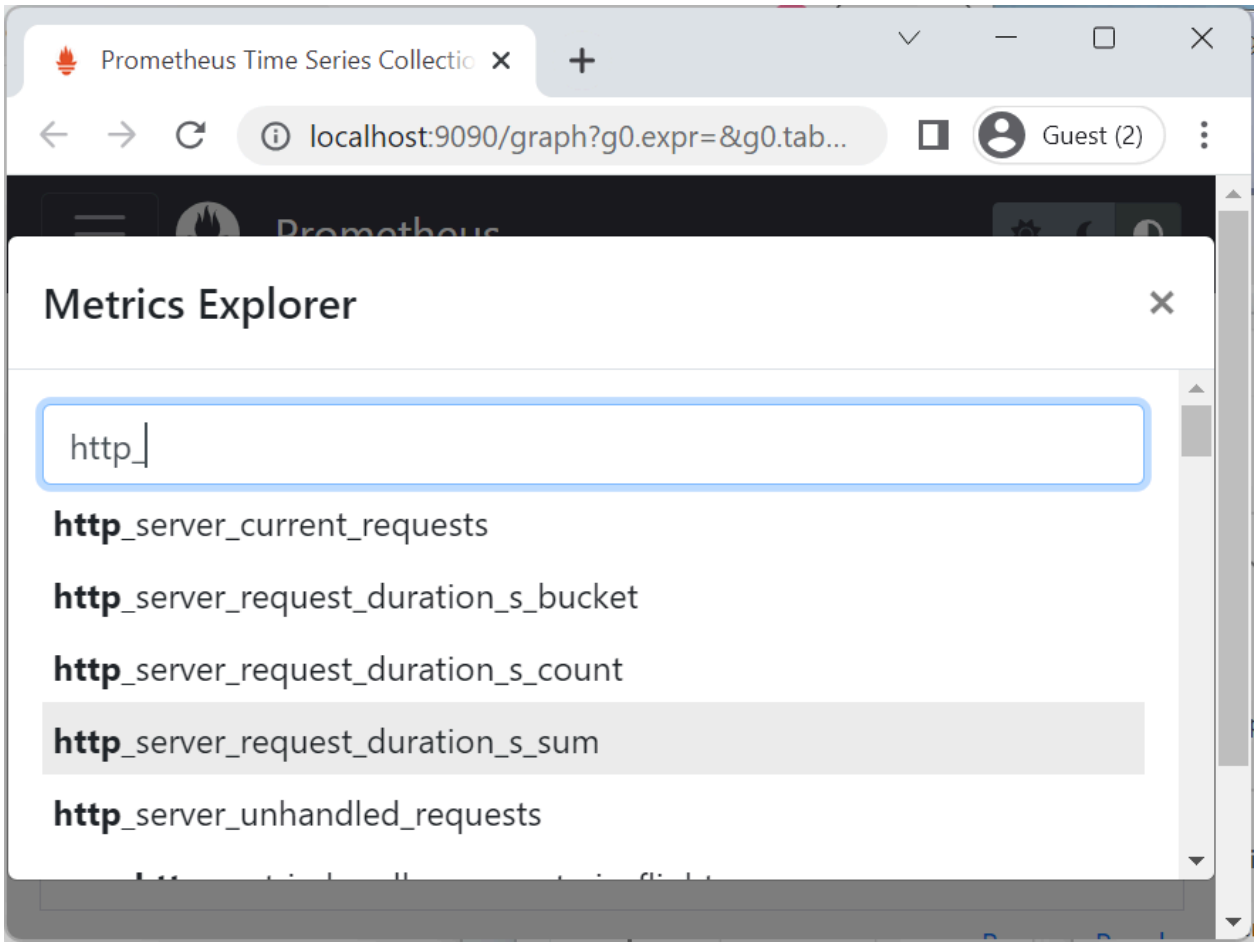
    static_configs:
      - targets: ["localhost:9090"]

  - job_name: 'MyASPNETApp'
    scrape_interval: 5s # Poll every 5 seconds for a more responsive demo.
    static_configs:
      - targets: ["localhost:5045"]  ## Enter the HTTP port number of the
demo app.
```

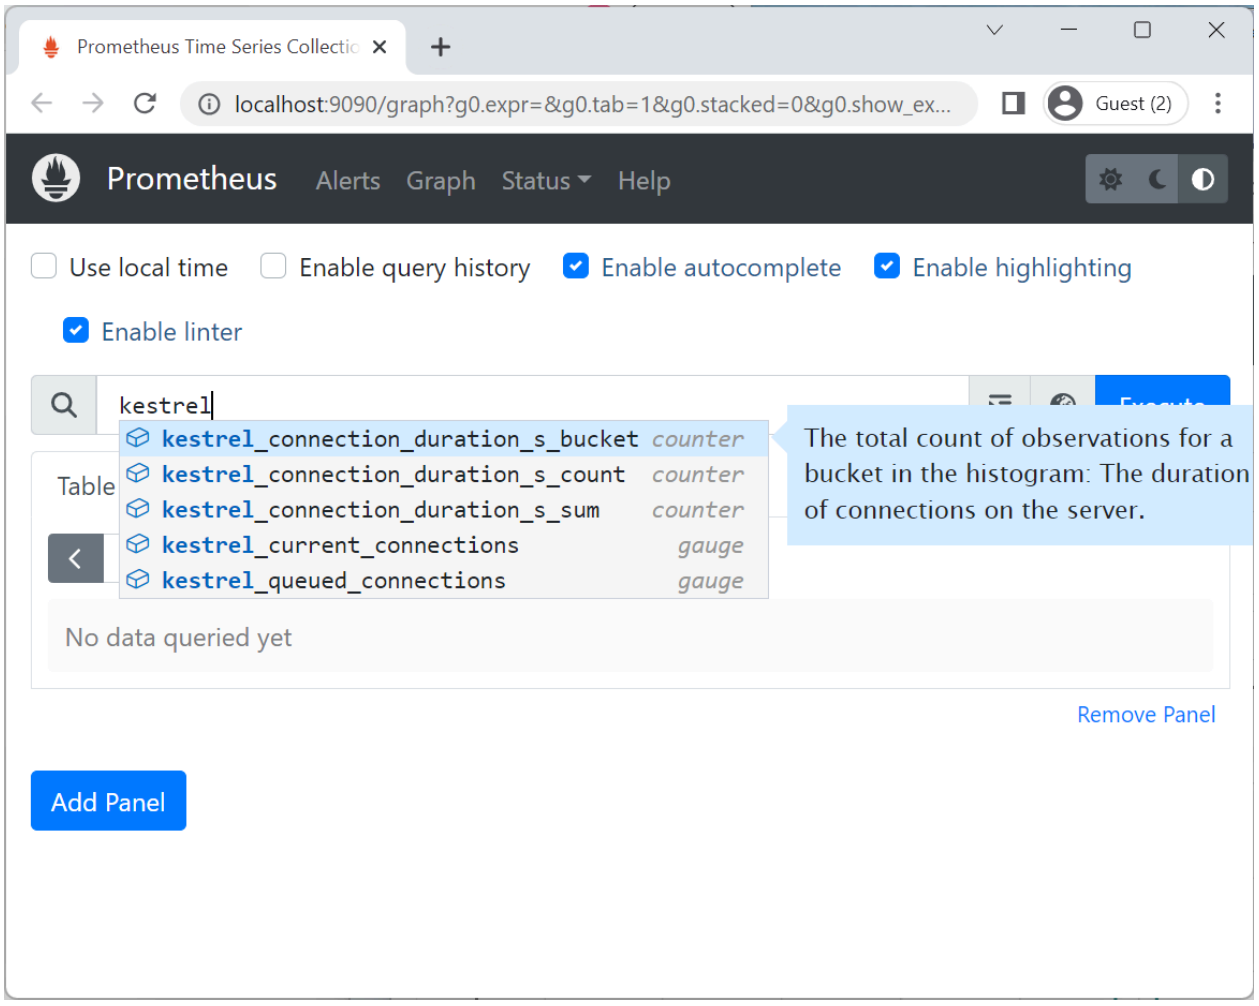


In the preceding highlighted YAML, replace `5045` with the port number that the example app is running on.

Start Prometheus

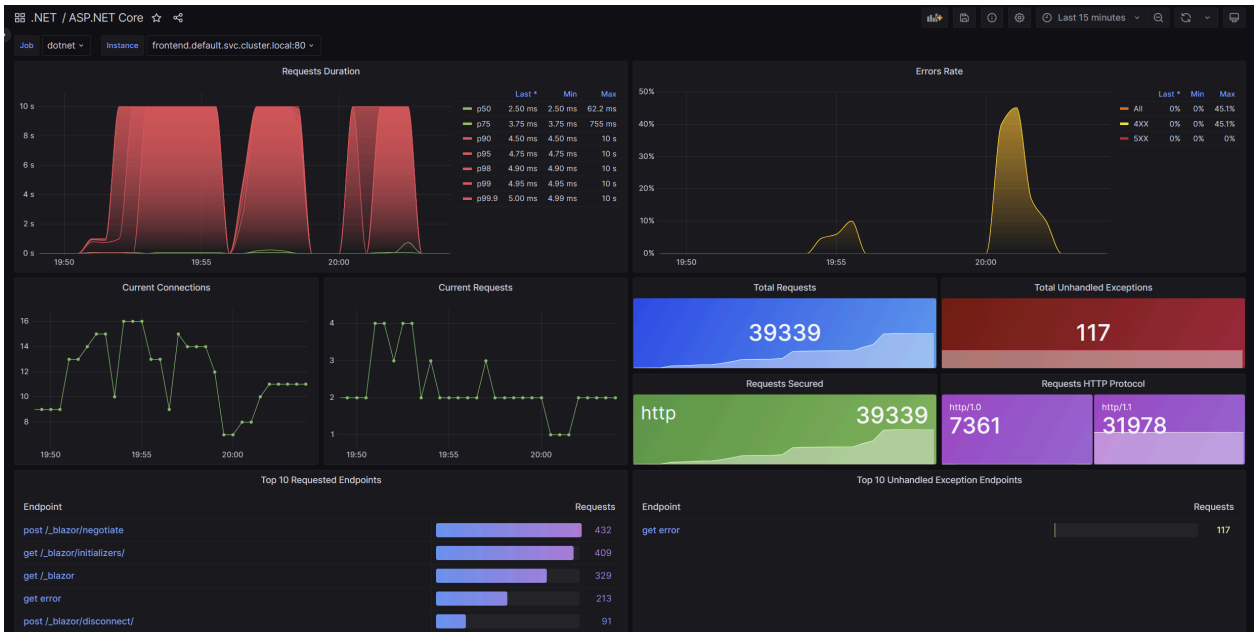


1. Reload the configuration or restart the Prometheus server.
2. Confirm that OpenTelemetryTest is in the UP state in the **Status** > **Targets** page of the Prometheus web portal.



Select the **Open metric explorer** icon to see available metrics:

Enter counter category such as `http_` in the **Expression** input box to see the available metrics:



Alternatively, enter counter category such as `kestrel` in the **Expression** input box to see the available metrics:

Show metrics on a Grafana dashboard

- Follow the installation instructions to install Grafana and connect it to a Prometheus data source.
- Follow Creating a Prometheus graph. Alternatively, pre-built dashboards for .NET metrics are available to download at .NET team dashboards @ grafana.com. Downloaded dashboard JSON can be imported into Grafana.

Test metrics in ASP.NET Core apps

It's possible to test metrics in ASP.NET Core apps. One way to do that is collect and assert metrics values in ASP.NET Core integration tests using MetricCollector<T>.

C#

```
public class BasicTests : IClassFixture<WebApplicationFactory<Program>>
{
    private readonly WebApplicationFactory<Program> _factory;
    public BasicTests(WebApplicationFactory<Program> factory) => _factory =
factory;

    [Fact]
    public async Task Get_RequestCounterIncreased()
    {
        // Arrange
        var client = _factory.CreateClient();
        var meterFactory =
_factory.Services.GetRequiredService<IMeterFactory>();
        var collector = new MetricCollector<double>(meterFactory,
            "Microsoft.AspNetCore.Hosting", "http.server.request.duration");

        // Act
        var response = await client.GetAsync("/");

        // Assert
        Assert.Contains("Hello OpenTelemetry!", await
response.Content.ReadAsStringAsync());

        await collector.WaitForMeasurementsAsync(minCount:
1).WaitAsync(TimeSpan.FromSeconds(5));
        Assert.Collection(collector.GetMeasurementSnapshot(),
            measurement =>
```

```
            {
                Assert.Equal("http", measurement.Tags["url.scheme"]);
                Assert.Equal("GET",
measurement.Tags["http.request.method"]);
                Assert.Equal("/", measurement.Tags["http.route"]);
            });
    }
}
```

The proceeding test:

- Bootstraps a web app in memory with WebApplicationFactory<TEntryPoint>. `Program` in the factory's generic argument specifies the web app.
- Collects metrics values with MetricCollector<T>
  - Requires a package reference to `Microsoft.Extensions.Diagnostics.Testing`
  - The `MetricCollector<T>` is created using the web app's IMeterFactory. This allows the collector to only report metrics values recorded by test.
  - Includes the meter name, `Microsoft.AspNetCore.Hosting`, and counter name, `http.server.request.duration` to collect.
- Makes an HTTP request to the web app.
- Asserts the test using results from the metrics collector.

ASP.NET Core meters and counters

See ASP.NET Core metrics for a list of ASP.NET Core meters and counters.

ASP.NET Core metrics

Article • 02/05/2024

This article describes the metrics built-in for ASP.NET Core produced using the System.Diagnostics.Metrics API. For a listing of metrics based on the older EventCounters API, see here.

> **Tip**
>
> For more information about how to collect, report, enrich, and test ASP.NET Core metrics, see Using ASP.NET Core metrics.

`Microsoft.AspNetCore.Hosting`

The `Microsoft.AspNetCore.Hosting` metrics report high-level information about HTTP requests received by ASP.NET Core:

- http.server.request.duration
- http.server.active_requests

Metric: `http.server.request.duration`

Expand table

Name	Instrument Type	Unit (UCUM)	Description
http.server.request.duration	Histogram	`s`	Measures the duration of inbound HTTP requests.

Expand table

Attribute	Type	Description	Examples	Presence
`http.route`	string	The matched route.	`{controller}/{action}/{id?}`	If it's available.
`error.type`	string	Describes a class of error the operation ended with.	`timeout`; `name_resolution_error`; `500`	If request has ended with an error.
`http.request.method`	string	HTTP request method.	`GET`; `POST`; `HEAD`	Always
`http.response.status_code`	int	HTTP response status code.	`200`	If one was sent.
`network.protocol.version`	string	Version of the protocol specified in `network.protocol.name`.	`3.1.1`	Always

Attribute	Type	Description	Examples	Presence
`url.scheme`	string	The URI scheme component identifying the used protocol.	`http`; `https`	Always
`aspnetcore.request.is_unhandled`	Boolean	True when the request wasn't handled by the application pipeline.	`true`	If the request was unhandled.

The time used to handle an inbound HTTP request as measured at the hosting layer of ASP.NET Core. The time measurement starts once the underlying web host has:

- Sufficiently parsed the HTTP request headers on the inbound network stream to identify the new request.
- Initialized the context data structures such as the HttpContext.

The time ends when:

- The ASP.NET Core handler pipeline is finished executing.
- All response data has been sent.
- The context data structures for the request are being disposed.

When using OpenTelemetry, the default buckets for this metric are set to [0.005, 0.01, 0.025, 0.05, 0.075, 0.1, 0.25, 0.5, 0.75, 1, 2.5, 5, 7.5, 10].

Available starting in: .NET 8.0.

Metric: `http.server.active_requests`

Expand table

Name	Instrument Type	Unit (UCUM)	Description
http.server.active_requests	UpDownCounter	`{request}`	Measures the number of concurrent HTTP requests that are currently in-flight.

Expand table

Attribute	Type	Description	Examples	Presence
`http.request.method`	string	HTTP request method. [1]	`GET`; `POST`; `HEAD`	Always
`url.scheme`	string	The URI scheme component identifying the used protocol.	`http`; `https`	Always

Available starting in: .NET 8.0.

`Microsoft.AspNetCore.Routing`

The `Microsoft.AspNetCore.Routing` metrics report information about routing HTTP requests to ASP.NET Core endpoints:

- aspnetcore.routing.match_attempts

Metric: `aspnetcore.routing.match_attempts`

Expand table

Name	Instrument Type	Unit (UCUM)	Description
aspnetcore.routing.match_attempts	Counter	`{match_attempt}`	Number of requests that were attempted to be matched to an endpoint.

Expand table

Attribute	Type	Description	Examples	Presence
`aspnetcore.routing.match_status`	string	Match result	`success`; `failure`	Always
`aspnetcore.routing.is_fallback_route`	boolean	A value that indicates whether the matched route is a fallback route.	`True`	If a route was successfully matched.
`http.route`	string	The matched route	`{controller}/{action}/{id?}`	If a route was successfully matched.

Available starting in: .NET 8.0.

`Microsoft.AspNetCore.Diagnostics`

The `Microsoft.AspNetCore.Diagnostics` metrics report diagnostics information from ASP.NET Core error handling middleware:

- aspnetcore.diagnostics.exceptions

Metric: `aspnetcore.diagnostics.exceptions`

Expand table

Name	Instrument Type	Unit (UCUM)	Description
aspnetcore.diagnostics.exceptions	Counter	`{exception}`	Number of exceptions caught by exception handling middleware.

Expand table

Attribute	Type	Description	Examples	Presence
`aspnetcore.diagnostics.exception.result`	string	ASP.NET Core exception middleware handling result	`handled`; `unhandled`	Always
`aspnetcore.diagnostics.handler.type`	string	Full type name of the IExceptionHandler implementation that handled the exception.	`Contoso.MyHandler`	If the exception was handled by this handler.
`exception.type`	string	The full name of exception type.	`System.OperationCanceledException`; `Contoso.MyException`	Always

Available starting in: .NET 8.0.

`Microsoft.AspNetCore.RateLimiting`

The `Microsoft.AspNetCore.RateLimiting` metrics report rate limiting information from ASP.NET Core rate-limiting middleware:

- aspnetcore.rate_limiting.active_request_leases
- aspnetcore.rate_limiting.request_lease.duration
- aspnetcore.rate_limiting.queued_requests
- aspnetcore.rate_limiting.request.time_in_queue
- aspnetcore.rate_limiting.requests

Metric: `aspnetcore.rate_limiting.active_request_leases`

Expand table

Name	Instrument Type	Unit (UCUM)	Description
aspnetcore.rate_limiting.active_request_leases	UpDownCounter	`{request}`	Number of requests that are currently active on the server that hold a rate limiting lease.

Expand table

Attribute	Type	Description	Examples	Presence
`aspnetcore.rate_limiting.policy`	string	Rate limiting policy name.	`fixed`; `sliding`; `token`	If the matched endpoint for the request had a rate-limiting policy.

Available starting in: .NET 8.0.

Metric: `aspnetcore.rate_limiting.request_lease.duration`

Expand table

Name	Instrument Type	Unit (UCUM)	Description
aspnetcore.rate_limiting.request_lease.duration	Histogram	`s`	The duration of the rate limiting lease held by requests on the server.

Expand table

Attribute	Type	Description	Examples	Presence
`aspnetcore.rate_limiting.policy`	string	Rate limiting policy name.	`fixed`; `sliding`; `token`	If the matched endpoint for the request had a rate-limiting policy.

Available starting in: .NET 8.0.

Metric: `aspnetcore.rate_limiting.queued_requests`

Expand table

Name	Instrument Type	Unit (UCUM)	Description
aspnetcore.rate_limiting.queued_requests	UpDownCounter	`{request}`	Number of requests that are currently queued waiting to acquire a rate limiting lease.

Expand table

Attribute	Type	Description	Examples	Presence
`aspnetcore.rate_limiting.policy`	string	Rate limiting policy name.	`fixed`; `sliding`; `token`	If the matched endpoint for the request had a rate-limiting policy.

Available starting in: .NET 8.0.

Metric: `aspnetcore.rate_limiting.request.time_in_queue`

Expand table

Name	Instrument Type	Unit (UCUM)	Description
aspnetcore.rate_limiting.request.time_in_queue	Histogram	`s`	The time a request spent in a queue waiting to acquire a rate limiting lease.

Expand table

Attribute	Type	Description	Examples	Presence
`aspnetcore.rate_limiting.policy`	string	Rate limiting policy name.	`fixed`; `sliding`; `token`	If the matched endpoint for the request had a rate-limiting policy.
`aspnetcore.rate_limiting.result`	string	The rate limiting result shows whether lease was acquired or contains a rejection reason.	`acquired`; `request_canceled`	Always

Available starting in: .NET 8.0.

Metric: `aspnetcore.rate_limiting.requests`

Expand table

Name	Instrument Type	Unit (UCUM)	Description
aspnetcore.rate_limiting.requests	Counter	`{request}`	Number of requests that tried to acquire a rate limiting lease.

Expand table

Attribute	Type	Description	Examples	Presence
`aspnetcore.rate_limiting.policy`	string	Rate limiting policy name.	`fixed`; `sliding`; `token`	If the matched endpoint for the request had a rate-limiting policy.
`aspnetcore.rate_limiting.result`	string	The rate limiting result shows whether lease was acquired or contains a rejection reason.	`acquired`; `request_canceled`	Always

Available starting in: .NET 8.0.

`Microsoft.AspNetCore.HeaderParsing`

The `Microsoft.AspNetCore.HeaderParsing` metrics report information about ASP.NET Core header parsing:

- aspnetcore.header_parsing.parse_errors
- aspnetcore.header_parsing.cache_accesses

Metric: `aspnetcore.header_parsing.parse_errors`

Expand table

Name	Instrument Type	Unit (UCUM)	Description
`aspnetcore.header_parsing.parse_errors`	Counter	`{parse_error}`	Number of errors that occurred when parsing HTTP request headers.

Expand table

Attribute	Type	Description	Examples	Presence
`aspnetcore.header_parsing.header.name`	string	The header name.	`Content-Type`	Always
`error.type`	string	The error message.	`Unable to parse media type value.`	Always

Available starting in: .NET 8.0.

Metric: `aspnetcore.header_parsing.cache_accesses`

The metric is emitted only for HTTP request header parsers that support caching.

Expand table

Name	Instrument Type	Unit (UCUM)	Description
`aspnetcore.header_parsing.cache_accesses`	Counter	`{cache_access}`	Number of times a cache storing parsed header values was accessed.

Expand table

Attribute	Type	Description	Examples	Presence
`aspnetcore.header_parsing.header.name`	string	The header name.	`Content-Type`	Always

Attribute	Type	Description	Examples	Presence
`aspnetcore.header_parsing.cache_access.type`	string	A value indicating whether the header's value was found in the cache or not.	`Hit`; `Miss`	Always

Available starting in: .NET 8.0.

`Microsoft.AspNetCore.Server.Kestrel`

The `Microsoft.AspNetCore.Server.Kestrel` metrics report HTTP connection information from ASP.NET Core Kestrel web server:

- kestrel.active_connections
- kestrel.connection.duration
- kestrel.rejected_connections
- kestrel.queued_connections
- kestrel.queued_requests
- kestrel.upgraded_connections
- kestrel.tls_handshake.duration
- kestrel.active_tls_handshakes

Metric: `kestrel.active_connections`

Expand table

Name	Instrument Type	Unit (UCUM)	Description
kestrel.active_connections	UpDownCounter	`{connection}`	Number of connections that are currently active on the server.

Expand table

Attribute	Type	Description	Examples	Presence
`network.transport`	string	OSI transport layer or inter-process communication method.	`tcp`; `unix`	Always
`network.type`	string	OSI network layer or non-OSI equivalent.	`ipv4`; `ipv6`	If the transport is `tcp` or `udp`.
`server.address`	string	Server address domain name if available without reverse DNS lookup; otherwise, IP address or Unix domain socket name.	`example.com`	Always
`server.port`	int	Server port number	`80`; `8080`; `443`	If the transport is `tcp` or `udp`.

Available starting in: .NET 8.0.

Metric: `kestrel.connection.duration`

Expand table

Name	Instrument Type	Unit (UCUM)	Description
kestrel.connection.duration	Histogram	`s`	The duration of connections on the server.

Expand table

Attribute	Type	Description	Examples	Presence
`error.type`	string	The full name of exception type.	`System.OperationCanceledException`; `Contoso.MyException`	If an exception was thrown.
`network.protocol.name`	string	OSI application layer or non-OSI equivalent.	`http`; `web_sockets`	Always
`network.protocol.version`	string	Version of the protocol specified in `network.protocol.name`.	`1.1`; `2`	Always
`network.transport`	string	OSI transport layer or inter-process communication method.	`tcp`; `unix`	Always
`network.type`	string	OSI network layer or non-OSI equivalent.	`ipv4`; `ipv6`	If the transport is `tcp` or `udp`.
`server.address`	string	Server address domain name if available without reverse DNS lookup; otherwise, IP address or Unix domain socket name.	`example.com`	Always
`server.port`	int	Server port number	`80`; `8080`; `443`	If the transport is `tcp` or `udp`.
`tls.protocol.version`	string	TLS protocol version.	`1.2`; `1.3`	If the connection is secured with TLS.

As this metric is tracking the connection duration, and ideally http connections are used for multiple requests, the buckets should be longer than those used for request durations. For example, using [0.01, 0.02, 0.05, 0.1, 0.2, 0.5, 1, 2, 5, 10, 30, 60, 120, 300] provides an upper bucket of 5 mins.

Available starting in: .NET 8.0.

Metric: `kestrel.rejected_connections`

Expand table

Name	Instrument Type	Unit (UCUM)	Description
kestrel.rejected_connections	Counter	`{connection}`	Number of connections rejected by the server.

Expand table

Attribute	Type	Description	Examples	Presence
`network.transport`	string	OSI transport layer or inter-process communication method.	`tcp`; `unix`	Always
`network.type`	string	OSI network layer or non-OSI equivalent.	`ipv4`; `ipv6`	If the transport is `tcp` or `udp`.
`server.address`	string	Server address domain name if available without reverse DNS lookup; otherwise, IP address or Unix domain socket name.	`example.com`	Always
`server.port`	int	Server port number	`80`; `8080`; `443`	If the transport is `tcp` or `udp`.

Connections are rejected when the currently active count exceeds the value configured with `MaxConcurrentConnections`.

Available starting in: .NET 8.0.

Metric: `kestrel.queued_connections`

Expand table

Name	Instrument Type	Unit (UCUM)	Description
kestrel.queued_connections	UpDownCounter	`{connection}`	Number of connections that are currently queued and are waiting to start.

Expand table

Attribute	Type	Description	Examples	Presence
`network.transport`	string	OSI transport layer or inter-process communication method.	`tcp`; `unix`	Always
`network.type`	string	OSI network layer or non-OSI equivalent.	`ipv4`; `ipv6`	If the transport is `tcp` or `udp`.
`server.address`	string	Server address domain name if available without reverse DNS lookup; otherwise, IP address or Unix	`example.com`	Always

Attribute	Type	Description	Examples	Presence
		domain socket name.		
`server.port`	int	Server port number	`80`; `8080`; `443`	If the transport is `tcp` or `udp`.

Available starting in: .NET 8.0.

Metric: `kestrel.queued_requests`

Expand table

Name	Instrument Type	Unit (UCUM)	Description
kestrel.queued_requests	UpDownCounter	`{request}`	Number of HTTP requests on multiplexed connections (HTTP/2 and HTTP/3) that are currently queued and are waiting to start.

Expand table

Attribute	Type	Description	Examples	Presence
`network.protocol.name`	string	OSI application layer or non-OSI equivalent.	`http`; `web_sockets`	Always
`network.protocol.version`	string	Version of the protocol specified in `network.protocol.name`.	`1.1`; `2`	Always
`network.transport`	string	OSI transport layer or inter-process communication method.	`tcp`; `unix`	Always
`network.type`	string	OSI network layer or non-OSI equivalent.	`ipv4`; `ipv6`	If the transport is `tcp` or `udp`.
`server.address`	string	Server address domain name if available without reverse DNS lookup; otherwise, IP address or Unix domain socket name.	`example.com`	Always
`server.port`	int	Server port number	`80`; `8080`; `443`	If the transport is `tcp` or `udp`.

Available starting in: .NET 8.0.

Metric: `kestrel.upgraded_connections`

Expand table

Name	Instrument Type	Unit (UCUM)	Description
kestrel.upgraded_connections	UpDownCounter	`{connection}`	Number of connections that are currently upgraded (WebSockets).

Expand table

Attribute	Type	Description	Examples	Presence
`network.transport`	string	OSI transport layer or inter-process communication method.	`tcp`; `unix`	Always
`network.type`	string	OSI network layer or non-OSI equivalent.	`ipv4`; `ipv6`	If the transport is `tcp` or `udp`.
`server.address`	string	Server address domain name if available without reverse DNS lookup; otherwise, IP address or Unix domain socket name.	`example.com`	Always
`server.port`	int	Server port number	`80`; `8080`; `443`	If the transport is `tcp` or `udp`.

The counter only tracks HTTP/1.1 connections.

Available starting in: .NET 8.0.

Metric: `kestrel.tls_handshake.duration`

Expand table

Name	Instrument Type	Unit (UCUM)	Description
kestrel.tls_handshake.duration	Histogram	`s`	The duration of TLS handshakes on the server.

Expand table

Attribute	Type	Description	Examples	Presence
`error.type`	string	The full name of exception type.	`System.OperationCanceledException`; `Contoso.MyException`	If an exception was thrown.
`network.transport`	string	OSI transport layer or inter-process communication method.	`tcp`; `unix`	Always
`network.type`	string	OSI network layer or non-OSI equivalent.	`ipv4`; `ipv6`	If the transport is `tcp` or `udp`.

Attribute	Type	Description	Examples	Presence
`server.address`	string	Server address domain name if available without reverse DNS lookup; otherwise, IP address or Unix domain socket name.	`example.com`	Always
`server.port`	int	Server port number	`80`; `8080`; `443`	If the transport is `tcp` or `udp`.
`tls.protocol.version`	string	TLS protocol version.	`1.2`; `1.3`	If the connection is secured with TLS.

When using OpenTelemetry, the default buckets for this metic are set to [0.005, 0.01, 0.025, 0.05, 0.075, 0.1, 0.25, 0.5, 0.75, 1, 2.5, 5, 7.5, 10].

Available starting in: .NET 8.0.

Metric: `kestrel.active_tls_handshakes`

Expand table

Name	Instrument Type	Unit (UCUM)	Description
kestrel.active_tls_handshakes	UpDownCounter	`{handshake}`	Number of TLS handshakes that are currently in progress on the server.

Expand table

Attribute	Type	Description	Examples	Presence
`network.transport`	string	OSI transport layer or inter-process communication method.	`tcp`; `unix`	Always
`network.type`	string	OSI network layer or non-OSI equivalent.	`ipv4`; `ipv6`	If the transport is `tcp` or `udp`.
`server.address`	string	Server address domain name if available without reverse DNS lookup; otherwise, IP address or Unix domain socket name.	`example.com`	Always
`server.port`	int	Server port number	`80`; `8080`; `443`	If the transport is `tcp` or `udp`.

Available starting in: .NET 8.0.

`Microsoft.AspNetCore.Http.Connections`

The `Microsoft.AspNetCore.Http.Connections` metrics report connection information from ASP.NET Core SignalR:

- signalr.server.connection.duration
- signalr.server.active_connections

Metric: `signalr.server.connection.duration`

Expand table

Name	Instrument Type	Unit (UCUM)	Description
signalr.server.connection.duration	Histogram	`s`	The duration of connections on the server.

Expand table

Attribute	Type	Description	Examples	Presence
`signalr.connection.status`	string	SignalR HTTP connection closure status.	`app_shutdown`; `timeout`	Always
`signalr.transport`	string	SignalR transport type	`web_sockets`; `long_polling`	Always

Available starting in: .NET 8.0.

Expand table

Value	Description
`normal_closure`	The connection was closed normally.
`timeout`	The connection was closed due to a timeout.
`app_shutdown`	The connection was closed because the app is shutting down.

`signalr.transport` is one of the following:

Expand table

Value	Protocol
`server_sent_events`	server-sent events
`long_polling`	Long Polling
`web_sockets`	WebSocket

As this metric is tracking the connection duration, and ideally SignalR connections are durable, the buckets should be longer than those used for request durations. For example, using [0, 0.01, 0.02, 0.05,

0.1, 0.2, 0.5, 1, 2, 5, 10, 30, 60, 120, 300] provides an upper bucket of 5 mins.

Available starting in: .NET 8.0.

Metric: `signalr.server.active_connections`

Expand table

Name	Instrument Type	Unit (UCUM)	Description
signalr.server.active_connections	UpDownCounter	`{connection}`	Number of connections that are currently active on the server.

Expand table

Attribute	Type	Description	Examples	Presence
`signalr.connection.status`	string	SignalR HTTP connection closure status.	`app_shutdown`; `timeout`	Always
`signalr.transport`	string	SignalR transport type	`web_sockets`; `long_polling`	Always

Available starting in: .NET 8.0.

Use HttpContext in ASP.NET Core

Article • 10/07/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

HttpContext encapsulates all information about an individual HTTP request and response. An `HttpContext` instance is initialized when an HTTP request is received. The `HttpContext` instance is accessible by middleware and app frameworks such as Web API controllers, Razor Pages, SignalR, gRPC, and more.

For more information about accessing the `HttpContext`, see Access HttpContext in ASP.NET Core.

`HttpRequest`

HttpContext.Request provides access to HttpRequest. `HttpRequest` has information about the incoming HTTP request, and it's initialized when an HTTP request is received by the server. `HttpRequest` isn't read-only, and middleware can change request values in the middleware pipeline.

Commonly used members on `HttpRequest` include:

Expand table

Property	Description	Example
HttpRequest.Path	The request path.	`/en/article/getstarted`
HttpRequest.Method	The request method.	`GET`
HttpRequest.Headers	A collection of request headers.	`user-agent=Edge` `x-custom-header=MyValue`
HttpRequest.RouteValues	A collection of route values. The collection is set when the request is	`language=en` `article=getstarted`

Property	Description	Example
	matched to a route.	
HttpRequest.Query	A collection of query values parsed from QueryString.	`filter=hello` `page=1`
HttpRequest.ReadFormAsync()	A method that reads the request body as a form and returns a form values collection. For information about why `ReadFormAsync` should be used to access form data, see Prefer ReadFormAsync over Request.Form.	`email=user@contoso.com`
HttpRequest.Body	A Stream for reading the request body.	UTF-8 JSON payload

Get request headers

HttpRequest.Headers provides access to the request headers sent with the HTTP request. There are two ways to access headers using this collection:

- Provide the header name to the indexer on the header collection. The header name isn't case-sensitive. The indexer can access any header value.
- The header collection also has properties for getting and setting commonly used HTTP headers. The properties provide a fast, IntelliSense driven way to access headers.

C#

```
var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

app.MapGet("/", (HttpRequest request) =>
{
    var userAgent = request.Headers.UserAgent;
    var customHeader = request.Headers["x-custom-header"];

    return Results.Ok(new { userAgent = userAgent, customHeader =
customHeader });
});

app.Run();
```

For information on efficiently handling headers that appear more than once, see A brief look at StringValues.

Read request body

An HTTP request can include a request body. The request body is data associated with the request, such as the content of an HTML form, UTF-8 JSON payload, or a file.

HttpRequest.Body allows the request body to be read with Stream:

```
C#

var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

app.MapPost("/uploadstream", async (IConfiguration config, HttpContext
context) =>
{
    var filePath = Path.Combine(config["StoredFilesPath"],
Path.GetRandomFileName());

    await using var writeStream = File.Create(filePath);
    await context.Request.Body.CopyToAsync(writeStream);
});

app.Run();
```

`HttpRequest.Body` can be read directly or used with other APIs that accept stream.

> ⓘ Note
>
> Minimal APIs supports binding HttpRequest.Body directly to a Stream parameter.

Enable request body buffering

The request body can only be read once, from beginning to end. Forward-only reading of the request body avoids the overhead of buffering the entire request body and reduces memory usage. However, in some scenarios, there's a need to read the request body multiple times. For example, middleware might need to read the request body and then rewind it so it's available for the endpoint.

The EnableBuffering extension method enables buffering of the HTTP request body and is the recommended way to enable multiple reads. Because a request can be any size, `EnableBuffering` supports options for buffering large request bodies to disk, or rejecting them entirely.

The middleware in the following example:

- Enables multiple reads with `EnableBuffering`. It must be called before reading the request body.
- Reads the request body.
- Rewinds the request body to the start so other middleware or the endpoint can read it.

C#

```
var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

app.Use(async (context, next) =>
{
    context.Request.EnableBuffering();
    await ReadRequestBody(context.Request.Body);
    context.Request.Body.Position = 0;

    await next.Invoke();
});

app.Run();
```

BodyReader

An alternative way to read the request body is to use the HttpRequest.BodyReader property. The `BodyReader` property exposes the request body as a PipeReader. This API is from I/O pipelines, an advanced, high-performance way to read the request body.

The reader directly accesses the request body and manages memory on the caller's behalf. Unlike `HttpRequest.Body`, the reader doesn't copy request data into a buffer. However, a reader is more complicated to use than a stream and should be used with caution.

For information on how to read content from `BodyReader`, see I/O pipelines PipeReader.

`HttpResponse`

HttpContext.Response provides access to HttpResponse. `HttpResponse` is used to set information on the HTTP response sent back to the client.

Commonly used members on `HttpResponse` include:

Expand table

Property	Description	Example
HttpResponse.StatusCode	The response code. Must be set before writing to the response body.	`200`
HttpResponse.ContentType	The response `content-type` header. Must be set before writing to the response body.	`application/json`
HttpResponse.Headers	A collection of response headers. Must be set before writing to the response body.	`server=Kestrel` `x-custom-header=MyValue`
HttpResponse.Body	A Stream for writing the response body.	Generated web page

Set response headers

HttpResponse.Headers provides access to the response headers sent with the HTTP response. There are two ways to access headers using this collection:

- Provide the header name to the indexer on the header collection. The header name isn't case-sensitive. The indexer can access any header value.
- The header collection also has properties for getting and setting commonly used HTTP headers. The properties provide a fast, IntelliSense driven way to access headers.

C#

```
var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

app.MapGet("/", (HttpResponse response) =>
{
    response.Headers.CacheControl = "no-cache";
    response.Headers["x-custom-header"] = "Custom value";

    return Results.File(File.OpenRead("helloworld.txt"));
});

app.Run();
```

An app can't modify headers after the response has started. Once the response starts, the headers are sent to the client. A response is started by flushing the response body or calling HttpResponse.StartAsync(CancellationToken). The HttpResponse.HasStarted property indicates whether the response has started. An error is thrown when attempting to modify headers after the response has started:

> System.InvalidOperationException: Headers are read-only, response has already started.

> **Note**
>
> Unless response buffering is enabled, all write operations (for example, WriteAsync) flush the response body internally and mark the response as started. Response buffering is disabled by default.

Write response body

An HTTP response can include a response body. The response body is data associated with the response, such as generated web page content, UTF-8 JSON payload, or a file.

HttpResponse.Body allows the response body to be written with Stream:

```C#
var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

app.MapPost("/downloadfile", async (IConfiguration config, HttpContext
context) =>
{
    var filePath = Path.Combine(config["StoredFilesPath"],
"helloworld.txt");

    await using var fileStream = File.OpenRead(filePath);
    await fileStream.CopyToAsync(context.Response.Body);
});

app.Run();
```

`HttpResponse.Body` can be written directly or used with other APIs that write to a stream.

BodyWriter

An alternative way to write the response body is to use the HttpResponse.BodyWriter property. The `BodyWriter` property exposes the response body as a PipeWriter. This API is from I/O pipelines, and it's an advanced, high-performance way to write the response.

The writer provides direct access to the response body and manages memory on the caller's behalf. Unlike `HttpResponse.Body`, the write doesn't copy request data into a

buffer. However, a writer is more complicated to use than a stream and writer code should be thoroughly tested.

For information on how to write content to `BodyWriter`, see I/O pipelines PipeWriter.

Set response trailers

HTTP/2 and HTTP/3 support response trailers. Trailers are headers sent with the response after the response body is complete. Because trailers are sent after the response body, trailers can be added to the response at any time.

The following code sets trailers using AppendTrailer:

C#

```
var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

app.MapGet("/", (HttpResponse response) =>
{
    // Write body
    response.WriteAsync("Hello world");

    if (response.SupportsTrailers())
    {
        response.AppendTrailer("trailername", "TrailerValue");
    }
});

app.Run();
```

`RequestAborted`

The HttpContext.RequestAborted cancellation token can be used to notify that the HTTP request has been aborted by the client or server. The cancellation token should be passed to long-running tasks so they can be canceled if the request is aborted. For example, aborting a database query or HTTP request to get data to return in the response.

C#

```
var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

var httpClient = new HttpClient();
app.MapPost("/books/{bookId}", async (int bookId, HttpContext context) =>
```

```
{
    var stream = await httpClient.GetStreamAsync(
        $"http://contoso/books/{bookId}.json", context.RequestAborted);

    // Proxy the response as JSON
    return Results.Stream(stream, "application/json");
});

app.Run();
```

The `RequestAborted` cancellation token doesn't need to be used for request body read operations because reads always throw immediately when the request is aborted. The `RequestAborted` token is also usually unnecessary when writing response bodies, because writes immediately no-op when the request is aborted.

In some cases, passing the `RequestAborted` token to write operations can be a convenient way to force a write loop to exit early with an OperationCanceledException. However, it's typically better to pass the `RequestAborted` token into any asynchronous operations responsible for retrieving the response body content instead.

> ⓘ Note
>
> Minimal APIs supports binding HttpContext.RequestAborted directly to a CancellationToken parameter.

`Abort()`

The HttpContext.Abort() method can be used to abort an HTTP request from the server. Aborting the HTTP request immediately triggers the HttpContext.RequestAborted cancellation token and sends a notification to the client that the server has aborted the request.

The middleware in the following example:

- Adds a custom check for malicious requests.
- Aborts the HTTP request if the request is malicious.

C#

```
var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

app.Use(async (context, next) =>
{
```

```
    if (RequestAppearsMalicious(context.Request))
    {
        // Malicious requests don't even deserve an error response (e.g.
400).
        context.Abort();
        return;
    }

    await next.Invoke();
});

app.Run();
```

User

The HttpContext.User property is used to get or set the user, represented by ClaimsPrincipal, for the request. The ClaimsPrincipal is typically set by ASP.NET Core authentication.

C#

```
var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

app.MapGet("/user/current", [Authorize] async (HttpContext context) =>
{
    var user = await GetUserAsync(context.User.Identity.Name);
    return Results.Ok(user);
});

app.Run();
```

> ⓘ Note
>
> Minimal APIs supports binding HttpContext.User directly to a ClaimsPrincipal parameter.

Features

The HttpContext.Features property provides access to the collection of feature interfaces for the current request. Since the feature collection is mutable even within the context of a request, middleware can be used to modify the collection and add support for additional features. Some advanced features are only available by accessing the associated interface through the feature collection.

The following example:

- Gets IHttpMinRequestBodyDataRateFeature from the features collection.
- Sets MinDataRate to null. This removes the minimum data rate that the request body must be sent by the client for this HTTP request.

```
C#

var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

app.MapGet("/long-running-stream", async (HttpContext context) =>
{
    var feature = context.Features.Get<IHttpMinRequestBodyDataRateFeature>
();
    if (feature != null)
    {
        feature.MinDataRate = null;
    }

    // await and read long-running stream from request body.
    await Task.Yield();
});

app.Run();
```

For more information about using request features and `HttpContext`, see Request Features in ASP.NET Core.

HttpContext isn't thread safe

This article primarily discusses using `HttpContext` in request and response flow from Razor Pages, controllers, middleware, etc. Consider the following when using `HttpContext` outside the request and response flow:

- The `HttpContext` is **NOT** thread safe, accessing it from multiple threads can result in exceptions, data corruption and generally unpredictable results.
- The IHttpContextAccessor interface should be used with caution. As always, the `HttpContext` must ***not*** be captured outside of the request flow.

  `IHttpContextAccessor`:
  - Relies on AsyncLocal<T> which can have a negative performance impact on asynchronous calls.
  - Creates a dependency on "ambient state" which can make testing more difficult.
- IHttpContextAccessor.HttpContext may be `null` if accessed outside of the request flow.

- To access information from `HttpContext` outside the request flow, copy the information inside the request flow. Be careful to copy the actual data and not just references. For example, rather than copying a reference to an `IHeaderDictionary`, copy the relevant header values or copy the entire dictionary key by key before leaving the request flow.
- Don't capture `IHttpContextAccessor.HttpContext` in a constructor.

The following sample logs GitHub branches when requested from the `/branch` endpoint:

C#

```
using System.Text.Json;
using HttpContextInBackgroundThread;
using Microsoft.Net.Http.Headers;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddHttpContextAccessor();
builder.Services.AddHostedService<PeriodicBranchesLoggerService>();

builder.Services.AddHttpClient("GitHub", httpClient =>
{
    httpClient.BaseAddress = new Uri("https://api.github.com/");

    // The GitHub API requires two headers. The Use-Agent header is added
    // dynamically through UserAgentHeaderHandler
    httpClient.DefaultRequestHeaders.Add(
        HeaderNames.Accept, "application/vnd.github.v3+json");
}).AddHttpMessageHandler<UserAgentHeaderHandler>();

builder.Services.AddTransient<UserAgentHeaderHandler>();

var app = builder.Build();

app.MapGet("/", () => "Hello World!");
```

```
app.MapGet("/branches", async (IHttpClientFactory httpClientFactory,
                          HttpContext context, Logger<Program> logger) =>
{
    var httpClient = httpClientFactory.CreateClient("GitHub");
    var httpResponseMessage = await httpClient.GetAsync(
        "repos/dotnet/AspNetCore.Docs/branches");

    if (!httpResponseMessage.IsSuccessStatusCode)
        return Results.BadRequest();

    await using var contentStream =
        await httpResponseMessage.Content.ReadAsStreamAsync();

    var response = await JsonSerializer.DeserializeAsync
        <IEnumerable<GitHubBranch>>(contentStream);

    app.Logger.LogInformation($"/branches request: " +
                              $"{JsonSerializer.Serialize(response)}");

    return Results.Ok(response);
});

app.Run();
```

The GitHub API requires two headers. The `User-Agent` header is added dynamically by the `UserAgentHeaderHandler`:

C#

```
using System.Text.Json;
using HttpContextInBackgroundThread;
using Microsoft.Net.Http.Headers;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddHttpContextAccessor();
builder.Services.AddHostedService<PeriodicBranchesLoggerService>();

builder.Services.AddHttpClient("GitHub", httpClient =>
{
    httpClient.BaseAddress = new Uri("https://api.github.com/");

    // The GitHub API requires two headers. The Use-Agent header is added
    // dynamically through UserAgentHeaderHandler
    httpClient.DefaultRequestHeaders.Add(
        HeaderNames.Accept, "application/vnd.github.v3+json");
}).AddHttpMessageHandler<UserAgentHeaderHandler>();

builder.Services.AddTransient<UserAgentHeaderHandler>();

var app = builder.Build();

app.MapGet("/", () => "Hello World!");
```

```
app.MapGet("/branches", async (IHttpClientFactory httpClientFactory,
                          HttpContext context, Logger<Program> logger) =>
{
    var httpClient = httpClientFactory.CreateClient("GitHub");
    var httpResponseMessage = await httpClient.GetAsync(
        "repos/dotnet/AspNetCore.Docs/branches");

    if (!httpResponseMessage.IsSuccessStatusCode)
        return Results.BadRequest();

    await using var contentStream =
        await httpResponseMessage.Content.ReadAsStreamAsync();

    var response = await JsonSerializer.DeserializeAsync
        <IEnumerable<GitHubBranch>>(contentStream);

    app.Logger.LogInformation($"/branches request: " +
                              $"{JsonSerializer.Serialize(response)}");

    return Results.Ok(response);
});

app.Run();
```

The `UserAgentHeaderHandler`:

C#

```
using Microsoft.Net.Http.Headers;

namespace HttpContextInBackgroundThread;

public class UserAgentHeaderHandler : DelegatingHandler
{
    private readonly IHttpContextAccessor _httpContextAccessor;
    private readonly ILogger _logger;

    public UserAgentHeaderHandler(IHttpContextAccessor httpContextAccessor,
                                  ILogger<UserAgentHeaderHandler> logger)
    {
        _httpContextAccessor = httpContextAccessor;
        _logger = logger;
    }

    protected override async Task<HttpResponseMessage>
                                    SendAsync(HttpRequestMessage request,
                                    CancellationToken cancellationToken)
    {
```

```
        var contextRequest = _httpContextAccessor.HttpContext?.Request;
        string? userAgentString = contextRequest?.Headers["user-
agent"].ToString();

        if (string.IsNullOrEmpty(userAgentString))
        {
            userAgentString = "Unknown";
        }

        request.Headers.Add(HeaderNames.UserAgent, userAgentString);
        _logger.LogInformation($"User-Agent: {userAgentString}");

        return await base.SendAsync(request, cancellationToken);
    }
}
```

In the preceding code, when the `HttpContext` is `null`, the `userAgent` string is set to `"Unknown"`. If possible, `HttpContext` should be explicitly passed to the service. Explicitly passing in `HttpContext` data:

- Makes the service API more useable outside the request flow.
- Is better for performance.
- Makes the code easier to understand and reason about than relying on ambient state.

When the service must access `HttpContext`, it should account for the possibility of `HttpContext` being `null` when not called from a request thread.

The application also includes `PeriodicBranchesLoggerService`, which logs the open GitHub branches of the specified repository every 30 seconds:

C#

```
using System.Text.Json;

namespace HttpContextInBackgroundThread;

public class PeriodicBranchesLoggerService : BackgroundService
{
    private readonly IHttpClientFactory _httpClientFactory;
    private readonly ILogger _logger;
    private readonly PeriodicTimer _timer;

    public PeriodicBranchesLoggerService(IHttpClientFactory
httpClientFactory,

ILogger<PeriodicBranchesLoggerService> logger)
    {
        _httpClientFactory = httpClientFactory;
        _logger = logger;
```

```
        _timer = new PeriodicTimer(TimeSpan.FromSeconds(30));
    }

    protected override async Task ExecuteAsync(CancellationToken
stoppingToken)
    {
        while (await _timer.WaitForNextTickAsync(stoppingToken))
        {
            try
            {
                // Cancel sending the request to sync branches if it takes
too long
                // rather than miss sending the next request scheduled 30
seconds from now.
                // Having a single loop prevents this service from sending
an unbounded
                // number of requests simultaneously.
                using var syncTokenSource =
CancellationTokenSource.CreateLinkedTokenSource(stoppingToken);
                syncTokenSource.CancelAfter(TimeSpan.FromSeconds(30));

                var httpClient = _httpClientFactory.CreateClient("GitHub");
                var httpResponseMessage = await
httpClient.GetAsync("repos/dotnet/AspNetCore.Docs/branches",

stoppingToken);

                if (httpResponseMessage.IsSuccessStatusCode)
                {
                    await using var contentStream =
                        await
httpResponseMessage.Content.ReadAsStreamAsync(stoppingToken);

                    // Sync the response with preferred datastore.
                    var response = await JsonSerializer.DeserializeAsync<
                        IEnumerable<GitHubBranch>>(contentStream,
cancellationToken: stoppingToken);

                    _logger.LogInformation(
                        $"Branch sync successful! Response:
{JsonSerializer.Serialize(response)}");
                }
                else
                {
                    _logger.LogError(1, $"Branch sync failed! HTTP status
code: {httpResponseMessage.StatusCode}");
                }
            }
            catch (Exception ex)
            {
                _logger.LogError(1, ex, "Branch sync failed!");
            }
        }
    }
```

```
    public override Task StopAsync(CancellationToken stoppingToken)
    {
        // This will cause any active call to WaitForNextTickAsync() to
return false immediately.
        _timer.Dispose();
        // This will cancel the stoppingToken and await
ExecuteAsync(stoppingToken).
        return base.StopAsync(stoppingToken);
    }
}
```

`PeriodicBranchesLoggerService` is a hosted service, which runs outside the request and response flow. Logging from the `PeriodicBranchesLoggerService` has a null `HttpContext`. The `PeriodicBranchesLoggerService` was written to not depend on the `HttpContext`.

C#

```
using System.Text.Json;
using HttpContextInBackgroundThread;
using Microsoft.Net.Http.Headers;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddHttpContextAccessor();
builder.Services.AddHostedService<PeriodicBranchesLoggerService>();

builder.Services.AddHttpClient("GitHub", httpClient =>
{
```

Routing in ASP.NET Core

Article • 09/18/2024

Routing is responsible for matching incoming HTTP requests and dispatching those requests to the app's executable endpoints. Endpoints are the app's units of executable request-handling code. Endpoints are defined in the app and configured when the app starts. The endpoint matching process can extract values from the request's URL and provide those values for request processing. Using endpoint information from the app, routing is also able to generate URLs that map to endpoints.

Apps can configure routing using:

- Controllers
- Razor Pages
- SignalR
- gRPC Services
- Endpoint-enabled middleware such as Health Checks.
- Delegates and lambdas registered with routing.

This article covers low-level details of ASP.NET Core routing. For information on configuring routing:

- For controllers, see Routing to controller actions in ASP.NET Core.
- For Razor Pages conventions, see Razor Pages route and app conventions in ASP.NET Core.
- For Blazor routing guidance, which adds to or supersedes the guidance in this article, see ASP.NET Core Blazor routing and navigation.

Routing basics

The following code shows a basic example of routing:

C#

```
var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

app.MapGet("/", () => "Hello World!");

app.Run();
```

The preceding example includes a single endpoint using the MapGet method:

- When an HTTP `GET` request is sent to the root URL `/`:
  - The request delegate executes.
  - `Hello World!` is written to the HTTP response.
- If the request method is not `GET` or the root URL is not `/`, no route matches and an HTTP 404 is returned.

Routing uses a pair of middleware, registered by UseRouting and UseEndpoints:

- `UseRouting` adds route matching to the middleware pipeline. This middleware looks at the set of endpoints defined in the app, and selects the best match based on the request.
- `UseEndpoints` adds endpoint execution to the middleware pipeline. It runs the delegate associated with the selected endpoint.

Apps typically don't need to call `UseRouting` or `UseEndpoints`. WebApplicationBuilder configures a middleware pipeline that wraps middleware added in `Program.cs` with `UseRouting` and `UseEndpoints`. However, apps can change the order in which `UseRouting` and `UseEndpoints` run by calling these methods explicitly. For example, the following code makes an explicit call to `UseRouting`:

C#

```
app.Use(async (context, next) =>
{
    // ...
    await next(context);
});

app.UseRouting();

app.MapGet("/", () => "Hello World!");
```

In the preceding code:

- The call to `app.Use` registers a custom middleware that runs at the start of the pipeline.
- The call to `UseRouting` configures the route matching middleware to run *after* the custom middleware.
- The endpoint registered with `MapGet` runs at the end of the pipeline.

If the preceding example didn't include a call to `UseRouting`, the custom middleware would run *after* the route matching middleware.

Note: Routes added directly to the WebApplication execute at the ***end*** of the pipeline.

Endpoints

The `MapGet` method is used to define an **endpoint**. An endpoint is something that can be:

- Selected, by matching the URL and HTTP method.
- Executed, by running the delegate.

Endpoints that can be matched and executed by the app are configured in `UseEndpoints`. For example, MapGet, MapPost, and similar methods connect request delegates to the routing system. Additional methods can be used to connect ASP.NET Core framework features to the routing system:

- MapRazorPages for Razor Pages
- MapControllers for controllers
- MapHub<THub> for SignalR
- MapGrpcService<TService> for gRPC

The following example shows routing with a more sophisticated route template:

C#

```
app.MapGet("/hello/{name:alpha}", (string name) => $"Hello {name}!");
```

The string `/hello/{name:alpha}` is a **route template**. A route template is used to configure how the endpoint is matched. In this case, the template matches:

- A URL like `/hello/Docs`
- Any URL path that begins with `/hello/` followed by a sequence of alphabetic characters. `:alpha` applies a route constraint that matches only alphabetic characters. Route constraints are explained later in this article.

The second segment of the URL path, `{name:alpha}`:

- Is bound to the `name` parameter.
- Is captured and stored in HttpRequest.RouteValues.

The following example shows routing with health checks and authorization:

```
C#

app.UseAuthentication();
app.UseAuthorization();

app.MapHealthChecks("/healthz").RequireAuthorization();
app.MapGet("/", () => "Hello World!");
```

The preceding example demonstrates how:

- The authorization middleware can be used with routing.
- Endpoints can be used to configure authorization behavior.

The MapHealthChecks call adds a health check endpoint. Chaining RequireAuthorization on to this call attaches an authorization policy to the endpoint.

Calling UseAuthentication and UseAuthorization adds the authentication and authorization middleware. These middleware are placed between UseRouting and `UseEndpoints` so that they can:

- See which endpoint was selected by `UseRouting`.
- Apply an authorization policy before UseEndpoints dispatches to the endpoint.

Endpoint metadata

In the preceding example, there are two endpoints, but only the health check endpoint has an authorization policy attached. If the request matches the health check endpoint, `/healthz`, an authorization check is performed. This demonstrates that endpoints can have extra data attached to them. This extra data is called endpoint **metadata**:

- The metadata can be processed by routing-aware middleware.
- The metadata can be of any .NET type.

Routing concepts

The routing system builds on top of the middleware pipeline by adding the powerful **endpoint** concept. Endpoints represent units of the app's functionality that are distinct

from each other in terms of routing, authorization, and any number of ASP.NET Core's systems.

ASP.NET Core endpoint definition

An ASP.NET Core endpoint is:

- Executable: Has a RequestDelegate.
- Extensible: Has a Metadata collection.
- Selectable: Optionally, has routing information.
- Enumerable: The collection of endpoints can be listed by retrieving the EndpointDataSource from DI.

The following code shows how to retrieve and inspect the endpoint matching the current request:

C#

```
app.Use(async (context, next) =>
{
    var currentEndpoint = context.GetEndpoint();

    if (currentEndpoint is null)
    {
        await next(context);
        return;
    }

    Console.WriteLine($"Endpoint: {currentEndpoint.DisplayName}");

    if (currentEndpoint is RouteEndpoint routeEndpoint)
    {
        Console.WriteLine($"  - Route Pattern:
{routeEndpoint.RoutePattern}");
    }

    foreach (var endpointMetadata in currentEndpoint.Metadata)
    {
        Console.WriteLine($"  - Metadata: {endpointMetadata}");
    }

    await next(context);
});

app.MapGet("/", () => "Inspect Endpoint.");
```

The endpoint, if selected, can be retrieved from the `HttpContext`. Its properties can be inspected. Endpoint objects are immutable and cannot be modified after creation. The

most common type of endpoint is a RouteEndpoint. `RouteEndpoint` includes information that allows it to be selected by the routing system.

In the preceding code, app.Use configures an inline middleware.

The following code shows that, depending on where `app.Use` is called in the pipeline, there may not be an endpoint:

C#

```
// Location 1: before routing runs, endpoint is always null here.
app.Use(async (context, next) =>
{
    Console.WriteLine($"1. Endpoint: {context.GetEndpoint()?.DisplayName ??
"(null)"}");
    await next(context);
});

app.UseRouting();

// Location 2: after routing runs, endpoint will be non-null if routing
found a match.
app.Use(async (context, next) =>
{
    Console.WriteLine($"2. Endpoint: {context.GetEndpoint()?.DisplayName ??
"(null)"}");
    await next(context);
});

// Location 3: runs when this endpoint matches
app.MapGet("/", (HttpContext context) =>
{
    Console.WriteLine($"3. Endpoint: {context.GetEndpoint()?.DisplayName ??
"(null)"}");
    return "Hello World!";
}).WithDisplayName("Hello");

app.UseEndpoints(_ => { });

// Location 4: runs after UseEndpoints - will only run if there was no
match.
app.Use(async (context, next) =>
{
    Console.WriteLine($"4. Endpoint: {context.GetEndpoint()?.DisplayName ??
"(null)"}");
    await next(context);
});
```

The preceding sample adds `Console.WriteLine` statements that display whether or not an endpoint has been selected. For clarity, the sample assigns a display name to the provided `/` endpoint.

The preceding sample also includes calls to `UseRouting` and `UseEndpoints` to control exactly when these middleware run within the pipeline.

Running this code with a URL of `/` displays:

```txt
1. Endpoint: (null)
2. Endpoint: Hello
3. Endpoint: Hello
```

Running this code with any other URL displays:

```txt
1. Endpoint: (null)
2. Endpoint: (null)
4. Endpoint: (null)
```

This output demonstrates that:

- The endpoint is always null before `UseRouting` is called.
- If a match is found, the endpoint is non-null between `UseRouting` and UseEndpoints.
- The `UseEndpoints` middleware is **terminal** when a match is found. Terminal middleware is defined later in this article.
- The middleware after `UseEndpoints` execute only when no match is found.

The `UseRouting` middleware uses the SetEndpoint method to attach the endpoint to the current context. It's possible to replace the `UseRouting` middleware with custom logic and still get the benefits of using endpoints. Endpoints are a low-level primitive like middleware, and aren't coupled to the routing implementation. Most apps don't need to replace `UseRouting` with custom logic.

The `UseEndpoints` middleware is designed to be used in tandem with the `UseRouting` middleware. The core logic to execute an endpoint isn't complicated. Use GetEndpoint to retrieve the endpoint, and then invoke its RequestDelegate property.

The following code demonstrates how middleware can influence or react to routing:

```C#
app.UseHttpMethodOverride();
app.UseRouting();
```

```
app.Use(async (context, next) =>
{
    if (context.GetEndpoint()?.Metadata.GetMetadata<RequiresAuditAttribute>
() is not null)
    {
        Console.WriteLine($"ACCESS TO SENSITIVE DATA AT:
{DateTime.UtcNow}");
    }

    await next(context);
});

app.MapGet("/", () => "Audit isn't required.");
app.MapGet("/sensitive", () => "Audit required for sensitive data.")
    .WithMetadata(new RequiresAuditAttribute());
```

C#

```
public class RequiresAuditAttribute : Attribute { }
```

The preceding example demonstrates two important concepts:

- Middleware can run before `UseRouting` to modify the data that routing operates upon.
  - Usually middleware that appears before routing modifies some property of the request, such as UseRewriter, UseHttpMethodOverride, or UsePathBase.
- Middleware can run between `UseRouting` and UseEndpoints to process the results of routing before the endpoint is executed.
  - Middleware that runs between `UseRouting` and `UseEndpoints`:
    - Usually inspects metadata to understand the endpoints.
    - Often makes security decisions, as done by `UseAuthorization` and `UseCors`.
  - The combination of middleware and metadata allows configuring policies per-endpoint.

The preceding code shows an example of a custom middleware that supports per-endpoint policies. The middleware writes an *audit log* of access to sensitive data to the console. The middleware can be configured to *audit* an endpoint with the `RequiresAuditAttribute` metadata. This sample demonstrates an *opt-in* pattern where only endpoints that are marked as sensitive are audited. It's possible to define this logic in reverse, auditing everything that isn't marked as safe, for example. The endpoint metadata system is flexible. This logic could be designed in whatever way suits the use case.

The preceding sample code is intended to demonstrate the basic concepts of endpoints. **The sample is not intended for production use**. A more complete version of an *audit*

log middleware would:

- Log to a file or database.
- Include details such as the user, IP address, name of the sensitive endpoint, and more.

The audit policy metadata `RequiresAuditAttribute` is defined as an `Attribute` for easier use with class-based frameworks such as controllers and SignalR. When using *route to code*:

- Metadata is attached with a builder API.
- Class-based frameworks include all attributes on the corresponding method and class when creating endpoints.

The best practices for metadata types are to define them either as interfaces or attributes. Interfaces and attributes allow code reuse. The metadata system is flexible and doesn't impose any limitations.

Compare terminal middleware with routing

The following example demonstrates both terminal middleware and routing:

C#

```
// Approach 1: Terminal Middleware.
app.Use(async (context, next) =>
{
    if (context.Request.Path == "/")
    {
        await context.Response.WriteAsync("Terminal Middleware.");
        return;
    }

    await next(context);
});

app.UseRouting();

// Approach 2: Routing.
app.MapGet("/Routing", () => "Routing.");
```

The style of middleware shown with `Approach 1:` is **terminal middleware**. It's called terminal middleware because it does a matching operation:

- The matching operation in the preceding sample is `Path == "/"` for the middleware and `Path == "/Routing"` for routing.

- When a match is successful, it executes some functionality and returns, rather than invoking the `next` middleware.

It's called terminal middleware because it terminates the search, executes some functionality, and then returns.

The following list compares terminal middleware with routing:

- Both approaches allow terminating the processing pipeline:
  - Middleware terminates the pipeline by returning rather than invoking `next`.
  - Endpoints are always terminal.
- Terminal middleware allows positioning the middleware at an arbitrary place in the pipeline:
  - Endpoints execute at the position of UseEndpoints.
- Terminal middleware allows arbitrary code to determine when the middleware matches:
  - Custom route matching code can be verbose and difficult to write correctly.
  - Routing provides straightforward solutions for typical apps. Most apps don't require custom route matching code.
- Endpoints interface with middleware such as `UseAuthorization` and `UseCors`.
  - Using a terminal middleware with `UseAuthorization` or `UseCors` requires manual interfacing with the authorization system.

An endpoint defines both:

- A delegate to process requests.
- A collection of arbitrary metadata. The metadata is used to implement cross-cutting concerns based on policies and configuration attached to each endpoint.

Terminal middleware can be an effective tool, but can require:

- A significant amount of coding and testing.
- Manual integration with other systems to achieve the desired level of flexibility.

Consider integrating with routing before writing a terminal middleware.

Existing terminal middleware that integrates with Map or MapWhen can usually be turned into a routing aware endpoint. MapHealthChecks demonstrates the pattern for router-ware:

- Write an extension method on IEndpointRouteBuilder.
- Create a nested middleware pipeline using CreateApplicationBuilder.
- Attach the middleware to the new pipeline. In this case, UseHealthChecks.
- Build the middleware pipeline into a RequestDelegate.

- Call `Map` and provide the new middleware pipeline.
- Return the builder object provided by `Map` from the extension method.

The following code shows use of MapHealthChecks:

```
C#

app.UseAuthentication();
app.UseAuthorization();

app.MapHealthChecks("/healthz").RequireAuthorization();
```

The preceding sample shows why returning the builder object is important. Returning the builder object allows the app developer to configure policies such as authorization for the endpoint. In this example, the health checks middleware has no direct integration with the authorization system.

The metadata system was created in response to the problems encountered by extensibility authors using terminal middleware. It's problematic for each middleware to implement its own integration with the authorization system.

URL matching

- Is the process by which routing matches an incoming request to an endpoint.
- Is based on data in the URL path and headers.
- Can be extended to consider any data in the request.

When a routing middleware executes, it sets an `Endpoint` and route values to a request feature on the HttpContext from the current request:

- Calling HttpContext.GetEndpoint gets the endpoint.
- `HttpRequest.RouteValues` gets the collection of route values.

Middleware that runs after the routing middleware can inspect the endpoint and take action. For example, an authorization middleware can interrogate the endpoint's metadata collection for an authorization policy. After all of the middleware in the request processing pipeline is executed, the selected endpoint's delegate is invoked.

The routing system in endpoint routing is responsible for all dispatching decisions. Because the middleware applies policies based on the selected endpoint, it's important that:

- Any decision that can affect dispatching or the application of security policies is made inside the routing system.

> ⚠ **Warning**
>
> For backward-compatibility, when a Controller or Razor Pages endpoint delegate is executed, the properties of **RouteContext.RouteData** are set to appropriate values based on the request processing performed thus far.
>
> The `RouteContext` type will be marked obsolete in a future release:
>
> - Migrate `RouteData.Values` to `HttpRequest.RouteValues`.
> - Migrate `RouteData.DataTokens` to retrieve **IDataTokensMetadata** from the endpoint metadata.

URL matching operates in a configurable set of phases. In each phase, the output is a set of matches. The set of matches can be narrowed down further by the next phase. The routing implementation does not guarantee a processing order for matching endpoints. **All** possible matches are processed at once. The URL matching phases occur in the following order. ASP.NET Core:

1. Processes the URL path against the set of endpoints and their route templates, collecting **all** of the matches.
2. Takes the preceding list and removes matches that fail with route constraints applied.
3. Takes the preceding list and removes matches that fail the set of MatcherPolicy instances.
4. Uses the EndpointSelector to make a final decision from the preceding list.

The list of endpoints is prioritized according to:

- The RouteEndpoint.Order
- The route template precedence

All matching endpoints are processed in each phase until the EndpointSelector is reached. The `EndpointSelector` is the final phase. It chooses the highest priority endpoint from the matches as the best match. If there are other matches with the same priority as the best match, an ambiguous match exception is thrown.

The route precedence is computed based on a **more specific** route template being given a higher priority. For example, consider the templates `/hello` and `/{message}`:

- Both match the URL path `/hello`.
- `/hello` is more specific and therefore higher priority.

In general, route precedence does a good job of choosing the best match for the kinds of URL schemes used in practice. Use Order only when necessary to avoid an ambiguity.

Due to the kinds of extensibility provided by routing, it isn't possible for the routing system to compute ahead of time the ambiguous routes. Consider an example such as the route templates `/{message:alpha}` and `/{message:int}`:

- The `alpha` constraint matches only alphabetic characters.
- The `int` constraint matches only numbers.
- These templates have the same route precedence, but there's no single URL they both match.
- If the routing system reported an ambiguity error at startup, it would block this valid use case.

> ⚠ **Warning**
>
> The order of operations inside **UseEndpoints** doesn't influence the behavior of routing, with one exception. **MapControllerRoute** and **MapAreaRoute** automatically assign an order value to their endpoints based on the order they are invoked. This simulates long-time behavior of controllers without the routing system providing the same guarantees as older routing implementations.
>
> Endpoint routing in ASP.NET Core:
>
> - Doesn't have the concept of routes.
> - Doesn't provide ordering guarantees. All endpoints are processed at once.

Route template precedence and endpoint selection order

Route template precedence is a system that assigns each route template a value based on how specific it is. Route template precedence:

- Avoids the need to adjust the order of endpoints in common cases.
- Attempts to match the common-sense expectations of routing behavior.

For example, consider templates `/Products/List` and `/Products/{id}`. It would be reasonable to assume that `/Products/List` is a better match than `/Products/{id}` for the URL path `/Products/List`. This works because the literal segment `/List` is considered to have better precedence than the parameter segment `/{id}`.

The details of how precedence works are coupled to how route templates are defined:

- Templates with more segments are considered more specific.
- A segment with literal text is considered more specific than a parameter segment.
- A parameter segment with a constraint is considered more specific than one without.
- A complex segment is considered as specific as a parameter segment with a constraint.
- Catch-all parameters are the least specific. See **catch-all** in the Route templates section for important information on catch-all routes.

URL generation concepts

URL generation:

- Is the process by which routing can create a URL path based on a set of route values.
- Allows for a logical separation between endpoints and the URLs that access them.

Endpoint routing includes the LinkGenerator API. `LinkGenerator` is a singleton service available from DI. The `LinkGenerator` API can be used outside of the context of an executing request. Mvc.IUrlHelper and scenarios that rely on IUrlHelper, such as Tag Helpers, HTML Helpers, and Action Results, use the `LinkGenerator` API internally to provide link generating capabilities.

The link generator is backed by the concept of an **address** and **address schemes**. An address scheme is a way of determining the endpoints that should be considered for link generation. For example, the route name and route values scenarios many users are familiar with from controllers and Razor Pages are implemented as an address scheme.

The link generator can link to controllers and Razor Pages via the following extension methods:

- GetPathByAction
- GetUriByAction
- GetPathByPage
- GetUriByPage

Overloads of these methods accept arguments that include the `HttpContext`. These methods are functionally equivalent to Url.Action and Url.Page, but offer additional flexibility and options.

The `GetPath*` methods are most similar to `Url.Action` and `Url.Page`, in that they generate a URI containing an absolute path. The `GetUri*` methods always generate an absolute URI containing a scheme and host. The methods that accept an `HttpContext`

generate a URI in the context of the executing request. The ambient route values, URL base path, scheme, and host from the executing request are used unless overridden.

LinkGenerator is called with an address. Generating a URI occurs in two steps:

1. An address is bound to a list of endpoints that match the address.
2. Each endpoint's RoutePattern is evaluated until a route pattern that matches the supplied values is found. The resulting output is combined with the other URI parts supplied to the link generator and returned.

The methods provided by LinkGenerator support standard link generation capabilities for any type of address. The most convenient way to use the link generator is through extension methods that perform operations for a specific address type:

Expand table

Extension Method	Description
GetPathByAddress	Generates a URI with an absolute path based on the provided values.
GetUriByAddress	Generates an absolute URI based on the provided values.

> ⚠ **Warning**
>
> Pay attention to the following implications of calling LinkGenerator methods:
>
> - Use `GetUri*` extension methods with caution in an app configuration that doesn't validate the `Host` header of incoming requests. If the `Host` header of incoming requests isn't validated, untrusted request input can be sent back to the client in URIs in a view or page. We recommend that all production apps configure their server to validate the `Host` header against known valid values.
> - Use LinkGenerator with caution in middleware in combination with `Map` or `MapWhen`. `Map*` changes the base path of the executing request, which affects the output of link generation. All of the LinkGenerator APIs allow specifying a base path. Specify an empty base path to undo the `Map*` affect on link generation.

Middleware example

In the following example, a middleware uses the LinkGenerator API to create a link to an action method that lists store products. Using the link generator by injecting it into a

class and calling `GenerateLink` is available to any class in an app:

```C#
public class ProductsMiddleware
{
    private readonly LinkGenerator _linkGenerator;

    public ProductsMiddleware(RequestDelegate next, LinkGenerator
linkGenerator) =>
        _linkGenerator = linkGenerator;

    public async Task InvokeAsync(HttpContext httpContext)
    {
        httpContext.Response.ContentType = MediaTypeNames.Text.Plain;

        var productsPath = _linkGenerator.GetPathByAction("Products",
"Store");

        await httpContext.Response.WriteAsync(
            $"Go to {productsPath} to see our products.");
    }
}
```

Route templates

Tokens within `{}` define route parameters that are bound if the route is matched. More than one route parameter can be defined in a route segment, but route parameters must be separated by a literal value. For example:

`{controller=Home}{action=Index}`

isn't a valid route, because there's no literal value between `{controller}` and `{action}`. Route parameters must have a name and may have additional attributes specified.

Literal text other than route parameters (for example, `{id}`) and the path separator `/` must match the text in the URL. Text matching is case-insensitive and based on the decoded representation of the URL's path. To match a literal route parameter delimiter `{` or `}`, escape the delimiter by repeating the character. For example `{{` or `}}`.

Asterisk `*` or double asterisk `**`:

- Can be used as a prefix to a route parameter to bind to the rest of the URI.
- Are called a **catch-all** parameters. For example, `blog/{**slug}`:
  - Matches any URI that starts with `blog/` and has any value following it.
  - The value following `blog/` is assigned to the slug route value.

Catch-all parameters can also match the empty string.

The catch-all parameter escapes the appropriate characters when the route is used to generate a URL, including path separator `/` characters. For example, the route `foo/{*path}` with route values `{ path = "my/path" }` generates `foo/my%2Fpath`. Note the escaped forward slash. To round-trip path separator characters, use the `**` route parameter prefix. The route `foo/{**path}` with `{ path = "my/path" }` generates `foo/my/path`.

URL patterns that attempt to capture a file name with an optional file extension have additional considerations. For example, consider the template `files/{filename}.{ext?}`. When values for both `filename` and `ext` exist, both values are populated. If only a value for `filename` exists in the URL, the route matches because the trailing `.` is optional. The following URLs match this route:

- `/files/myFile.txt`
- `/files/myFile`

Route parameters may have **default values** designated by specifying the default value after the parameter name separated by an equals sign (`=`). For example, `{controller=Home}` defines `Home` as the default value for `controller`. The default value is used if no value is present in the URL for the parameter. Route parameters are made optional by appending a question mark (`?`) to the end of the parameter name. For example, `id?`. The difference between optional values and default route parameters is:

- A route parameter with a default value always produces a value.
- An optional parameter has a value only when a value is provided by the request URL.

Route parameters may have constraints that must match the route value bound from the URL. Adding `:` and constraint name after the route parameter name specifies an inline constraint on a route parameter. If the constraint requires arguments, they're enclosed in parentheses `(...)` after the constraint name. Multiple *inline constraints* can be specified by appending another `:` and constraint name.

The constraint name and arguments are passed to the IInlineConstraintResolver service to create an instance of IRouteConstraint to use in URL processing. For example, the route template `blog/{article:minlength(10)}` specifies a `minlength` constraint with the argument `10`. For more information on route constraints and a list of the constraints provided by the framework, see the Route constraints section.

Route parameters may also have parameter transformers. Parameter transformers transform a parameter's value when generating links and matching actions and pages to URLs. Like constraints, parameter transformers can be added inline to a route parameter by adding a `:` and transformer name after the route parameter name. For example, the route template `blog/{article:slugify}` specifies a `slugify` transformer. For more information on parameter transformers, see the Parameter transformers section.

The following table demonstrates example route templates and their behavior:

Expand table

Route Template	Example Matching URI	The request URI...
`hello`	`/hello`	Only matches the single path `/hello`.
`{Page=Home}`	`/`	Matches and sets `Page` to `Home`.
`{Page=Home}`	`/Contact`	Matches and sets `Page` to `Contact`.
`{controller}/{action}/{id?}`	`/Products/List`	Maps to the `Products` controller and `List` action.
`{controller}/{action}/{id?}`	`/Products/Details/123`	Maps to the `Products` controller and `Details` action with `id` set to 123.
`{controller=Home}/{action=Index}/{id?}`	`/`	Maps to the `Home` controller and `Index` method. `id` is ignored.
`{controller=Home}/{action=Index}/{id?}`	`/Products`	Maps to the `Products` controller and `Index` method. `id` is ignored.

Using a template is generally the simplest approach to routing. Constraints and defaults can also be specified outside the route template.

Complex segments

Complex segments are processed by matching up literal delimiters from right to left in a non-greedy way. For example, `[Route("/a{b}c{d}")]` is a complex segment. Complex segments work in a particular way that must be understood to use them successfully.

The example in this section demonstrates why complex segments only really work well when the delimiter text doesn't appear inside the parameter values. Using a regex and then manually extracting the values is needed for more complex cases.

> ⚠ **Warning**
>
> When using System.Text.RegularExpressions to process untrusted input, pass a timeout. A malicious user can provide input to `RegularExpressions` causing a Denial-of-Service attack. ASP.NET Core framework APIs that use `RegularExpressions` pass a timeout.

This is a summary of the steps that routing performs with the template `/a{b}c{d}` and the URL path `/abcd`. The `|` is used to help visualize how the algorithm works:

- The first literal, right to left, is `c`. So `/abcd` is searched from right and finds `/ab|c|d`.
- Everything to the right (`d`) is now matched to the route parameter `{d}`.
- The next literal, right to left, is `a`. So `/ab|c|d` is searched starting where we left off, then `a` is found `/|a|b|c|d`.
- The value to the right (`b`) is now matched to the route parameter `{b}`.
- There is no remaining text and no remaining route template, so this is a match.

Here's an example of a negative case using the same template `/a{b}c{d}` and the URL path `/aabcd`. The `|` is used to help visualize how the algorithm works. This case isn't a match, which is explained by the same algorithm:

- The first literal, right to left, is `c`. So `/aabcd` is searched from right and finds `/aab|c|d`.
- Everything to the right (`d`) is now matched to the route parameter `{d}`.
- The next literal, right to left, is `a`. So `/aab|c|d` is searched starting where we left off, then `a` is found `/a|a|b|c|d`.
- The value to the right (`b`) is now matched to the route parameter `{b}`.
- At this point there is remaining text `a`, but the algorithm has run out of route template to parse, so this is not a match.

Since the matching algorithm is non-greedy:

- It matches the smallest amount of text possible in each step.
- Any case where the delimiter value appears inside the parameter values results in not matching.

Regular expressions provide much more control over their matching behavior.

Greedy matching, also known as *maximal matching* attempts to find the longest possible match in the input text that satisfies the regex pattern. Non-greedy matching, also known as *lazy matching*, seeks the shortest possible match in the input text that satisfies the regex pattern.

Routing with special characters

Routing with special characters can lead to unexpected results. For example, consider a controller with the following action method:

C#

```
[HttpGet("{id?}/name")]
public async Task<ActionResult<string>> GetName(string id)
{
    var todoItem = await _context.TodoItems.FindAsync(id);

    if (todoItem == null || todoItem.Name == null)
    {
        return NotFound();
    }

    return todoItem.Name;
}
```

When `string id` contains the following encoded values, unexpected results might occur:

Expand table

ASCII	Encoded
`/`	`%2F`
` `	`+`

Route parameters are not always URL decoded. This problem may be addressed in the future. For more information, see this GitHub issue;

Route constraints

Route constraints execute when a match has occurred to the incoming URL and the URL path is tokenized into route values. Route constraints generally inspect the route value

associated via the route template and make a true or false decision about whether the value is acceptable. Some route constraints use data outside the route value to consider whether the request can be routed. For example, the HttpMethodRouteConstraint can accept or reject a request based on its HTTP verb. Constraints are used in routing requests and link generation.

> ⚠ **Warning**
>
> Don't use constraints for input validation. If constraints are used for input validation, invalid input results in a `404` Not Found response. Invalid input should produce a `400` Bad Request with an appropriate error message. Route constraints are used to disambiguate similar routes, not to validate the inputs for a particular route.

The following table demonstrates example route constraints and their expected behavior:

Expand table

constraint	Example	Example Matches	Notes
`int`	`{id:int}`	`123456789`, `-123456789`	Matches any integer
`bool`	`{active:bool}`	`true`, `FALSE`	Matches `true` or `false`. Case-insensitive
`datetime`	`{dob:datetime}`	`2016-12-31`, `2016-12-31 7:32pm`	Matches a valid `DateTime` value in the invariant culture. See preceding warning.
`decimal`	`{price:decimal}`	`49.99`, `-1,000.01`	Matches a valid `decimal` value in the invariant culture. See preceding warning.
`double`	`{weight:double}`	`1.234`, `-1,001.01e8`	Matches a valid `double` value in the invariant culture. See preceding warning.
`float`	`{weight:float}`	`1.234`, `-1,001.01e8`	Matches a valid `float` value in the invariant

constraint	Example	Example Matches	Notes
			culture. See preceding warning.
`guid`	`{id:guid}`	`CD2C1638-1638-72D5-1638-DEADBEEF1638`	Matches a valid `Guid` value
`long`	`{ticks:long}`	`123456789`, `-123456789`	Matches a valid `long` value
`minlength(value)`	`{username:minlength(4)}`	`Rick`	String must be at least 4 characters
`maxlength(value)`	`{filename:maxlength(8)}`	`MyFile`	String must be no more than 8 characters
`length(length)`	`{filename:length(12)}`	`somefile.txt`	String must be exactly 12 characters long
`length(min,max)`	`{filename:length(8,16)}`	`somefile.txt`	String must be at least 8 and no more than 16 characters long
`min(value)`	`{age:min(18)}`	`19`	Integer value must be at least 18
`max(value)`	`{age:max(120)}`	`91`	Integer value must be no more than 120
`range(min,max)`	`{age:range(18,120)}`	`91`	Integer value must be at least 18 but no more than 120
`alpha`	`{name:alpha}`	`Rick`	String must consist of one or more alphabetical characters, `a`-`z` and case-insensitive.
`regex(expression)`	`{ssn:regex(^\\d{{3}}-\\d{{2}}-\\d{{4}}$)}`	`123-45-6789`	String must match the regular expression. See tips about defining a regular expression.
`required`	`{name:required}`	`Rick`	Used to enforce that a non-parameter value is present during URL generation

> ⚠ **Warning**
>
> When using System.Text.RegularExpressions to process untrusted input, pass a timeout. A malicious user can provide input to `RegularExpressions` causing a Denial-of-Service attack. ASP.NET Core framework APIs that use `RegularExpressions` pass a timeout.

Multiple, colon delimited constraints can be applied to a single parameter. For example, the following constraint restricts a parameter to an integer value of 1 or greater:

C#

```
[Route("users/{id:int:min(1)}")]
public User GetUserById(int id) { }
```

> ⚠ **Warning**
>
> Route constraints that verify the URL and are converted to a CLR type always use the invariant culture. For example, conversion to the CLR type `int` or `DateTime`. These constraints assume that the URL is not localizable. The framework-provided route constraints don't modify the values stored in route values. All route values parsed from the URL are stored as strings. For example, the `float` constraint attempts to convert the route value to a float, but the converted value is used only to verify it can be converted to a float.

Regular expressions in constraints

> ⚠ **Warning**
>
> When using System.Text.RegularExpressions to process untrusted input, pass a timeout. A malicious user can provide input to `RegularExpressions` causing a Denial-of-Service attack. ASP.NET Core framework APIs that use `RegularExpressions` pass a timeout.

Regular expressions can be specified as inline constraints using the `regex(...)` route constraint. Methods in the MapControllerRoute family also accept an object literal of constraints. If that form is used, string values are interpreted as regular expressions.

The following code uses an inline regex constraint:

C#

```
app.MapGet("{message:regex(^\\d{{3}}-\\d{{2}}-\\d{{4}}$)}",
    () => "Inline Regex Constraint Matched");
```

The following code uses an object literal to specify a regex constraint:

C#

```
app.MapControllerRoute(
    name: "people",
    pattern: "people/{ssn}",
    constraints: new { ssn = "^\\d{3}-\\d{2}-\\d{4}$", },
    defaults: new { controller = "People", action = "List" });
```

The ASP.NET Core framework adds `RegexOptions.IgnoreCase | RegexOptions.Compiled | RegexOptions.CultureInvariant` to the regular expression constructor. See RegexOptions for a description of these members.

Regular expressions use delimiters and tokens similar to those used by routing and the C# language. Regular expression tokens must be escaped. To use the regular expression `^\d{3}-\d{2}-\d{4}$` in an inline constraint, use one of the following:

- Replace `\` characters provided in the string as `\\` characters in the C# source file in order to escape the `\` string escape character.
- Verbatim string literals.

To escape routing parameter delimiter characters `{`, `}`, `[`, `]`, double the characters in the expression, for example, `{{`, `}}`, `[[`, `]]`. The following table shows a regular expression and its escaped version:

Expand table

Regular expression	Escaped regular expression
`^\d{3}-\d{2}-\d{4}$`	`^\\d{{3}}-\\d{{2}}-\\d{{4}}$`
`^[a-z]{2}$`	`^[[a-z]]{{2}}$`

Regular expressions used in routing often start with the `^` character and match the starting position of the string. The expressions often end with the `$` character and match the end of the string. The `^` and `$` characters ensure that the regular expression matches the entire route parameter value. Without the `^` and `$` characters, the regular

expression matches any substring within the string, which is often undesirable. The following table provides examples and explains why they match or fail to match:

Expand table

Expression	String	Match	Comment
`[a-z]{2}`	hello	Yes	Substring matches
`[a-z]{2}`	123abc456	Yes	Substring matches
`[a-z]{2}`	mz	Yes	Matches expression
`[a-z]{2}`	MZ	Yes	Not case sensitive
`^[a-z]{2}$`	hello	No	See `^` and `$` above
`^[a-z]{2}$`	123abc456	No	See `^` and `$` above

For more information on regular expression syntax, see .NET Framework Regular Expressions.

To constrain a parameter to a known set of possible values, use a regular expression. For example, `{action:regex(^(list|get|create)$)}` only matches the `action` route value to `list`, `get`, or `create`. If passed into the constraints dictionary, the string `^(list|get|create)$` is equivalent. Constraints that are passed in the constraints dictionary that don't match one of the known constraints are also treated as regular expressions. Constraints that are passed within a template that don't match one of the known constraints are not treated as regular expressions.

Custom route constraints

Custom route constraints can be created by implementing the IRouteConstraint interface. The `IRouteConstraint` interface contains Match, which returns `true` if the constraint is satisfied and `false` otherwise.

Custom route constraints are rarely needed. Before implementing a custom route constraint, consider alternatives, such as model binding.

The ASP.NET Core Constraints folder provides good examples of creating constraints. For example, GuidRouteConstraint.

To use a custom `IRouteConstraint`, the route constraint type must be registered with the app's ConstraintMap in the service container. A `ConstraintMap` is a dictionary that maps route constraint keys to `IRouteConstraint` implementations that validate those

constraints. An app's `ConstraintMap` can be updated in `Program.cs` either as part of an AddRouting call or by configuring RouteOptions directly with `builder.Services.Configure<RouteOptions>`. For example:

C#

```
builder.Services.AddRouting(options =>
    options.ConstraintMap.Add("noZeroes", typeof(NoZeroesRouteConstraint)));
```

The preceding constraint is applied in the following code:

C#

```
[ApiController]
[Route("api/[controller]")]
public class NoZeroesController : ControllerBase
{
    [HttpGet("{id:noZeroes}")]
    public IActionResult Get(string id) =>
        Content(id);
}
```

The implementation of `NoZeroesRouteConstraint` prevents `0` being used in a route parameter:

C#

```
public class NoZeroesRouteConstraint : IRouteConstraint
{
    private static readonly Regex _regex = new(
        @"^[1-9]*$",
        RegexOptions.CultureInvariant | RegexOptions.IgnoreCase,
        TimeSpan.FromMilliseconds(100));

    public bool Match(
        HttpContext? httpContext, IRouter? route, string routeKey,
        RouteValueDictionary values, RouteDirection routeDirection)
    {
        if (!values.TryGetValue(routeKey, out var routeValue))
        {
            return false;
        }

        var routeValueString = Convert.ToString(routeValue,
CultureInfo.InvariantCulture);

        if (routeValueString is null)
        {
            return false;
        }
```

```
        return _regex.IsMatch(routeValueString);
    }
}
```

> ⚠ **Warning**
>
> When using System.Text.RegularExpressions to process untrusted input, pass a timeout. A malicious user can provide input to `RegularExpressions` causing a Denial-of-Service attack. ASP.NET Core framework APIs that use `RegularExpressions` pass a timeout.

The preceding code:

- Prevents `0` in the `{id}` segment of the route.
- Is shown to provide a basic example of implementing a custom constraint. It should not be used in a production app.

The following code is a better approach to preventing an `id` containing a `0` from being processed:

C#

```
[HttpGet("{id}")]
public IActionResult Get(string id)
{
    if (id.Contains('0'))
    {
        return StatusCode(StatusCodes.Status406NotAcceptable);
    }

    return Content(id);
}
```

The preceding code has the following advantages over the `NoZeroesRouteConstraint` approach:

- It doesn't require a custom constraint.
- It returns a more descriptive error when the route parameter includes `0`.

Parameter transformers

Parameter transformers:

- Execute when generating a link using LinkGenerator.
- Implement Microsoft.AspNetCore.Routing.IOutboundParameterTransformer.
- Are configured using ConstraintMap.
- Take the parameter's route value and transform it to a new string value.
- Result in using the transformed value in the generated link.

For example, a custom `slugify` parameter transformer in route pattern `blog\{article:slugify}` with `Url.Action(new { article = "MyTestArticle" })` generates `blog\my-test-article`.

Consider the following `IOutboundParameterTransformer` implementation:

C#

```
public class SlugifyParameterTransformer : IOutboundParameterTransformer
{
    public string? TransformOutbound(object? value)
    {
        if (value is null)
        {
            return null;
        }

        return Regex.Replace(
            value.ToString()!,
                "([a-z])([A-Z])",
            "$1-$2",
            RegexOptions.CultureInvariant,
            TimeSpan.FromMilliseconds(100))
            .ToLowerInvariant();
    }
}
```

To use a parameter transformer in a route pattern, configure it using ConstraintMap in `Program.cs`:

C#

```
builder.Services.AddRouting(options =>
    options.ConstraintMap["slugify"] = typeof(SlugifyParameterTransformer));
```

The ASP.NET Core framework uses parameter transformers to transform the URI where an endpoint resolves. For example, parameter transformers transform the route values used to match an `area`, `controller`, `action`, and `page`:

C#

```
app.MapControllerRoute(
    name: "default",
    pattern: "{controller:slugify=Home}/{action:slugify=Index}/{id?}");
```

With the preceding route template, the action `SubscriptionManagementController.GetAll` is matched with the URI `/subscription-management/get-all`. A parameter transformer doesn't change the route values used to generate a link. For example, `Url.Action("GetAll", "SubscriptionManagement")` outputs `/subscription-management/get-all`.

ASP.NET Core provides API conventions for using parameter transformers with generated routes:

- The Microsoft.AspNetCore.Mvc.ApplicationModels.RouteTokenTransformerConvention MVC convention applies a specified parameter transformer to all attribute routes in the app. The parameter transformer transforms attribute route tokens as they are replaced. For more information, see Use a parameter transformer to customize token replacement.
- Razor Pages uses the PageRouteTransformerConvention API convention. This convention applies a specified parameter transformer to all automatically discovered Razor Pages. The parameter transformer transforms the folder and file name segments of Razor Pages routes. For more information, see Use a parameter transformer to customize page routes.

URL generation reference

This section contains a reference for the algorithm implemented by URL generation. In practice, most complex examples of URL generation use controllers or Razor Pages. See routing in controllers for additional information.

The URL generation process begins with a call to LinkGenerator.GetPathByAddress or a similar method. The method is provided with an address, a set of route values, and optionally information about the current request from `HttpContext`.

The first step is to use the address to resolve a set of candidate endpoints using an IEndpointAddressScheme<TAddress> that matches the address's type.

Once the set of candidates is found by the address scheme, the endpoints are ordered and processed iteratively until a URL generation operation succeeds. URL generation does **not** check for ambiguities, the first result returned is the final result.

Troubleshooting URL generation with logging

The first step in troubleshooting URL generation is setting the logging level of `Microsoft.AspNetCore.Routing` to `TRACE`. `LinkGenerator` logs many details about its processing which can be useful to troubleshoot problems.

See URL generation reference for details on URL generation.

Addresses

Addresses are the concept in URL generation used to bind a call into the link generator to a set of candidate endpoints.

Addresses are an extensible concept that come with two implementations by default:

- Using *endpoint name* (`string`) as the address:
  - Provides similar functionality to MVC's route name.
  - Uses the IEndpointNameMetadata metadata type.
  - Resolves the provided string against the metadata of all registered endpoints.
  - Throws an exception on startup if multiple endpoints use the same name.
  - Recommended for general-purpose use outside of controllers and Razor Pages.
- Using *route values* (RouteValuesAddress) as the address:
  - Provides similar functionality to controllers and Razor Pages legacy URL generation.
  - Very complex to extend and debug.
  - Provides the implementation used by `IUrlHelper`, Tag Helpers, HTML Helpers, Action Results, etc.

The role of the address scheme is to make the association between the address and matching endpoints by arbitrary criteria:

- The endpoint name scheme performs a basic dictionary lookup.
- The route values scheme has a complex best subset of set algorithm.

Ambient values and explicit values

From the current request, routing accesses the route values of the current request `HttpContext.Request.RouteValues`. The values associated with the current request are referred to as the **ambient values**. For the purpose of clarity, the documentation refers to the route values passed in to methods as **explicit values**.

The following example shows ambient values and explicit values. It provides ambient values from the current request and explicit values:

C#

```
public class WidgetController : ControllerBase
{
    private readonly LinkGenerator _linkGenerator;

    public WidgetController(LinkGenerator linkGenerator) =>
        _linkGenerator = linkGenerator;

    public IActionResult Index()
    {
        var indexPath = _linkGenerator.GetPathByAction(
            HttpContext, values: new { id = 17 })!;

        return Content(indexPath);
    }

    // ...
```

The preceding code:

- Returns `/Widget/Index/17`
- Gets LinkGenerator via DI.

The following code provides only explicit values and no ambient values:

C#

```
var subscribePath = _linkGenerator.GetPathByAction(
    "Subscribe", "Home", new { id = 17 })!;
```

The preceding method returns `/Home/Subscribe/17`

The following code in the `WidgetController` returns `/Widget/Subscribe/17`:

C#

```
var subscribePath = _linkGenerator.GetPathByAction(
    HttpContext, "Subscribe", null, new { id = 17 });
```

The following code provides the controller from ambient values in the current request and explicit values:

C#

```
public class GadgetController : ControllerBase
{
    public IActionResult Index() =>
        Content(Url.Action("Edit", new { id = 17 })!);
}
```

In the preceding code:

- `/Gadget/Edit/17` is returned.
- Url gets the IUrlHelper.
- Action generates a URL with an absolute path for an action method. The URL contains the specified `action` name and `route` values.

The following code provides ambient values from the current request and explicit values:

C#

```
public class IndexModel : PageModel
{
    public void OnGet()
    {
        var editUrl = Url.Page("./Edit", new { id = 17 });

        // ...
    }
}
```

The preceding code sets `url` to `/Edit/17` when the Edit Razor Page contains the following page directive:

`@page "{id:int}"`

If the Edit page doesn't contain the `"{id:int}"` route template, `url` is `/Edit?id=17`.

The behavior of MVC's IUrlHelper adds a layer of complexity in addition to the rules described here:

- `IUrlHelper` always provides the route values from the current request as ambient values.
- IUrlHelper.Action always copies the current `action` and `controller` route values as explicit values unless overridden by the developer.
- IUrlHelper.Page always copies the current `page` route value as an explicit value unless overridden.

- `IUrlHelper.Page` always overrides the current `handler` route value with `null` as an explicit values unless overridden.

Users are often surprised by the behavioral details of ambient values, because MVC doesn't seem to follow its own rules. For historical and compatibility reasons, certain route values such as `action`, `controller`, `page`, and `handler` have their own special-case behavior.

The equivalent functionality provided by `LinkGenerator.GetPathByAction` and `LinkGenerator.GetPathByPage` duplicates these anomalies of `IUrlHelper` for compatibility.

URL generation process

Once the set of candidate endpoints are found, the URL generation algorithm:

- Processes the endpoints iteratively.
- Returns the first successful result.

The first step in this process is called **route value invalidation**. Route value invalidation is the process by which routing decides which route values from the ambient values should be used and which should be ignored. Each ambient value is considered and either combined with the explicit values, or ignored.

The best way to think about the role of ambient values is that they attempt to save application developers typing, in some common cases. Traditionally, the scenarios where ambient values are helpful are related to MVC:

- When linking to another action in the same controller, the controller name doesn't need to be specified.
- When linking to another controller in the same area, the area name doesn't need to be specified.
- When linking to the same action method, route values don't need to be specified.
- When linking to another part of the app, you don't want to carry over route values that have no meaning in that part of the app.

Calls to `LinkGenerator` or `IUrlHelper` that return `null` are usually caused by not understanding route value invalidation. Troubleshoot route value invalidation by explicitly specifying more of the route values to see if that solves the problem.

Route value invalidation works on the assumption that the app's URL scheme is hierarchical, with a hierarchy formed from left-to-right. Consider the basic controller route template `{controller}/{action}/{id?}` to get an intuitive sense of how this works

in practice. A **change** to a value **invalidates** all of the route values that appear to the right. This reflects the assumption about hierarchy. If the app has an ambient value for `id`, and the operation specifies a different value for the `controller`:

- `id` won't be reused because `{controller}` is to the left of `{id?}`.

Some examples demonstrating this principle:

- If the explicit values contain a value for `id`, the ambient value for `id` is ignored. The ambient values for `controller` and `action` can be used.
- If the explicit values contain a value for `action`, any ambient value for `action` is ignored. The ambient values for `controller` can be used. If the explicit value for `action` is different from the ambient value for `action`, the `id` value won't be used. If the explicit value for `action` is the same as the ambient value for `action`, the `id` value can be used.
- If the explicit values contain a value for `controller`, any ambient value for `controller` is ignored. If the explicit value for `controller` is different from the ambient value for `controller`, the `action` and `id` values won't be used. If the explicit value for `controller` is the same as the ambient value for `controller`, the `action` and `id` values can be used.

This process is further complicated by the existence of attribute routes and dedicated conventional routes. Controller conventional routes such as `{controller}/{action}/{id?}` specify a hierarchy using route parameters. For dedicated conventional routes and attribute routes to controllers and Razor Pages:

- There is a hierarchy of route values.
- They don't appear in the template.

For these cases, URL generation defines the **required values** concept. Endpoints created by controllers and Razor Pages have required values specified that allow route value invalidation to work.

The route value invalidation algorithm in detail:

- The required value names are combined with the route parameters, then processed from left-to-right.
- For each parameter, the ambient value and explicit value are compared:
  - If the ambient value and explicit value are the same, the process continues.
  - If the ambient value is present and the explicit value isn't, the ambient value is used when generating the URL.

    - If the ambient value isn't present and the explicit value is, reject the ambient value and all subsequent ambient values.
    - If the ambient value and the explicit value are present, and the two values are different, reject the ambient value and all subsequent ambient values.

At this point, the URL generation operation is ready to evaluate route constraints. The set of accepted values is combined with the parameter default values, which is provided to constraints. If the constraints all pass, the operation continues.

Next, the **accepted values** can be used to expand the route template. The route template is processed:

- From left-to-right.
- Each parameter has its accepted value substituted.
- With the following special cases:
    - If the accepted values is missing a value and the parameter has a default value, the default value is used.
    - If the accepted values is missing a value and the parameter is optional, processing continues.
    - If any route parameter to the right of a missing optional parameter has a value, the operation fails.
    - Contiguous default-valued parameters and optional parameters are collapsed where possible.

Values explicitly provided that don't match a segment of the route are added to the query string. The following table shows the result when using the route template `{controller}/{action}/{id?}`.

Expand table

Ambient Values	Explicit Values	Result
controller = "Home"	action = "About"	`/Home/About`
controller = "Home"	controller = "Order", action = "About"	`/Order/About`
controller = "Home", color = "Red"	action = "About"	`/Home/About`
controller = "Home"	action = "About", color = "Red"	`/Home/About?color=Red`

Optional route parameter order

Optional route parameters must come after all required route parameters and literals. In the following code, the `id` and `name` parameters must come after the `color` parameter:

C#

```
using Microsoft.AspNetCore.Mvc;

namespace WebApplication1.Controllers;

[Route("api/[controller]")]
public class MyController : ControllerBase
{
    // GET /api/my/red/2/joe
    // GET /api/my/red/2
    // GET /api/my
    [HttpGet("{color}/{id:int?}/{name?}")]
    public IActionResult GetByIdAndOptionalName(string color, int id = 1,
string? name = null)
    {
        return Ok($"{color} {id} {name ?? ""}");
    }
}
```

Problems with route value invalidation

The following code shows an example of a URL generation scheme that's not supported by routing:

C#

```
app.MapControllerRoute(
    "default",
    "{culture}/{controller=Home}/{action=Index}/{id?}");

app.MapControllerRoute(
    "blog",
    "{culture}/{**slug}",
    new { controller = "Blog", action = "ReadPost" });
```

In the preceding code, the `culture` route parameter is used for localization. The desire is to have the `culture` parameter always accepted as an ambient value. However, the `culture` parameter is not accepted as an ambient value because of the way required values work:

- In the `"default"` route template, the `culture` route parameter is to the left of `controller`, so changes to `controller` won't invalidate `culture`.

- In the `"blog"` route template, the `culture` route parameter is considered to be to the right of `controller`, which appears in the required values.

Parse URL paths with `LinkParser`

The LinkParser class adds support for parsing a URL path into a set of route values. The ParsePathByEndpointName method takes an endpoint name and a URL path, and returns a set of route values extracted from the URL path.

In the following example controller, the `GetProduct` action uses a route template of `api/Products/{id}` and has a Name of `GetProduct`:

C#

```
[ApiController]
[Route("api/[controller]")]
public class ProductsController : ControllerBase
{
    [HttpGet("{id}", Name = nameof(GetProduct))]
    public IActionResult GetProduct(string id)
    {
        // ...
```

In the same controller class, the `AddRelatedProduct` action expects a URL path, `pathToRelatedProduct`, which can be provided as a query-string parameter:

C#

```
[HttpPost("{id}/Related")]
public IActionResult AddRelatedProduct(
    string id, string pathToRelatedProduct, [FromServices] LinkParser
linkParser)
{
    var routeValues = linkParser.ParsePathByEndpointName(
        nameof(GetProduct), pathToRelatedProduct);
    var relatedProductId = routeValues?["id"];

    // ...
```

In the preceding example, the `AddRelatedProduct` action extracts the `id` route value from the URL path. For example, with a URL path of `/api/Products/1`, the `relatedProductId` value is set to `1`. This approach allows the API's clients to use URL paths when referring to resources, without requiring knowledge of how such a URL is structured.

Configure endpoint metadata

The following links provide information on how to configure endpoint metadata:

- Enable Cors with endpoint routing
- IAuthorizationPolicyProvider sample using a custom `[MinimumAgeAuthorize]` attribute
- Test authentication with the [Authorize] attribute
- RequireAuthorization
- Selecting the scheme with the [Authorize] attribute
- Apply policies using the [Authorize] attribute
- Role-based authorization in ASP.NET Core

Host matching in routes with RequireHost

RequireHost applies a constraint to the route which requires the specified host. The `RequireHost` or [Host] parameter can be a:

- Host: `www.domain.com`, matches `www.domain.com` with any port.
- Host with wildcard: `*.domain.com`, matches `www.domain.com`, `subdomain.domain.com`, or `www.subdomain.domain.com` on any port.
- Port: `*:5000`, matches port 5000 with any host.
- Host and port: `www.domain.com:5000` or `*.domain.com:5000`, matches host and port.

Multiple parameters can be specified using `RequireHost` or `[Host]`. The constraint matches hosts valid for any of the parameters. For example, `[Host("domain.com", "*.domain.com")]` matches `domain.com`, `www.domain.com`, and `subdomain.domain.com`.

The following code uses `RequireHost` to require the specified host on the route:

C#

```
app.MapGet("/", () => "Contoso").RequireHost("contoso.com");
app.MapGet("/", () => "AdventureWorks").RequireHost("adventure-works.com");

app.MapHealthChecks("/healthz").RequireHost("*:8080");
```

The following code uses the `[Host]` attribute on the controller to require any of the specified hosts:

C#

```
[Host("contoso.com", "adventure-works.com")]
public class HostsController : Controller
{
    public IActionResult Index() =>
        View();

    [Host("example.com")]
    public IActionResult Example() =>
        View();
}
```

When the `[Host]` attribute is applied to both the controller and action method:

- The attribute on the action is used.
- The controller attribute is ignored.

> ⚠ **Warning**
>
> API that relies on the Host header, such as HttpRequest.Host and RequireHost, are subject to potential spoofing by clients.
>
> To prevent host and port spoofing, use one of the following approaches:
>
> - Use HttpContext.Connection (ConnectionInfo.LocalPort) where the ports are checked.
> - Employ Host filtering.

Route groups

The MapGroup extension method helps organize groups of endpoints with a common prefix. It reduces repetitive code and allows for customizing entire groups of endpoints with a single call to methods like RequireAuthorization and WithMetadata which add endpoint metadata.

For example, the following code creates two similar groups of endpoints:

C#

```
app.MapGroup("/public/todos")
    .MapTodosApi()
    .WithTags("Public");

app.MapGroup("/private/todos")
    .MapTodosApi()
```

```
    .WithTags("Private")
    .AddEndpointFilterFactory(QueryPrivateTodos)
    .RequireAuthorization();

EndpointFilterDelegate QueryPrivateTodos(EndpointFilterFactoryContext
factoryContext, EndpointFilterDelegate next)
{
    var dbContextIndex = -1;

    foreach (var argument in factoryContext.MethodInfo.GetParameters())
    {
        if (argument.ParameterType == typeof(TodoDb))
        {
            dbContextIndex = argument.Position;
            break;
        }
    }

    // Skip filter if the method doesn't have a TodoDb parameter.
    if (dbContextIndex < 0)
    {
        return next;
    }

    return async invocationContext =>
    {
        var dbContext = invocationContext.GetArgument<TodoDb>
(dbContextIndex);
        dbContext.IsPrivate = true;

        try
        {
            return await next(invocationContext);
        }
        finally
        {
            // This should only be relevant if you're pooling or otherwise
reusing the DbContext instance.
            dbContext.IsPrivate = false;
        }
    };
}
```

C#

```
public static RouteGroupBuilder MapTodosApi(this RouteGroupBuilder group)
{
    group.MapGet("/", GetAllTodos);
    group.MapGet("/{id}", GetTodo);
    group.MapPost("/", CreateTodo);
    group.MapPut("/{id}", UpdateTodo);
    group.MapDelete("/{id}", DeleteTodo);
```

```
    return group;
}
```

In this scenario, you can use a relative address for the `Location` header in the `201 Created` result:

C#

```
public static async Task<Created<Todo>> CreateTodo(Todo todo, TodoDb
database)
{
    await database.AddAsync(todo);
    await database.SaveChangesAsync();

    return TypedResults.Created($"{todo.Id}", todo);
}
```

The first group of endpoints will only match requests prefixed with `/public/todos` and are accessible without any authentication. The second group of endpoints will only match requests prefixed with `/private/todos` and require authentication.

The `QueryPrivateTodos` endpoint filter factory is a local function that modifies the route handler's `TodoDb` parameters to allow to access and store private todo data.

Route groups also support nested groups and complex prefix patterns with route parameters and constraints. In the following example, and route handler mapped to the `user` group can capture the `{org}` and `{group}` route parameters defined in the outer group prefixes.

The prefix can also be empty. This can be useful for adding endpoint metadata or filters to a group of endpoints without changing the route pattern.

C#

```
var all = app.MapGroup("").WithOpenApi();
var org = all.MapGroup("{org}");
var user = org.MapGroup("{user}");
user.MapGet("", (string org, string user) => $"{org}/{user}");
```

Adding filters or metadata to a group behaves the same way as adding them individually to each endpoint before adding any extra filters or metadata that may have been added to an inner group or specific endpoint.

C#

```
var outer = app.MapGroup("/outer");
var inner = outer.MapGroup("/inner");

inner.AddEndpointFilter((context, next) =>
{
    app.Logger.LogInformation("/inner group filter");
    return next(context);
});

outer.AddEndpointFilter((context, next) =>
{
    app.Logger.LogInformation("/outer group filter");
    return next(context);
});

inner.MapGet("/", () => "Hi!").AddEndpointFilter((context, next) =>
{
    app.Logger.LogInformation("MapGet filter");
    return next(context);
});
```

In the above example, the outer filter will log the incoming request before the inner filter even though it was added second. Because the filters were applied to different groups, the order they were added relative to each other does not matter. The order filters are added does matter if applied to the same group or specific endpoint.

A request to `/outer/inner/` will log the following:

.NET CLI

```
/outer group filter
/inner group filter
MapGet filter
```

Performance guidance for routing

When an app has performance problems, routing is often suspected as the problem. The reason routing is suspected is that frameworks like controllers and Razor Pages report the amount of time spent inside the framework in their logging messages. When there's a significant difference between the time reported by controllers and the total time of the request:

- Developers eliminate their app code as the source of the problem.
- It's common to assume routing is the cause.

Routing is performance tested using thousands of endpoints. It's unlikely that a typical app will encounter a performance problem just by being too large. The most common root cause of slow routing performance is usually a badly-behaving custom middleware.

This following code sample demonstrates a basic technique for narrowing down the source of delay:

C#

```
var logger = app.Services.GetRequiredService<ILogger<Program>>();

app.Use(async (context, next) =>
{
    var stopwatch = Stopwatch.StartNew();
    await next(context);
    stopwatch.Stop();

    logger.LogInformation("Time 1: {ElapsedMilliseconds}ms",
stopwatch.ElapsedMilliseconds);
});

app.UseRouting();

app.Use(async (context, next) =>
{
    var stopwatch = Stopwatch.StartNew();
    await next(context);
    stopwatch.Stop();

    logger.LogInformation("Time 2: {ElapsedMilliseconds}ms",
stopwatch.ElapsedMilliseconds);
});

app.UseAuthorization();

app.Use(async (context, next) =>
{
    var stopwatch = Stopwatch.StartNew();
    await next(context);
    stopwatch.Stop();

    logger.LogInformation("Time 3: {ElapsedMilliseconds}ms",
stopwatch.ElapsedMilliseconds);
});

app.MapGet("/", () => "Timing Test.");
```

To time routing:

- Interleave each middleware with a copy of the timing middleware shown in the preceding code.

- Add a unique identifier to correlate the timing data with the code.

This is a basic way to narrow down the delay when it's significant, for example, more than `10ms`. Subtracting `Time 2` from `Time 1` reports the time spent inside the `UseRouting` middleware.

The following code uses a more compact approach to the preceding timing code:

C#

```
public sealed class AutoStopwatch : IDisposable
{
    private readonly ILogger _logger;
    private readonly string _message;
    private readonly Stopwatch _stopwatch;
    private bool _disposed;

    public AutoStopwatch(ILogger logger, string message) =>
        (_logger, _message, _stopwatch) = (logger, message,
Stopwatch.StartNew());

    public void Dispose()
    {
        if (_disposed)
        {
            return;
        }

        _logger.LogInformation("{Message}: {ElapsedMilliseconds}ms",
            _message, _stopwatch.ElapsedMilliseconds);

        _disposed = true;
    }
}
```

C#

```
var logger = app.Services.GetRequiredService<ILogger<Program>>();
var timerCount = 0;

app.Use(async (context, next) =>
{
    using (new AutoStopwatch(logger, $"Time {++timerCount}"))
    {
        await next(context);
    }
});

app.UseRouting();

app.Use(async (context, next) =>
```

```
{
    using (new AutoStopwatch(logger, $"Time {++timerCount}"))
    {
        await next(context);
    }
});

app.UseAuthorization();

app.Use(async (context, next) =>
{
    using (new AutoStopwatch(logger, $"Time {++timerCount}"))
    {
        await next(context);
    }
});

app.MapGet("/", () => "Timing Test.");
```

Potentially expensive routing features

The following list provides some insight into routing features that are relatively expensive compared with basic route templates:

- Regular expressions: It's possible to write regular expressions that are complex, or have long running time with a small amount of input.
- Complex segments (`{x}-{y}-{z}`):
  - Are significantly more expensive than parsing a regular URL path segment.
  - Result in many more substrings being allocated.
- Synchronous data access: Many complex apps have database access as part of their routing. Use extensibility points such as MatcherPolicy and EndpointSelectorContext, which are asynchronous.

Guidance for large route tables

By default ASP.NET Core uses a routing algorithm that trades memory for CPU time. This has the nice effect that route matching time is dependent only on the length of the path to match and not the number of routes. However, this approach can be potentially problematic in some cases, when the app has a large number of routes (in the thousands) and there is a high amount of variable prefixes in the routes. For example, if the routes have parameters in early segments of the route, like `{parameter}/some/literal`.

It is unlikely for an app to run into a situation where this is a problem unless:

- There are a high number of routes in the app using this pattern.
- There is a large number of routes in the app.

How to determine if an app is running into the large route table problem

- There are two symptoms to look for:
  - The app is slow to start on the first request.
    - Note that this is required but not sufficient. There are many other non-route problems than can cause slow app startup. Check for the condition below to accurately determine the app is running into this situation.
  - The app consumes a lot of memory during startup and a memory dump shows a large number of `Microsoft.AspNetCore.Routing.Matching.DfaNode` instances.

How to address this issue

There are several techniques and optimizations that can be applied to routes that largely improve this scenario:

- Apply route constraints to your parameters, for example `{parameter:int}`, `{parameter:guid}`, `{parameter:regex(\\d+)}`, etc. where possible.
  - This allows the routing algorithm to internally optimize the structures used for matching and drastically reduce the memory used.
  - In the vast majority of cases this will suffice to get back to an acceptable behavior.
- Change the routes to move parameters to later segments in the template.
  - This reduces the number of possible "paths" to match an endpoint given a path.
- Use a dynamic route and perform the mapping to a controller/page dynamically.
  - This can be achieved using `MapDynamicControllerRoute` and `MapDynamicPageRoute`.

Short-circuit middleware after routing

When routing matches an endpoint, it typically lets the rest of the middleware pipeline run before invoking the endpoint logic. Services can reduce resource usage by filtering out known requests early in the pipeline. Use the ShortCircuit extension method to cause routing to invoke the endpoint logic immediately and then end the request. For example, a given route might not need to go through authentication or CORS middleware. The following example short-circuits requests that match the `/short-circuit` route:

C#

```
app.MapGet("/short-circuit", () => "Short circuiting!").ShortCircuit();
```

The ShortCircuit(IEndpointConventionBuilder, Nullable<Int32>) method can optionally take a status code.

Use the MapShortCircuit method to set up short-circuiting for multiple routes at once, by passing to it a params array of URL prefixes. For example, browsers and bots often probe servers for well known paths like `robots.txt` and `favicon.ico`. If the app doesn't have those files, one line of code can configure both routes:

C#

```
app.MapShortCircuit(404, "robots.txt", "favicon.ico");
```

`MapShortCircuit` returns IEndpointConventionBuilder so that additional route constraints like host filtering can be added to it.

The `ShortCircuit` and `MapShortCircuit` methods do not affect middleware placed before `UseRouting`. Trying to use these methods with endpoints that also have `[Authorize]` or `[RequireCors]` metadata will cause requests to fail with an `InvalidOperationException`. This metadata is applied by [Authorize] or [EnableCors] attributes or by RequireCors or RequireAuthorization methods.

To see the effect of short-circuiting middleware, set the "Microsoft" logging category to "Information" in `appsettings.Development.json`:

JSON

```
{
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "Microsoft": "Information",
      "Microsoft.Hosting.Lifetime": "Information"
    }
  }
}
```

Run the following code:

C#

```
var app = WebApplication.Create();

app.UseHttpLogging();

app.MapGet("/", () => "No short-circuiting!");
app.MapGet("/short-circuit", () => "Short circuiting!").ShortCircuit();
app.MapShortCircuit(404, "robots.txt", "favicon.ico");

app.Run();
```

The following example is from the console logs produced by running the `/` endpoint. It includes output from the logging middleware:

```
info: Microsoft.AspNetCore.Routing.EndpointMiddleware[0]
      Executing endpoint 'HTTP: GET /'
info: Microsoft.AspNetCore.Routing.EndpointMiddleware[1]
      Executed endpoint 'HTTP: GET /'
info: Microsoft.AspNetCore.HttpLogging.HttpLoggingMiddleware[2]
      Response:
      StatusCode: 200
      Content-Type: text/plain; charset=utf-8
      Date: Wed, 03 May 2023 21:05:59 GMT
      Server: Kestrel
      Alt-Svc: h3=":5182"; ma=86400
      Transfer-Encoding: chunked
```

The following example is from running the `/short-circuit` endpoint. It doesn't have anything from the logging middleware because the middleware was short-circuited:

```
info: Microsoft.AspNetCore.Routing.EndpointRoutingMiddleware[4]
      The endpoint 'HTTP: GET /short-circuit' is being executed without
running additional middleware.
info: Microsoft.AspNetCore.Routing.EndpointRoutingMiddleware[5]
      The endpoint 'HTTP: GET /short-circuit' has been executed without
running additional middleware.
```

Guidance for library authors

This section contains guidance for library authors building on top of routing. These details are intended to ensure that app developers have a good experience using libraries and frameworks that extend routing.

Define endpoints

To create a framework that uses routing for URL matching, start by defining a user experience that builds on top of UseEndpoints.

DO build on top of IEndpointRouteBuilder. This allows users to compose your framework with other ASP.NET Core features without confusion. Every ASP.NET Core template includes routing. Assume routing is present and familiar for users.

```
C#

// Your framework
app.MapMyFramework(...);

app.MapHealthChecks("/healthz");
```

DO return a sealed concrete type from a call to `MapMyFramework(...)` that implements IEndpointConventionBuilder. Most framework `Map...` methods follow this pattern. The `IEndpointConventionBuilder` interface:

- Allows for metadata to be composed.
- Is targeted by a variety of extension methods.

Declaring your own type allows you to add your own framework-specific functionality to the builder. It's ok to wrap a framework-declared builder and forward calls to it.

```
C#

// Your framework
app.MapMyFramework(...)
    .RequireAuthorization()
    .WithMyFrameworkFeature(awesome: true);

app.MapHealthChecks("/healthz");
```

CONSIDER writing your own EndpointDataSource. `EndpointDataSource` is the low-level primitive for declaring and updating a collection of endpoints. `EndpointDataSource` is a powerful API used by controllers and Razor Pages. For more information, see Dynamic endpoint routing.

The routing tests have a basic example of a non-updating data source.

CONSIDER implementing GetGroupedEndpoints. This gives complete control over running group conventions and the final metadata on the grouped endpoints. For

example, this allows custom `EndpointDataSource` implementations to run endpoint filters added to groups.

DO NOT attempt to register an `EndpointDataSource` by default. Require users to register your framework in UseEndpoints. The philosophy of routing is that nothing is included by default, and that `UseEndpoints` is the place to register endpoints.

Creating routing-integrated middleware

CONSIDER defining metadata types as an interface.

DO make it possible to use metadata types as an attribute on classes and methods.

C#

```
public interface ICoolMetadata
{
    bool IsCool { get; }
}

[AttributeUsage(AttributeTargets.Class | AttributeTargets.Method)]
public class CoolMetadataAttribute : Attribute, ICoolMetadata
{
    public bool IsCool => true;
}
```

Frameworks like controllers and Razor Pages support applying metadata attributes to types and methods. If you declare metadata types:

- Make them accessible as attributes.
- Most users are familiar with applying attributes.

Declaring a metadata type as an interface adds another layer of flexibility:

- Interfaces are composable.
- Developers can declare their own types that combine multiple policies.

DO make it possible to override metadata, as shown in the following example:

C#

```
[AttributeUsage(AttributeTargets.Class | AttributeTargets.Method)]
public class SuppressCoolMetadataAttribute : Attribute, ICoolMetadata
{
    public bool IsCool => false;
}
```

```
[CoolMetadata]
public class MyController : Controller
{
    public void MyCool() { }

    [SuppressCoolMetadata]
    public void Uncool() { }
}
```

The best way to follow these guidelines is to avoid defining **marker metadata**:

- Don't just look for the presence of a metadata type.
- Define a property on the metadata and check the property.

The metadata collection is ordered and supports overriding by priority. In the case of controllers, metadata on the action method is most specific.

DO make middleware useful with and without routing:

C#

```
app.UseAuthorization(new AuthorizationPolicy() { ... });

// Your framework
app.MapMyFramework(...).RequireAuthorization();
```

As an example of this guideline, consider the `UseAuthorization` middleware. The authorization middleware allows you to pass in a fallback policy. The fallback policy, if specified, applies to both:

- Endpoints without a specified policy.
- Requests that don't match an endpoint.

This makes the authorization middleware useful outside of the context of routing. The authorization middleware can be used for traditional middleware programming.

Debug diagnostics

For detailed routing diagnostic output, set `Logging:LogLevel:Microsoft` to `Debug`. In the development environment, set the log level in `appsettings.Development.json`:

JSON

```
{
  "Logging": {
    "LogLevel": {
```

```
      "Default": "Information",
      "Microsoft": "Debug",
      "Microsoft.Hosting.Lifetime": "Information"
    }
  }
}
```

Handle errors in ASP.NET Core

Article • 09/21/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

By Tom Dykstra

This article covers common approaches to handling errors in ASP.NET Core web apps. See also Handle errors in ASP.NET Core controller-based web APIs and Handle errors in minimal APIs.

For Blazor error handling guidance, which adds to or supersedes the guidance in this article, see Handle errors in ASP.NET Core Blazor apps.

Developer exception page

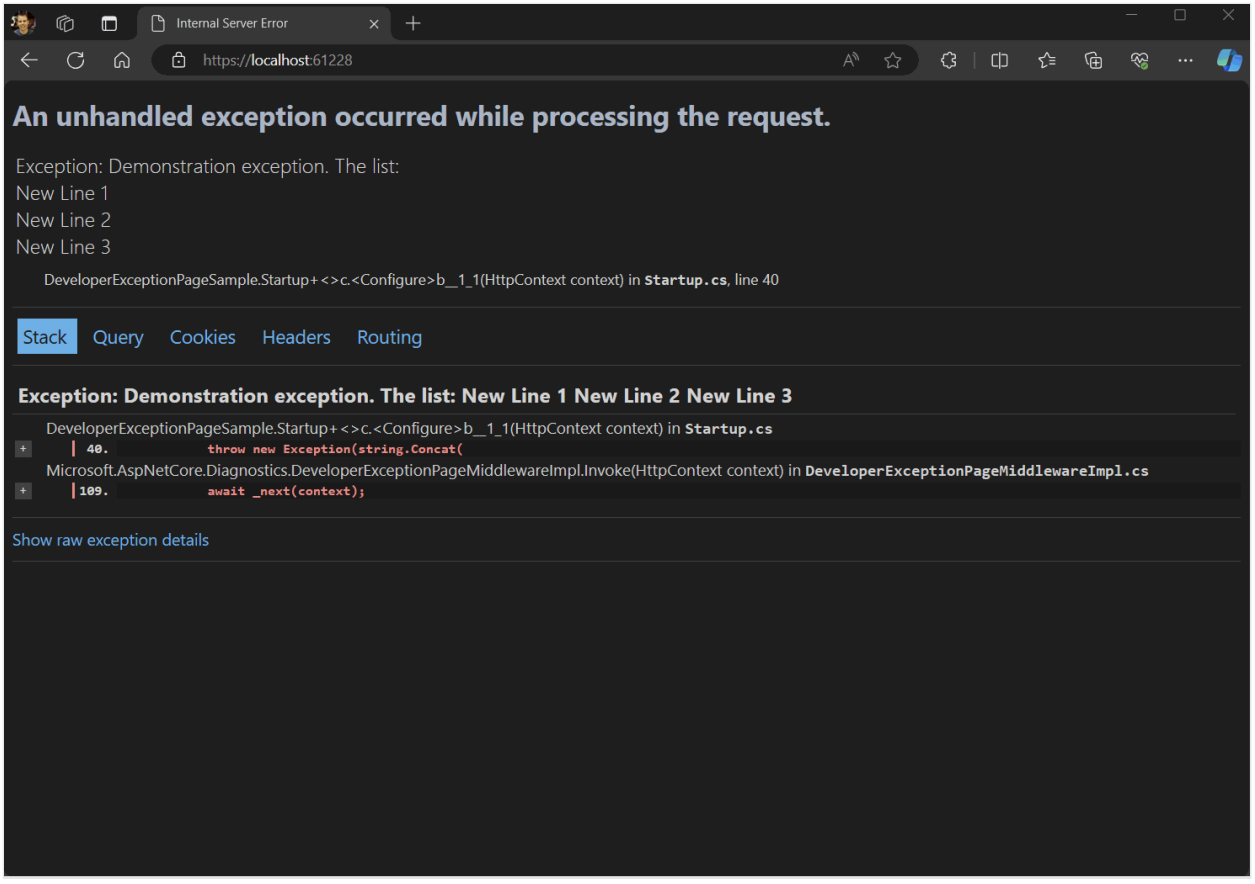
The *Developer Exception Page* displays detailed information about unhandled request exceptions. It uses DeveloperExceptionPageMiddleware to capture synchronous and asynchronous exceptions from the HTTP pipeline and to generate error responses. The developer exception page runs early in the middleware pipeline, so that it can catch unhandled exceptions thrown in middleware that follows.

ASP.NET Core apps enable the developer exception page by default when both:

- Running in the Development environment.
- The app was created with the current templates, that is, by using WebApplication.CreateBuilder.

Apps created using earlier templates, that is, by using WebHost.CreateDefaultBuilder, can enable the developer exception page by calling app.UseDeveloperExceptionPage.

> **⚠ Warning**
>
> Don't enable the Developer Exception Page **unless the app is running in the Development environment**. Don't share detailed exception information publicly



when the app runs in production. For more information on configuring environments, see Use multiple environments in ASP.NET Core.

The Developer Exception Page can include the following information about the exception and the request:

- Stack trace
- Query string parameters, if any
- Cookies, if any
- Headers
- Endpoint metadata, if any

The Developer Exception Page isn't guaranteed to provide any information. Use Logging for complete error information.

The following image shows a sample developer exception page with animation to show the tabs and the information displayed:

In response to a request with an `Accept: text/plain` header, the Developer Exception Page returns plain text instead of HTML. For example:

text

```
Status: 500 Internal Server Error
Time: 9.39 msSize: 480 bytes
```

```
FormattedRawHeadersRequest
Body
text/plain; charset=utf-8, 480 bytes
System.InvalidOperationException: Sample Exception
   at WebApplicationMinimal.Program.<>c.<Main>b__0_0() in
C:\Source\WebApplicationMinimal\Program.cs:line 12
   at lambda_method1(Closure, Object, HttpContext)
   at
Microsoft.AspNetCore.Diagnostics.DeveloperExceptionPageMiddlewareImpl.Invoke
(HttpContext context)

HEADERS
=======
Accept: text/plain
Host: localhost:7267
traceparent: 00-0eab195ea19d07b90a46cd7d6bf2f
```

Exception handler page

To configure a custom error handling page for the Production environment, call UseExceptionHandler. This exception handling middleware:

- Catches and logs unhandled exceptions.
- Re-executes the request in an alternate pipeline using the path indicated. The request isn't re-executed if the response has started. The template-generated code re-executes the request using the `/Error` path.

> **⚠ Warning**
>
> If the alternate pipeline throws an exception of its own, Exception Handling Middleware rethrows the original exception.

Since this middleware can re-execute the request pipeline:

- Middlewares need to handle reentrancy with the same request. This normally means either cleaning up their state after calling `_next` or caching their processing on the `HttpContext` to avoid redoing it. When dealing with the request body, this either means buffering or caching the results like the Form reader.
- For the UseExceptionHandler(IApplicationBuilder, String) overload that is used in templates, only the request path is modified, and the route data is cleared. Request data such as headers, method, and items are all reused as-is.
- Scoped services remain the same.

In the following example, UseExceptionHandler adds the exception handling middleware in non-Development environments:

```
C#

var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}
```

The Razor Pages app template provides an Error page (`.cshtml`) and PageModel class (`ErrorModel`) in the *Pages* folder. For an MVC app, the project template includes an `Error` action method and an Error view for the Home controller.

The exception handling middleware re-executes the request using the *original* HTTP method. If an error handler endpoint is restricted to a specific set of HTTP methods, it runs only for those HTTP methods. For example, an MVC controller action that uses the `[HttpGet]` attribute runs only for GET requests. To ensure that *all* requests reach the custom error handling page, don't restrict them to a specific set of HTTP methods.

To handle exceptions differently based on the original HTTP method:

- For Razor Pages, create multiple handler methods. For example, use `OnGet` to handle GET exceptions and use `OnPost` to handle POST exceptions.
- For MVC, apply HTTP verb attributes to multiple actions. For example, use `[HttpGet]` to handle GET exceptions and use `[HttpPost]` to handle POST exceptions.

To allow unauthenticated users to view the custom error handling page, ensure that it supports anonymous access.

Access the exception

Use IExceptionHandlerPathFeature to access the exception and the original request path in an error handler. The following example uses `IExceptionHandlerPathFeature` to get more information about the exception that was thrown:

```
C#

[ResponseCache(Duration = 0, Location = ResponseCacheLocation.None, NoStore
= true)]
```

```
[IgnoreAntiforgeryToken]
public class ErrorModel : PageModel
{
    public string? RequestId { get; set; }

    public bool ShowRequestId => !string.IsNullOrEmpty(RequestId);

    public string? ExceptionMessage { get; set; }

    public void OnGet()
    {
        RequestId = Activity.Current?.Id ?? HttpContext.TraceIdentifier;

        var exceptionHandlerPathFeature =
            HttpContext.Features.Get<IExceptionHandlerPathFeature>();

        if (exceptionHandlerPathFeature?.Error is FileNotFoundException)
        {
            ExceptionMessage = "The file was not found.";
        }

        if (exceptionHandlerPathFeature?.Path == "/")
        {
            ExceptionMessage ??= string.Empty;
            ExceptionMessage += " Page: Home.";
        }
    }
}
```

> ⚠ **Warning**
>
> Do **not** serve sensitive error information to clients. Serving errors is a security risk.

Exception handler lambda

An alternative to a custom exception handler page is to provide a lambda to UseExceptionHandler. Using a lambda allows access to the error before returning the response.

The following code uses a lambda for exception handling:

C#

```
var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
```

```
    app.UseExceptionHandler(exceptionHandlerApp =>
    {
        exceptionHandlerApp.Run(async context =>
        {
            context.Response.StatusCode =
StatusCodes.Status500InternalServerError;

            // using static System.Net.Mime.MediaTypeNames;
            context.Response.ContentType = Text.Plain;

            await context.Response.WriteAsync("An exception was thrown.");

            var exceptionHandlerPathFeature =
                context.Features.Get<IExceptionHandlerPathFeature>();

            if (exceptionHandlerPathFeature?.Error is FileNotFoundException)
            {
                await context.Response.WriteAsync(" The file was not
found.");
            }

            if (exceptionHandlerPathFeature?.Path == "/")
            {
                await context.Response.WriteAsync(" Page: Home.");
            }
        });
    });

    app.UseHsts();
}
```

Another way to use a lambda is to set the status code based on the exception type, as in the following example:

C#

```
var builder = WebApplication.CreateBuilder(args);
builder.Services.AddProblemDetails();
var app = builder.Build();
if (app.Environment.IsDevelopment())
{
    app.UseExceptionHandler(new ExceptionHandlerOptions
    {
        StatusCodeSelector = ex => ex is TimeoutException
            ? StatusCodes.Status503ServiceUnavailable
            : StatusCodes.Status500InternalServerError
    });
}
```

> ⚠ **Warning**

Do **not** serve sensitive error information to clients. Serving errors is a security risk.

IExceptionHandler

IExceptionHandler is an interface that gives the developer a callback for handling known exceptions in a central location.

`IExceptionHandler` implementations are registered by calling IServiceCollection.AddExceptionHandler<T>. The lifetime of an `IExceptionHandler` instance is singleton. Multiple implementations can be added, and they're called in the order registered.

If an exception handler handles a request, it can return `true` to stop processing. If an exception isn't handled by any exception handler, then control falls back to the default behavior and options from the middleware. Different metrics and logs are emitted for handled versus unhandled exceptions.

The following example shows an `IExceptionHandler` implementation:

C#

```
using Microsoft.AspNetCore.Diagnostics;

namespace ErrorHandlingSample
{
    public class CustomExceptionHandler : IExceptionHandler
    {
        private readonly ILogger<CustomExceptionHandler> logger;
        public CustomExceptionHandler(ILogger<CustomExceptionHandler>
logger)
        {
            this.logger = logger;
        }
        public ValueTask<bool> TryHandleAsync(
            HttpContext httpContext,
            Exception exception,
            CancellationToken cancellationToken)
        {
            var exceptionMessage = exception.Message;
            logger.LogError(
                "Error Message: {exceptionMessage}, Time of occurrence
{time}",
                exceptionMessage, DateTime.UtcNow);
            // Return false to continue with the default behavior
            // - or - return true to signal that this exception is handled
            return ValueTask.FromResult(false);
        }
```

```
    }
}
```

The following example shows how to register an `IExceptionHandler` implementation for dependency injection:

C#

```
using ErrorHandlingSample;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddDatabaseDeveloperPageExceptionFilter();
builder.Services.AddRazorPages();
builder.Services.AddExceptionHandler<CustomExceptionHandler>();

var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

// Remaining Program.cs code omitted for brevity
```

When the preceding code runs in the Development environment:

- The `CustomExceptionHandler` is called first to handle an exception.
- After logging the exception, the `TryHandleAsync` method returns `false`, so the developer exception page is shown.

In other environments:

- The `CustomExceptionHandler` is called first to handle an exception.
- After logging the exception, the `TryHandleAsync` method returns `false`, so the /Error page is shown.

UseStatusCodePages

By default, an ASP.NET Core app doesn't provide a status code page for HTTP error status codes, such as *404 - Not Found*. When the app sets an HTTP 400-599 error status code that doesn't have a body, it returns the status code and an empty response body. To enable default text-only handlers for common error status codes, call UseStatusCodePages in `Program.cs`:

C#

```
var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseStatusCodePages();
```

Call `UseStatusCodePages` before request handling middleware. For example, call `UseStatusCodePages` before the Static File Middleware and the Endpoints Middleware.

When `UseStatusCodePages` isn't used, navigating to a URL without an endpoint returns a browser-dependent error message indicating the endpoint can't be found. When `UseStatusCodePages` is called, the browser returns the following response:

Console

```
Status Code: 404; Not Found
```

`UseStatusCodePages` isn't typically used in production because it returns a message that isn't useful to users.

> ⓘ **Note**
>
> The status code pages middleware does **not** catch exceptions. To provide a custom error handling page, use the exception handler page.

UseStatusCodePages with format string

To customize the response content type and text, use the overload of UseStatusCodePages that takes a content type and format string:

C#

```
var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}
```

```
// using static System.Net.Mime.MediaTypeNames;
app.UseStatusCodePages(Text.Plain, "Status Code Page: {0}");
```

In the preceding code, `{0}` is a placeholder for the error code.

`UseStatusCodePages` with a format string isn't typically used in production because it returns a message that isn't useful to users.

UseStatusCodePages with lambda

To specify custom error-handling and response-writing code, use the overload of UseStatusCodePages that takes a lambda expression:

C#

```
var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseStatusCodePages(async statusCodeContext =>
{
    // using static System.Net.Mime.MediaTypeNames;
    statusCodeContext.HttpContext.Response.ContentType = Text.Plain;

    await statusCodeContext.HttpContext.Response.WriteAsync(
        $"Status Code Page:
{statusCodeContext.HttpContext.Response.StatusCode}");
});
```

`UseStatusCodePages` with a lambda isn't typically used in production because it returns a message that isn't useful to users.

UseStatusCodePagesWithRedirects

The UseStatusCodePagesWithRedirects extension method:

- Sends a 302 - Found status code to the client.
- Redirects the client to the error handling endpoint provided in the URL template. The error handling endpoint typically displays error information and returns HTTP 200.

C#

```
var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseStatusCodePagesWithRedirects("/StatusCode/{0}");
```

The URL template can include a `{0}` placeholder for the status code, as shown in the preceding code. If the URL template starts with `~` (tilde), the `~` is replaced by the app's `PathBase`. When specifying an endpoint in the app, create an MVC view or Razor page for the endpoint.

This method is commonly used when the app:

- Should redirect the client to a different endpoint, usually in cases where a different app processes the error. For web apps, the client's browser address bar reflects the redirected endpoint.
- Shouldn't preserve and return the original status code with the initial redirect response.

UseStatusCodePagesWithReExecute

The UseStatusCodePagesWithReExecute extension method:

- Generates the response body by re-executing the request pipeline using an alternate path.
- Does not alter the status code before or after re-executing the pipeline.

The new pipeline execution may alter the response's status code, as the new pipeline has full control of the status code. If the new pipeline does not alter the status code, the original status code will be sent to the client.

C#

```
var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}
```

```
app.UseStatusCodePagesWithReExecute("/StatusCode/{0}");
```

If an endpoint within the app is specified, create an MVC view or Razor page for the endpoint.

This method is commonly used when the app should:

- Process the request without redirecting to a different endpoint. For web apps, the client's browser address bar reflects the originally requested endpoint.
- Preserve and return the original status code with the response.

The URL template must start with `/` and may include a placeholder `{0}` for the status code. To pass the status code as a query-string parameter, pass a second argument into `UseStatusCodePagesWithReExecute`. For example:

C#

```
var app = builder.Build();
app.UseStatusCodePagesWithReExecute("/StatusCode", "?statusCode={0}");
```

The endpoint that processes the error can get the original URL that generated the error, as shown in the following example:

C#

```
[ResponseCache(Duration = 0, Location = ResponseCacheLocation.None, NoStore
= true)]
public class StatusCodeModel : PageModel
{
    public int OriginalStatusCode { get; set; }

    public string? OriginalPathAndQuery { get; set; }

    public void OnGet(int statusCode)
    {
        OriginalStatusCode = statusCode;
```

```
        var statusCodeReExecuteFeature =
            HttpContext.Features.Get<IStatusCodeReExecuteFeature>();

        if (statusCodeReExecuteFeature is not null)
        {
            OriginalPathAndQuery = $"
{statusCodeReExecuteFeature.OriginalPathBase}"
                                   + $"
{statusCodeReExecuteFeature.OriginalPath}"
                                   + $"
{statusCodeReExecuteFeature.OriginalQueryString}";

        }
    }
}
```

Since this middleware can re-execute the request pipeline:

- Middlewares need to handle reentrancy with the same request. This normally means either cleaning up their state after calling `_next` or caching their processing on the `HttpContext` to avoid redoing it. When dealing with the request body, this either means buffering or caching the results like the Form reader.
- Scoped services remain the same.

Disable status code pages

To disable status code pages for an MVC controller or action method, use the [SkipStatusCodePages] attribute.

To disable status code pages for specific requests in a Razor Pages handler method or in an MVC controller, use IStatusCodePagesFeature:

C#

```
public void OnGet()
{
    var statusCodePagesFeature =
        HttpContext.Features.Get<IStatusCodePagesFeature>();

    if (statusCodePagesFeature is not null)
    {
        statusCodePagesFeature.Enabled = false;
    }
}
```

Exception-handling code

Code in exception handling pages can also throw exceptions. Production error pages should be tested thoroughly and take extra care to avoid throwing exceptions of their own.

Response headers

Once the headers for a response are sent:

- The app can't change the response's status code.
- Any exception pages or handlers can't run. The response must be completed or the connection aborted.

Server exception handling

In addition to the exception handling logic in an app, the HTTP server implementation can handle some exceptions. If the server catches an exception before response headers are sent, the server sends a `500 - Internal Server Error` response without a response body. If the server catches an exception after response headers are sent, the server closes the connection. Requests that aren't handled by the app are handled by the server. Any exception that occurs when the server is handling the request is handled by the server's exception handling. The app's custom error pages, exception handling middleware, and filters don't affect this behavior.

Startup exception handling

Only the hosting layer can handle exceptions that take place during app startup. The host can be configured to capture startup errors and capture detailed errors.

The hosting layer can show an error page for a captured startup error only if the error occurs after host address/port binding. If binding fails:

- The hosting layer logs a critical exception.
- The dotnet process crashes.
- No error page is displayed when the HTTP server is Kestrel.

When running on IIS (or Azure App Service) or IIS Express, a *502.5 - Process Failure* is returned by the ASP.NET Core Module if the process can't start. For more information, see Troubleshoot ASP.NET Core on Azure App Service and IIS.

Database error page

The Database developer page exception filter AddDatabaseDeveloperPageExceptionFilter captures database-related exceptions that can be resolved by using Entity Framework Core migrations. When these exceptions occur, an HTML response is generated with details of possible actions to resolve the issue. This page is enabled only in the Development environment. The following code adds the Database developer page exception filter:

```
C#

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddDatabaseDeveloperPageExceptionFilter();
builder.Services.AddRazorPages();
```

Exception filters

In MVC apps, exception filters can be configured globally or on a per-controller or per-action basis. In Razor Pages apps, they can be configured globally or per page model. These filters handle any unhandled exceptions that occur during the execution of a controller action or another filter. For more information, see Filters in ASP.NET Core.

Exception filters are useful for trapping exceptions that occur within MVC actions, but they're not as flexible as the built-in exception handling middleware, UseExceptionHandler. We recommend using `UseExceptionHandler`, unless you need to perform error handling differently based on which MVC action is chosen.

Model state errors

For information about how to handle model state errors, see Model binding and Model validation.

Problem details

Problem Details are not the only response format to describe an HTTP API error, however, they are commonly used to report errors for HTTP APIs.

The problem details service implements the IProblemDetailsService interface, which supports creating problem details in ASP.NET Core. The AddProblemDetails(IServiceCollection) extension method on IServiceCollection registers the default `IProblemDetailsService` implementation.

In ASP.NET Core apps, the following middleware generates problem details HTTP responses when `AddProblemDetails` is called, except when the Accept request HTTP header doesn't include one of the content types supported by the registered IProblemDetailsWriter (default: `application/json`):

- ExceptionHandlerMiddleware: Generates a problem details response when a custom handler is not defined.
- StatusCodePagesMiddleware: Generates a problem details response by default.
- DeveloperExceptionPageMiddleware: Generates a problem details response in development when the `Accept` request HTTP header doesn't include `text/html`.

The following code configures the app to generate a problem details response for all HTTP client and server error responses that ***don't have body content yet***:

C#

```
builder.Services.AddProblemDetails();

var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler();
    app.UseHsts();
}

app.UseStatusCodePages();
```

The next section shows how to customize the problem details response body.

Customize problem details

The automatic creation of a `ProblemDetails` can be customized using any of the following options:

1. Use ProblemDetailsOptions.CustomizeProblemDetails
2. Use a custom IProblemDetailsWriter
3. Call the IProblemDetailsService in a middleware

`CustomizeProblemDetails` operation

The generated problem details can be customized using CustomizeProblemDetails, and the customizations are applied to all auto-generated problem details.

The following code uses ProblemDetailsOptions to set CustomizeProblemDetails:

C#

```
builder.Services.AddProblemDetails(options =>
    options.CustomizeProblemDetails = ctx =>
            ctx.ProblemDetails.Extensions.Add("nodeId",
Environment.MachineName));

var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler();
    app.UseHsts();
}

app.UseStatusCodePages();
```

For example, an HTTP Status 400 Bad Request endpoint result produces the following problem details response body:

JSON

```
{
  "type": "https://tools.ietf.org/html/rfc9110#section-15.5.1",
  "title": "Bad Request",
  "status": 400,
  "nodeId": "my-machine-name"
}
```

Custom `IProblemDetailsWriter`

An IProblemDetailsWriter implementation can be created for advanced customizations.

C#

```
public class SampleProblemDetailsWriter : IProblemDetailsWriter
{
    // Indicates that only responses with StatusCode == 400
    // are handled by this writer. All others are
    // handled by different registered writers if available.
    public bool CanWrite(ProblemDetailsContext context)
        => context.HttpContext.Response.StatusCode == 400;

    public ValueTask WriteAsync(ProblemDetailsContext context)
    {
        // Additional customizations.

        // Write to the response.
        var response = context.HttpContext.Response;
```

```
        return new
ValueTask(response.WriteAsJsonAsync(context.ProblemDetails));
    }
}
```

Note: When using a custom `IProblemDetailsWriter`, the custom `IProblemDetailsWriter` must be registered before calling AddRazorPages, AddControllers, AddControllersWithViews, or AddMvc:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddTransient<IProblemDetailsWriter,
SampleProblemDetailsWriter>();

var app = builder.Build();

// Middleware to handle writing problem details to the response.
app.Use(async (context, next) =>
{
    await next(context);
    var mathErrorFeature = context.Features.Get<MathErrorFeature>();
    if (mathErrorFeature is not null)
    {
        if (context.RequestServices.GetService<IProblemDetailsWriter>() is
            { } problemDetailsService)
        {

            if (problemDetailsService.CanWrite(new ProblemDetailsContext() {
HttpContext = context }))
            {
                (string Detail, string Type) details =
mathErrorFeature.MathError switch
                {
                    MathErrorType.DivisionByZeroError => ("Divison by zero
is not defined.",
                        "https://en.wikipedia.org/wiki/Division_by_zero"),
                    _ => ("Negative or complex numbers are not valid
input.",
                        "https://en.wikipedia.org/wiki/Square_root")
                };

                await problemDetailsService.WriteAsync(new
ProblemDetailsContext
                {
                    HttpContext = context,
                    ProblemDetails =
                    {
                        Title = "Bad Input",
                        Detail = details.Detail,
                        Type = details.Type
```

```
                    }
                });
            }
        }
    }
});

// /divide?numerator=2&denominator=4
app.MapGet("/divide", (HttpContext context, double numerator, double
denominator) =>
{
    if (denominator == 0)
    {
        var errorType = new MathErrorFeature
        {
            MathError = MathErrorType.DivisionByZeroError
        };
        context.Features.Set(errorType);
        return Results.BadRequest();
    }

    return Results.Ok(numerator / denominator);
});

// /squareroot?radicand=16
app.MapGet("/squareroot", (HttpContext context, double radicand) =>
{
    if (radicand < 0)
    {
        var errorType = new MathErrorFeature
        {
            MathError = MathErrorType.NegativeRadicandError
        };
        context.Features.Set(errorType);
        return Results.BadRequest();
    }

    return Results.Ok(Math.Sqrt(radicand));
});

app.Run();
```

Problem details from Middleware

An alternative approach to using ProblemDetailsOptions with CustomizeProblemDetails is to set the ProblemDetails in middleware. A problem details response can be written by calling IProblemDetailsService.WriteAsync:

```
C#
```

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddControllers();

builder.Services.AddProblemDetails();

var app = builder.Build();

app.UseHttpsRedirection();
app.UseStatusCodePages();

// Middleware to handle writing problem details to the response.
app.Use(async (context, next) =>
{
    await next(context);
    var mathErrorFeature = context.Features.Get<MathErrorFeature>();
    if (mathErrorFeature is not null)
    {
        if (context.RequestServices.GetService<IProblemDetailsService>() is
                                                                { }
problemDetailsService)
        {
            (string Detail, string Type) details =
mathErrorFeature.MathError switch
            {
                MathErrorType.DivisionByZeroError => ("Divison by zero is
not defined.",
                "https://en.wikipedia.org/wiki/Division_by_zero"),
                _ => ("Negative or complex numbers are not valid input.",
                "https://en.wikipedia.org/wiki/Square_root")
            };

            await problemDetailsService.WriteAsync(new ProblemDetailsContext
            {
                HttpContext = context,
                ProblemDetails =
                {
                    Title = "Bad Input",
                    Detail = details.Detail,
                    Type = details.Type
                }
            });
        }
    }
});

// /divide?numerator=2&denominator=4
app.MapGet("/divide", (HttpContext context, double numerator, double
denominator) =>
{
    if (denominator == 0)
    {
        var errorType = new MathErrorFeature { MathError =
```

```
MathErrorType.DivisionByZeroError };
        context.Features.Set(errorType);
        return Results.BadRequest();
    }

    return Results.Ok(numerator / denominator);
});

// /squareroot?radicand=16
app.MapGet("/squareroot", (HttpContext context, double radicand) =>
{
    if (radicand < 0)
    {
        var errorType = new MathErrorFeature { MathError =

MathErrorType.NegativeRadicandError };
        context.Features.Set(errorType);
        return Results.BadRequest();
    }

    return Results.Ok(Math.Sqrt(radicand));
});

app.MapControllers();

app.Run();
```

In the preceding code, the minimal API endpoints `/divide` and `/squareroot` return the expected custom problem response on error input.

The API controller endpoints return the default problem response on error input, not the custom problem response. The default problem response is returned because the API controller has written to the response stream, Problem details for error status codes, before IProblemDetailsService.WriteAsync is called and the response is **not** written again.

The following `ValuesController` returns BadRequestResult, which writes to the response stream and therefore prevents the custom problem response from being returned.

C#

```
[Route("api/[controller]/[action]")]
[ApiController]
public class ValuesController : ControllerBase
{
    // /api/values/divide/1/2
    [HttpGet("{Numerator}/{Denominator}")]
    public IActionResult Divide(double Numerator, double Denominator)
    {
```

```
        if (Denominator == 0)
        {
            var errorType = new MathErrorFeature
            {
                MathError = MathErrorType.DivisionByZeroError
            };
            HttpContext.Features.Set(errorType);
            return BadRequest();
        }

        return Ok(Numerator / Denominator);
    }

    // /api/values/squareroot/4
    [HttpGet("{radicand}")]
    public IActionResult Squareroot(double radicand)
    {
        if (radicand < 0)
        {
            var errorType = new MathErrorFeature
            {
                MathError = MathErrorType.NegativeRadicandError
            };
            HttpContext.Features.Set(errorType);
            return BadRequest();
        }
        return Ok(Math.Sqrt(radicand));
    }

}
```

The following `Values3Controller` returns ControllerBase.Problem so the expected custom problem result is returned:

C#

```
[Route("api/[controller]/[action]")]
[ApiController]
public class Values3Controller : ControllerBase
{
    // /api/values3/divide/1/2
    [HttpGet("{Numerator}/{Denominator}")]
    public IActionResult Divide(double Numerator, double Denominator)
    {
        if (Denominator == 0)
        {
            var errorType = new MathErrorFeature
            {
                MathError = MathErrorType.DivisionByZeroError
            };
            HttpContext.Features.Set(errorType);
```

```
            return Problem(
                title: "Bad Input",
                detail: "Divison by zero is not defined.",
                type: "https://en.wikipedia.org/wiki/Division_by_zero",
                statusCode: StatusCodes.Status400BadRequest
                );
        }

        return Ok(Numerator / Denominator);
    }

    // /api/values3/squareroot/4
    [HttpGet("{radicand}")]
    public IActionResult Squareroot(double radicand)
    {
        if (radicand < 0)
        {
            var errorType = new MathErrorFeature
            {
                MathError = MathErrorType.NegativeRadicandError
            };
            HttpContext.Features.Set(errorType);
            return Problem(
                title: "Bad Input",
                detail: "Negative or complex numbers are not valid input.",
                type: "https://en.wikipedia.org/wiki/Square_root",
                statusCode: StatusCodes.Status400BadRequest
                );
        }

        return Ok(Math.Sqrt(radicand));
    }

}
```

Produce a ProblemDetails payload for exceptions

Consider the following app:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddControllers();
builder.Services.AddProblemDetails();

var app = builder.Build();

app.UseExceptionHandler();
app.UseStatusCodePages();
```

```
if (app.Environment.IsDevelopment())
{
    app.UseDeveloperExceptionPage();
}

app.MapControllers();
app.Run();
```

In non-development environments, when an exception occurs, the following is a standard ProblemDetails response that is returned to the client:

JSON

```
{
"type":"https://tools.ietf.org/html/rfc7231#section-6.6.1",
"title":"An error occurred while processing your request.",
"status":500,"traceId":"00-b644<snip>-00"
}
```

For most apps, the preceding code is all that's needed for exceptions. However, the following section shows how to get more detailed problem responses.

An alternative to a custom exception handler page is to provide a lambda to UseExceptionHandler. Using a lambda allows access to the error and writing a problem details response with IProblemDetailsService.WriteAsync:

C#

```
using Microsoft.AspNetCore.Diagnostics;
using static System.Net.Mime.MediaTypeNames;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddControllers();
builder.Services.AddProblemDetails();

var app = builder.Build();

app.UseExceptionHandler();
app.UseStatusCodePages();

if (app.Environment.IsDevelopment())
{
    app.UseDeveloperExceptionPage();
}
else
{
    app.UseExceptionHandler(exceptionHandlerApp =>
    {
```

```
        exceptionHandlerApp.Run(async context =>
        {
            context.Response.StatusCode =
StatusCodes.Status500InternalServerError;
            context.Response.ContentType = Text.Plain;

            var title = "Bad Input";
            var detail = "Invalid input";
            var type = "https://errors.example.com/badInput";

            if (context.RequestServices.GetService<IProblemDetailsService>()
is
                { } problemDetailsService)
            {
                var exceptionHandlerFeature =
                context.Features.Get<IExceptionHandlerFeature>();

                var exceptionType = exceptionHandlerFeature?.Error;
                if (exceptionType != null &&
                   exceptionType.Message.Contains("infinity"))
                {
                    title = "Argument exception";
                    detail = "Invalid input";
                    type = "https://errors.example.com/argumentException";
                }

                await problemDetailsService.WriteAsync(new
ProblemDetailsContext
                {
                    HttpContext = context,
                    ProblemDetails =
                {
                    Title = title,
                    Detail = detail,
                    Type = type
                }
                });
            }
        });
    });
}

app.MapControllers();
app.Run();
```

> ⚠ **Warning**
>
> Do **not** serve sensitive error information to clients. Serving errors is a security risk.

An alternative approach to generate problem details is to use the third-party NuGet package Hellang.Middleware.ProblemDetails that can be used to map exceptions and

client errors to problem details.

Make HTTP requests using IHttpClientFactory in ASP.NET Core

Article • 07/26/2024

>
> For the current release, see the .NET 8 version of this article.

By Kirk Larkin, Steve Gordon, Glenn Condron, and Ryan Nowak.

An IHttpClientFactory can be registered and used to configure and create HttpClient instances in an app. `IHttpClientFactory` offers the following benefits:

- Provides a central location for naming and configuring logical `HttpClient` instances. For example, a client named *github* could be registered and configured to access GitHub. A default client can be registered for general access.
- Codifies the concept of outgoing middleware via delegating handlers in `HttpClient`. Provides extensions for Polly-based middleware to take advantage of delegating handlers in `HttpClient`.
- Manages the pooling and lifetime of underlying `HttpClientMessageHandler` instances. Automatic management avoids common DNS (Domain Name System) problems that occur when manually managing `HttpClient` lifetimes.
- Adds a configurable logging experience (via `ILogger`) for all requests sent through clients created by the factory.

The sample code in this topic version uses System.Text.Json to deserialize JSON content returned in HTTP responses. For samples that use `Json.NET` and `ReadAsAsync<T>`, use the version selector to select a 2.x version of this topic.

Consumption patterns

There are several ways `IHttpClientFactory` can be used in an app:

- Basic usage
- Named clients

- Typed clients
- Generated clients

The best approach depends upon the app's requirements.

Basic usage

Register `IHttpClientFactory` by calling `AddHttpClient` in `Program.cs`:

C#

```
var builder = WebApplication.CreateBuilder(args);

// Add services to the container.
builder.Services.AddHttpClient();
```

An `IHttpClientFactory` can be requested using dependency injection (DI). The following code uses `IHttpClientFactory` to create an `HttpClient` instance:

C#

```
public class BasicModel : PageModel
{
    private readonly IHttpClientFactory _httpClientFactory;

    public BasicModel(IHttpClientFactory httpClientFactory) =>
        _httpClientFactory = httpClientFactory;

    public IEnumerable<GitHubBranch>? GitHubBranches { get; set; }

    public async Task OnGet()
    {
        var httpRequestMessage = new HttpRequestMessage(
            HttpMethod.Get,
            "https://api.github.com/repos/dotnet/AspNetCore.Docs/branches")
        {
            Headers =
            {
                { HeaderNames.Accept, "application/vnd.github.v3+json" },
                { HeaderNames.UserAgent, "HttpRequestsSample" }
            }
        };

        var httpClient = _httpClientFactory.CreateClient();
        var httpResponseMessage = await
httpClient.SendAsync(httpRequestMessage);

        if (httpResponseMessage.IsSuccessStatusCode)
        {
            using var contentStream =
```

```
                await httpResponseMessage.Content.ReadAsStreamAsync();

            GitHubBranches = await JsonSerializer.DeserializeAsync
                <IEnumerable<GitHubBranch>>(contentStream);
        }
    }
}
```

Using `IHttpClientFactory` like in the preceding example is a good way to refactor an existing app. It has no impact on how `HttpClient` is used. In places where `HttpClient` instances are created in an existing app, replace those occurrences with calls to CreateClient.

Named clients

Named clients are a good choice when:

- The app requires many distinct uses of `HttpClient`.
- Many `HttpClient`s have different configuration.

Specify configuration for a named `HttpClient` during its registration in `Program.cs`:

C#

```
builder.Services.AddHttpClient("GitHub", httpClient =>
{
    httpClient.BaseAddress = new Uri("https://api.github.com/");

    // using Microsoft.Net.Http.Headers;
    // The GitHub API requires two headers.
    httpClient.DefaultRequestHeaders.Add(
        HeaderNames.Accept, "application/vnd.github.v3+json");
    httpClient.DefaultRequestHeaders.Add(
        HeaderNames.UserAgent, "HttpRequestsSample");
});
```

In the preceding code the client is configured with:

- The base address `https://api.github.com/`.
- Two headers required to work with the GitHub API.

CreateClient

Each time CreateClient is called:

- A new instance of `HttpClient` is created.

- The configuration action is called.

To create a named client, pass its name into `CreateClient`:

C#

```
public class NamedClientModel : PageModel
{
    private readonly IHttpClientFactory _httpClientFactory;

    public NamedClientModel(IHttpClientFactory httpClientFactory) =>
        _httpClientFactory = httpClientFactory;

    public IEnumerable<GitHubBranch>? GitHubBranches { get; set; }

    public async Task OnGet()
    {
        var httpClient = _httpClientFactory.CreateClient("GitHub");
        var httpResponseMessage = await httpClient.GetAsync(
            "repos/dotnet/AspNetCore.Docs/branches");

        if (httpResponseMessage.IsSuccessStatusCode)
        {
            using var contentStream =
                await httpResponseMessage.Content.ReadAsStreamAsync();

            GitHubBranches = await JsonSerializer.DeserializeAsync
                <IEnumerable<GitHubBranch>>(contentStream);
        }
    }
}
```

In the preceding code, the request doesn't need to specify a hostname. The code can pass just the path, since the base address configured for the client is used.

Typed clients

Typed clients:

- Provide the same capabilities as named clients without the need to use strings as keys.
- Provides IntelliSense and compiler help when consuming clients.
- Provide a single location to configure and interact with a particular `HttpClient`. For example, a single typed client might be used:
  - For a single backend endpoint.
  - To encapsulate all logic dealing with the endpoint.
- Work with DI and can be injected where required in the app.

A typed client accepts an `HttpClient` parameter in its constructor:

C#

```
public class GitHubService
{
    private readonly HttpClient _httpClient;

    public GitHubService(HttpClient httpClient)
    {
        _httpClient = httpClient;

        _httpClient.BaseAddress = new Uri("https://api.github.com/");

        // using Microsoft.Net.Http.Headers;
        // The GitHub API requires two headers.
        _httpClient.DefaultRequestHeaders.Add(
            HeaderNames.Accept, "application/vnd.github.v3+json");
        _httpClient.DefaultRequestHeaders.Add(
            HeaderNames.UserAgent, "HttpRequestsSample");
    }

    public async Task<IEnumerable<GitHubBranch>?>
GetAspNetCoreDocsBranchesAsync() =>
        await _httpClient.GetFromJsonAsync<IEnumerable<GitHubBranch>>(
            "repos/dotnet/AspNetCore.Docs/branches");
}
```

In the preceding code:

- The configuration is moved into the typed client.
- The provided `HttpClient` instance is stored as a private field.

API-specific methods can be created that expose `HttpClient` functionality. For example, the `GetAspNetCoreDocsBranches` method encapsulates code to retrieve docs GitHub branches.

The following code calls AddHttpClient in `Program.cs` to register the `GitHubService` typed client class:

C#

```
builder.Services.AddHttpClient<GitHubService>();
```

The typed client is registered as transient with DI. In the preceding code, `AddHttpClient` registers `GitHubService` as a transient service. This registration uses a factory method to:

1. Create an instance of `HttpClient`.

2. Create an instance of `GitHubService`, passing in the instance of `HttpClient` to its constructor.

The typed client can be injected and consumed directly:

C#

```
public class TypedClientModel : PageModel
{
    private readonly GitHubService _gitHubService;

    public TypedClientModel(GitHubService gitHubService) =>
        _gitHubService = gitHubService;

    public IEnumerable<GitHubBranch>? GitHubBranches { get; set; }

    public async Task OnGet()
    {
        try
        {
            GitHubBranches = await
_gitHubService.GetAspNetCoreDocsBranchesAsync();
        }
        catch (HttpRequestException)
        {
            // ...
        }
    }
}
```

The configuration for a typed client can also be specified during its registration in `Program.cs`, rather than in the typed client's constructor:

C#

```
builder.Services.AddHttpClient<GitHubService>(httpClient =>
{
    httpClient.BaseAddress = new Uri("https://api.github.com/");

    // ...
});
```

Generated clients

`IHttpClientFactory` can be used in combination with third-party libraries such as Refit. Refit is a REST library for .NET. It converts REST APIs into live interfaces. Call `AddRefitClient` to generate a dynamic implementation of an interface, which uses `HttpClient` to make the external HTTP calls.

A custom interface represents the external API:

```
C#

public interface IGitHubClient
{
    [Get("/repos/dotnet/AspNetCore.Docs/branches")]
    Task<IEnumerable<GitHubBranch>> GetAspNetCoreDocsBranchesAsync();
}
```

Call `AddRefitClient` to generate the dynamic implementation and then call `ConfigureHttpClient` to configure the underlying `HttpClient`:

```
C#

builder.Services.AddRefitClient<IGitHubClient>()
    .ConfigureHttpClient(httpClient =>
    {
        httpClient.BaseAddress = new Uri("https://api.github.com/");

        // using Microsoft.Net.Http.Headers;
        // The GitHub API requires two headers.
        httpClient.DefaultRequestHeaders.Add(
            HeaderNames.Accept, "application/vnd.github.v3+json");
        httpClient.DefaultRequestHeaders.Add(
            HeaderNames.UserAgent, "HttpRequestsSample");
    });
```

Use DI to access the dynamic implementation of `IGitHubClient`:

```
C#

public class RefitModel : PageModel
{
    private readonly IGitHubClient _gitHubClient;

    public RefitModel(IGitHubClient gitHubClient) =>
        _gitHubClient = gitHubClient;

    public IEnumerable<GitHubBranch>? GitHubBranches { get; set; }

    public async Task OnGet()
    {
        try
        {
            GitHubBranches = await
_gitHubClient.GetAspNetCoreDocsBranchesAsync();
        }
        catch (ApiException)
        {
```

```
            // ...
        }
    }
}
```

Make POST, PUT, and DELETE requests

In the preceding examples, all HTTP requests use the GET HTTP verb. `HttpClient` also supports other HTTP verbs, including:

- POST
- PUT
- DELETE
- PATCH

For a complete list of supported HTTP verbs, see HttpMethod.

The following example shows how to make an HTTP POST request:

C#

```
public async Task CreateItemAsync(TodoItem todoItem)
{
    var todoItemJson = new StringContent(
        JsonSerializer.Serialize(todoItem),
        Encoding.UTF8,
        Application.Json); // using static System.Net.Mime.MediaTypeNames;

    using var httpResponseMessage =
        await _httpClient.PostAsync("/api/TodoItems", todoItemJson);

    httpResponseMessage.EnsureSuccessStatusCode();
}
```

In the preceding code, the `CreateItemAsync` method:

- Serializes the `TodoItem` parameter to JSON using `System.Text.Json`.
- Creates an instance of StringContent to package the serialized JSON for sending in the HTTP request's body.
- Calls PostAsync to send the JSON content to the specified URL. This is a relative URL that gets added to the HttpClient.BaseAddress.
- Calls EnsureSuccessStatusCode to throw an exception if the response status code doesn't indicate success.

`HttpClient` also supports other types of content. For example, MultipartContent and StreamContent. For a complete list of supported content, see HttpContent.

The following example shows an HTTP PUT request:

C#

```
public async Task SaveItemAsync(TodoItem todoItem)
{
    var todoItemJson = new StringContent(
        JsonSerializer.Serialize(todoItem),
        Encoding.UTF8,
        Application.Json);

    using var httpResponseMessage =
        await _httpClient.PutAsync($"/api/TodoItems/{todoItem.Id}",
todoItemJson);

    httpResponseMessage.EnsureSuccessStatusCode();
}
```

The preceding code is similar to the POST example. The `SaveItemAsync` method calls PutAsync instead of `PostAsync`.

The following example shows an HTTP DELETE request:

C#

```
public async Task DeleteItemAsync(long itemId)
{
    using var httpResponseMessage =
        await _httpClient.DeleteAsync($"/api/TodoItems/{itemId}");

    httpResponseMessage.EnsureSuccessStatusCode();
}
```

In the preceding code, the `DeleteItemAsync` method calls DeleteAsync. Because HTTP DELETE requests typically contain no body, the `DeleteAsync` method doesn't provide an overload that accepts an instance of `HttpContent`.

To learn more about using different HTTP verbs with `HttpClient`, see HttpClient.

Outgoing request middleware

`HttpClient` has the concept of delegating handlers that can be linked together for outgoing HTTP requests. `IHttpClientFactory`:

- Simplifies defining the handlers to apply for each named client.
- Supports registration and chaining of multiple handlers to build an outgoing request middleware pipeline. Each of these handlers is able to perform work before and after the outgoing request. This pattern:
  - Is similar to the inbound middleware pipeline in ASP.NET Core.
  - Provides a mechanism to manage cross-cutting concerns around HTTP requests, such as:
    - caching
    - error handling
    - serialization
    - logging

To create a delegating handler:

- Derive from DelegatingHandler.
- Override SendAsync. Execute code before passing the request to the next handler in the pipeline:

C#

```
public class ValidateHeaderHandler : DelegatingHandler
{
    protected override async Task<HttpResponseMessage> SendAsync(
        HttpRequestMessage request, CancellationToken cancellationToken)
    {
        if (!request.Headers.Contains("X-API-KEY"))
        {
            return new HttpResponseMessage(HttpStatusCode.BadRequest)
            {
                Content = new StringContent(
                    "The API key header X-API-KEY is required.")
            };
        }

        return await base.SendAsync(request, cancellationToken);
    }
}
```

The preceding code checks if the `X-API-KEY` header is in the request. If `X-API-KEY` is missing, BadRequest is returned.

More than one handler can be added to the configuration for an `HttpClient` with Microsoft.Extensions.DependencyInjection.HttpClientBuilderExtensions.AddHttpMessageHandler:

C#

```
builder.Services.AddTransient<ValidateHeaderHandler>();

builder.Services.AddHttpClient("HttpMessageHandler")
    .AddHttpMessageHandler<ValidateHeaderHandler>();
```

In the preceding code, the `ValidateHeaderHandler` is registered with DI. Once registered, AddHttpMessageHandler can be called, passing in the type for the handler.

Multiple handlers can be registered in the order that they should execute. Each handler wraps the next handler until the final `HttpClientHandler` executes the request:

C#

```
builder.Services.AddTransient<SampleHandler1>();
builder.Services.AddTransient<SampleHandler2>();

builder.Services.AddHttpClient("MultipleHttpMessageHandlers")
    .AddHttpMessageHandler<SampleHandler1>()
    .AddHttpMessageHandler<SampleHandler2>();
```

In the preceding code, `SampleHandler1` runs first, before `SampleHandler2`.

Use DI in outgoing request middleware

When `IHttpClientFactory` creates a new delegating handler, it uses DI to fulfill the handler's constructor parameters. `IHttpClientFactory` creates a **separate** DI scope for each handler, which can lead to surprising behavior when a handler consumes a *scoped* service.

For example, consider the following interface and its implementation, which represents a task as an operation with an identifier, `OperationId`:

C#

```
public interface IOperationScoped
{
    string OperationId { get; }
}

public class OperationScoped : IOperationScoped
{
    public string OperationId { get; } = Guid.NewGuid().ToString()[^4..];
}
```

As its name suggests, `IOperationScoped` is registered with DI using a *scoped* lifetime:

C#

```
builder.Services.AddScoped<IOperationScoped, OperationScoped>();
```

The following delegating handler consumes and uses `IOperationScoped` to set the `X-OPERATION-ID` header for the outgoing request:

C#

```
public class OperationHandler : DelegatingHandler
{
    private readonly IOperationScoped _operationScoped;

    public OperationHandler(IOperationScoped operationScoped) =>
        _operationScoped = operationScoped;

    protected override async Task<HttpResponseMessage> SendAsync(
        HttpRequestMessage request, CancellationToken cancellationToken)
    {
        request.Headers.Add("X-OPERATION-ID", _operationScoped.OperationId);

        return await base.SendAsync(request, cancellationToken);
    }
}
```

In the HttpRequestsSample download, navigate to `/Operation` and refresh the page. The request scope value changes for each request, but the handler scope value only changes every 5 seconds.

Handlers can depend upon services of any scope. Services that handlers depend upon are disposed when the handler is disposed.

Use one of the following approaches to share per-request state with message handlers:

- Pass data into the handler using HttpRequestMessage.Options.
- Use IHttpContextAccessor to access the current request.
- Create a custom AsyncLocal<T> storage object to pass the data.

Use Polly-based handlers

`IHttpClientFactory` integrates with the third-party library Polly. Polly is a comprehensive resilience and transient fault-handling library for .NET. It allows developers to express policies such as Retry, Circuit Breaker, Timeout, Bulkhead Isolation, and Fallback in a fluent and thread-safe manner.

Extension methods are provided to enable the use of Polly policies with configured `HttpClient` instances. The Polly extensions support adding Polly-based handlers to clients. Polly requires the Microsoft.Extensions.Http.Polly NuGet package.

Handle transient faults

Faults typically occur when external HTTP calls are transient. AddTransientHttpErrorPolicy allows a policy to be defined to handle transient errors. Policies configured with `AddTransientHttpErrorPolicy` handle the following responses:

- HttpRequestException
- HTTP 5xx
- HTTP 408

`AddTransientHttpErrorPolicy` provides access to a `PolicyBuilder` object configured to handle errors representing a possible transient fault:

C#

```
builder.Services.AddHttpClient("PollyWaitAndRetry")
    .AddTransientHttpErrorPolicy(policyBuilder =>
        policyBuilder.WaitAndRetryAsync(
            3, retryNumber => TimeSpan.FromMilliseconds(600)));
```

In the preceding code, a `WaitAndRetryAsync` policy is defined. Failed requests are retried up to three times with a delay of 600 ms between attempts.

Dynamically select policies

Extension methods are provided to add Polly-based handlers, for example, AddPolicyHandler. The following `AddPolicyHandler` overload inspects the request to decide which policy to apply:

C#

```
var timeoutPolicy = Policy.TimeoutAsync<HttpResponseMessage>(
    TimeSpan.FromSeconds(10));
var longTimeoutPolicy = Policy.TimeoutAsync<HttpResponseMessage>(
    TimeSpan.FromSeconds(30));

builder.Services.AddHttpClient("PollyDynamic")
    .AddPolicyHandler(httpRequestMessage =>
        httpRequestMessage.Method == HttpMethod.Get ? timeoutPolicy :
longTimeoutPolicy);
```

In the preceding code, if the outgoing request is an HTTP GET, a 10-second timeout is applied. For any other HTTP method, a 30-second timeout is used.

Add multiple Polly handlers

It's common to nest Polly policies:

C#

```
builder.Services.AddHttpClient("PollyMultiple")
    .AddTransientHttpErrorPolicy(policyBuilder =>
        policyBuilder.RetryAsync(3))
    .AddTransientHttpErrorPolicy(policyBuilder =>
        policyBuilder.CircuitBreakerAsync(5, TimeSpan.FromSeconds(30)));
```

In the preceding example:

- Two handlers are added.
- The first handler uses AddTransientHttpErrorPolicy to add a retry policy. Failed requests are retried up to three times.
- The second `AddTransientHttpErrorPolicy` call adds a circuit breaker policy. Further external requests are blocked for 30 seconds if 5 failed attempts occur sequentially. Circuit breaker policies are stateful. All calls through this client share the same circuit state.

Add policies from the Polly registry

An approach to managing regularly used policies is to define them once and register them with a `PolicyRegistry`. For example:

C#

```
var timeoutPolicy = Policy.TimeoutAsync<HttpResponseMessage>(
    TimeSpan.FromSeconds(10));
var longTimeoutPolicy = Policy.TimeoutAsync<HttpResponseMessage>(
    TimeSpan.FromSeconds(30));

var policyRegistry = builder.Services.AddPolicyRegistry();

policyRegistry.Add("Regular", timeoutPolicy);
policyRegistry.Add("Long", longTimeoutPolicy);

builder.Services.AddHttpClient("PollyRegistryRegular")
    .AddPolicyHandlerFromRegistry("Regular");
```

```
builder.Services.AddHttpClient("PollyRegistryLong")
    .AddPolicyHandlerFromRegistry("Long");
```

In the preceding code:

- Two policies, `Regular` and `Long`, are added to the Polly registry.
- AddPolicyHandlerFromRegistry configures individual named clients to use these policies from the Polly registry.

For more information on `IHttpClientFactory` and Polly integrations, see the Polly wiki.

HttpClient and lifetime management

A new `HttpClient` instance is returned each time `CreateClient` is called on the `IHttpClientFactory`. An HttpMessageHandler is created per named client. The factory manages the lifetimes of the `HttpMessageHandler` instances.

`IHttpClientFactory` pools the `HttpMessageHandler` instances created by the factory to reduce resource consumption. An `HttpMessageHandler` instance may be reused from the pool when creating a new `HttpClient` instance if its lifetime hasn't expired.

Pooling of handlers is desirable as each handler typically manages its own underlying HTTP connections. Creating more handlers than necessary can result in connection delays. Some handlers also keep connections open indefinitely, which can prevent the handler from reacting to DNS (Domain Name System) changes.

The default handler lifetime is two minutes. The default value can be overridden on a per named client basis:

C#

```
builder.Services.AddHttpClient("HandlerLifetime")
    .SetHandlerLifetime(TimeSpan.FromMinutes(5));
```

`HttpClient` instances can generally be treated as .NET objects **not** requiring disposal. Disposal cancels outgoing requests and guarantees the given `HttpClient` instance can't be used after calling Dispose. `IHttpClientFactory` tracks and disposes resources used by `HttpClient` instances.

Keeping a single `HttpClient` instance alive for a long duration is a common pattern used before the inception of `IHttpClientFactory`. This pattern becomes unnecessary after migrating to `IHttpClientFactory`.

Alternatives to IHttpClientFactory

Using `IHttpClientFactory` in a DI-enabled app avoids:

- Resource exhaustion problems by pooling `HttpMessageHandler` instances.
- Stale DNS problems by cycling `HttpMessageHandler` instances at regular intervals.

There are alternative ways to solve the preceding problems using a long-lived SocketsHttpHandler instance.

- Create an instance of `SocketsHttpHandler` when the app starts and use it for the life of the app.
- Configure PooledConnectionLifetime to an appropriate value based on DNS refresh times.
- Create `HttpClient` instances using `new HttpClient(handler, disposeHandler: false)` as needed.

The preceding approaches solve the resource management problems that `IHttpClientFactory` solves in a similar way.

- The `SocketsHttpHandler` shares connections across `HttpClient` instances. This sharing prevents socket exhaustion.
- The `SocketsHttpHandler` cycles connections according to `PooledConnectionLifetime` to avoid stale DNS problems.

Logging

Clients created via `IHttpClientFactory` record log messages for all requests. Enable the appropriate information level in the logging configuration to see the default log messages. Additional logging, such as the logging of request headers, is only included at trace level.

The log category used for each client includes the name of the client. A client named *MyNamedClient*, for example, logs messages with a category of "System.Net.Http.HttpClient.**MyNamedClient**.LogicalHandler". Messages suffixed with *LogicalHandler* occur outside the request handler pipeline. On the request, messages are logged before any other handlers in the pipeline have processed it. On the response, messages are logged after any other pipeline handlers have received the response.

Logging also occurs inside the request handler pipeline. In the *MyNamedClient* example, those messages are logged with the log category "System.Net.Http.HttpClient.**MyNamedClient**.ClientHandler". For the request, this occurs

after all other handlers have run and immediately before the request is sent. On the response, this logging includes the state of the response before it passes back through the handler pipeline.

Enabling logging outside and inside the pipeline enables inspection of the changes made by the other pipeline handlers. This may include changes to request headers or to the response status code.

Including the name of the client in the log category enables log filtering for specific named clients.

Configure the HttpMessageHandler

It may be necessary to control the configuration of the inner `HttpMessageHandler` used by a client.

An `IHttpClientBuilder` is returned when adding named or typed clients. The ConfigurePrimaryHttpMessageHandler extension method can be used to define a delegate. The delegate is used to create and configure the primary `HttpMessageHandler` used by that client:

C#

```
builder.Services.AddHttpClient("ConfiguredHttpMessageHandler")
    .ConfigurePrimaryHttpMessageHandler(() =>
        new HttpClientHandler
        {
            AllowAutoRedirect = true,
            UseDefaultCredentials = true
        });
```

Cookies

The pooled `HttpMessageHandler` instances results in `CookieContainer` objects being shared. Unanticipated `CookieContainer` object sharing often results in incorrect code. For apps that require cookies, consider either:

- Disabling automatic cookie handling
- Avoiding `IHttpClientFactory`

Call ConfigurePrimaryHttpMessageHandler to disable automatic cookie handling:

C#

```
builder.Services.AddHttpClient("NoAutomaticCookies")
    .ConfigurePrimaryHttpMessageHandler(() =>
        new HttpClientHandler
        {
            UseCookies = false
        });
```

Use IHttpClientFactory in a console app

In a console app, add the following package references to the project:

- Microsoft.Extensions.Hosting
- Microsoft.Extensions.Http

In the following example:

- IHttpClientFactory and `GitHubService` are registered in the Generic Host's service container.
- `GitHubService` is requested from DI, which in-turn requests an instance of `IHttpClientFactory`.
- `GitHubService` uses `IHttpClientFactory` to create an instance of `HttpClient`, which it uses to retrieve docs GitHub branches.

C#

```
using System.Text.Json;
using System.Text.Json.Serialization;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.Extensions.Hosting;
using Microsoft.Extensions.Logging;

var host = new HostBuilder()
    .ConfigureServices(services =>
    {
        services.AddHttpClient();
        services.AddTransient<GitHubService>();
    })
    .Build();

try
{
    var gitHubService = host.Services.GetRequiredService<GitHubService>();
    var gitHubBranches = await
gitHubService.GetAspNetCoreDocsBranchesAsync();

    Console.WriteLine($"{gitHubBranches?.Count() ?? 0} GitHub Branches");

    if (gitHubBranches is not null)
```

```
    {
        foreach (var gitHubBranch in gitHubBranches)
        {
            Console.WriteLine($"- {gitHubBranch.Name}");
        }
    }
}
catch (Exception ex)
{
    host.Services.GetRequiredService<ILogger<Program>>()
        .LogError(ex, "Unable to load branches from GitHub.");
}

public class GitHubService
{
    private readonly IHttpClientFactory _httpClientFactory;

    public GitHubService(IHttpClientFactory httpClientFactory) =>
        _httpClientFactory = httpClientFactory;

    public async Task<IEnumerable<GitHubBranch>?>
GetAspNetCoreDocsBranchesAsync()
    {
        var httpRequestMessage = new HttpRequestMessage(
            HttpMethod.Get,
            "https://api.github.com/repos/dotnet/AspNetCore.Docs/branches")
        {
            Headers =
            {
                { "Accept", "application/vnd.github.v3+json" },
                { "User-Agent", "HttpRequestsConsoleSample" }
            }
        };

        var httpClient = _httpClientFactory.CreateClient();
        var httpResponseMessage = await
httpClient.SendAsync(httpRequestMessage);

        httpResponseMessage.EnsureSuccessStatusCode();

        using var contentStream =
            await httpResponseMessage.Content.ReadAsStreamAsync();

        return await JsonSerializer.DeserializeAsync
            <IEnumerable<GitHubBranch>>(contentStream);
    }
}

public record GitHubBranch(
    [property: JsonPropertyName("name")] string Name);
```

Header propagation middleware

Header propagation is an ASP.NET Core middleware to propagate HTTP headers from the incoming request to the outgoing `HttpClient` requests. To use header propagation:

- Install the Microsoft.AspNetCore.HeaderPropagation package.
- Configure the `HttpClient` and middleware pipeline in `Program.cs`:

```
C#

// Add services to the container.
builder.Services.AddControllers();

builder.Services.AddHttpClient("PropagateHeaders")
    .AddHeaderPropagation();

builder.Services.AddHeaderPropagation(options =>
{
    options.Headers.Add("X-TraceId");
});

var app = builder.Build();

// Configure the HTTP request pipeline.
app.UseHttpsRedirection();

app.UseHeaderPropagation();

app.MapControllers();
```

- Make outbound requests using the configured `HttpClient` instance, which includes the added headers.

Static files in ASP.NET Core

Article • 11/05/2024

> **ⓘ Important**
>

>
> For the current release, see the **.NET 8 version of this article**.

By Rick Anderson

Static files, such as HTML, CSS, images, and JavaScript, are assets an ASP.NET Core app serves directly to clients by default.

For Blazor static files guidance, which adds to or supersedes the guidance in this article, see ASP.NET Core Blazor static files.

Serve static files

Static files are stored within the project's web root directory. The default directory is `{content root}/wwwroot`, but it can be changed with the UseWebRoot method. For more information, see Content root and Web root.

The CreateBuilder method sets the content root to the current directory:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();
builder.Services.AddControllersWithViews();

var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.MapStaticAssets();
```

```
app.UseAuthorization();

app.MapDefaultControllerRoute().WithStaticAssets();
app.MapRazorPages().WithStaticAssets();

app.Run();
```

Static files are accessible via a path relative to the web root. For example, the **Web Application** project templates contain several folders within the `wwwroot` folder:

- `wwwroot`
  - `css`
  - `js`
  - `lib`

Consider an app with the `wwwroot/images/MyImage.jpg` file. The URI format to access a file in the `images` folder is `https://<hostname>/images/<image_file_name>`. For example, `https://localhost:5001/images/MyImage.jpg`

MapStaticAssets

Creating performant web apps requires optimizing asset delivery to the browser. Possible optimizations include:

- Serve a given asset once until the file changes or the browser clears its cache. Set the ETag header.
- Prevent the browser from using old or stale assets after an app is updated. Set the Last-Modified header.
- Set up proper caching headers.
- Use caching middleware.
- Serve compressed versions of the assets when possible.
- Use a CDN to serve the assets closer to the user.
- Minimize the size of assets served to the browser. This optimization doesn't include minification.

MapStaticAssets are routing endpoint conventions that optimize the delivery of static assets in an app. It's designed to work with all UI frameworks, including Blazor, Razor Pages, and MVC.

UseStaticFiles also serves static files, but it doesn't provide the same level of optimization as `MapStaticAssets`. For a comparison of `UseStaticFiles` and `MapStaticAssets`, see Optimizing static web asset delivery .

Serve files in web root

The default web app templates call the MapStaticAssets method in `Program.cs`, which enables static files to be served:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();
builder.Services.AddControllersWithViews();

var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.MapStaticAssets();

app.UseAuthorization();

app.MapDefaultControllerRoute().WithStaticAssets();
app.MapRazorPages().WithStaticAssets();

app.Run();
```

The parameterless `UseStaticFiles` method overload marks the files in web root as servable. The following markup references `wwwroot/images/MyImage.jpg`:

HTML

```
<img src="~/images/MyImage.jpg" class="img" alt="My image" />
```

In the preceding markup, the tilde character `~` points to the web root.

Serve files outside of web root

Consider a directory hierarchy in which the static files to be served reside outside of the web root:

- `wwwroot`
  - `css`
  - `images`

    - `js`
- `MyStaticFiles`
    - `images`
        - `red-rose.jpg`

A request can access the `red-rose.jpg` file by configuring the Static File Middleware as follows:

C#

```
using Microsoft.Extensions.FileProviders;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();
builder.Services.AddControllersWithViews();

var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();

app.UseStaticFiles();    //Serve files from wwwroot
app.UseStaticFiles(new StaticFileOptions
 {
     FileProvider = new PhysicalFileProvider(
            Path.Combine(builder.Environment.ContentRootPath,
"MyStaticFiles")),
     RequestPath = "/StaticFiles"
 });

app.UseAuthorization();

app.MapDefaultControllerRoute().WithStaticAssets();
app.MapRazorPages().WithStaticAssets();

app.Run();
```

In the preceding code, the *MyStaticFiles* directory hierarchy is exposed publicly via the *StaticFiles* URI segment. A request to `https://<hostname>/StaticFiles/images/red-rose.jpg` serves the `red-rose.jpg` file.

The following markup references `MyStaticFiles/images/red-rose.jpg`:

HTML

```
<img src="~/StaticFiles/images/red-rose.jpg" class="img" alt="A red rose" />
```

To serve files from multiple locations, see Serve files from multiple locations.

Set HTTP response headers

A StaticFileOptions object can be used to set HTTP response headers. In addition to configuring static file serving from the web root, the following code sets the Cache-Control header:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();
builder.Services.AddControllersWithViews();

var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();

 var cacheMaxAgeOneWeek = (60 * 60 * 24 * 7).ToString();
 app.UseStaticFiles(new StaticFileOptions
 {
     OnPrepareResponse = ctx =>
     {
         ctx.Context.Response.Headers.Append(
              "Cache-Control", $"public, max-age={cacheMaxAgeOneWeek}");
     }
 });

app.UseAuthorization();

app.MapDefaultControllerRoute().WithStaticAssets();
app.MapRazorPages().WithStaticAssets();

app.Run();
```

The preceding code makes static files publicly available in the local cache for one week.

Static file authorization

The ASP.NET Core templates call MapStaticAssets before calling UseAuthorization. Most apps follow this pattern. When the Static File Middleware is called before the authorization middleware:

- No authorization checks are performed on the static files.
- Static files served by the Static File Middleware, such as those under `wwwroot`, are publicly accessible.

To serve static files based on authorization:

- Store them outside of `wwwroot`.
- Call `UseStaticFiles`, specifying a path, after calling `UseAuthorization`.
- Set the fallback authorization policy.

C#

```
using Microsoft.AspNetCore.Authorization;
using Microsoft.AspNetCore.Identity;
using Microsoft.EntityFrameworkCore;
using Microsoft.Extensions.FileProviders;
using StaticFileAuth.Data;

var builder = WebApplication.CreateBuilder(args);

var connectionString =
builder.Configuration.GetConnectionString("DefaultConnection");
builder.Services.AddDbContext<ApplicationDbContext>(options =>
    options.UseSqlServer(connectionString));
builder.Services.AddDatabaseDeveloperPageExceptionFilter();

builder.Services.AddDefaultIdentity<IdentityUser>(options =>
options.SignIn.RequireConfirmedAccount = true)
    .AddEntityFrameworkStores<ApplicationDbContext>();
builder.Services.AddRazorPages();

builder.Services.AddAuthorization(options =>
{
    options.FallbackPolicy = new AuthorizationPolicyBuilder()
        .RequireAuthenticatedUser()
        .Build();
});

var app = builder.Build();

if (app.Environment.IsDevelopment())
{
    app.UseMigrationsEndPoint();
}
```

```
else
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseRouting();

app.UseAuthentication();
app.UseAuthorization();

app.UseStaticFiles(new StaticFileOptions
{
    FileProvider = new PhysicalFileProvider(
           Path.Combine(builder.Environment.ContentRootPath,
"MyStaticFiles")),
    RequestPath = "/StaticFiles"
});

app.MapRazorPages();

app.Run();
```

In the preceding code, the fallback authorization policy requires ***all*** users to be authenticated. Endpoints such as controllers, Razor Pages, etc that specify their own authorization requirements don't use the fallback authorization policy. For example, Razor Pages, controllers, or action methods with `[AllowAnonymous]` or `[Authorize(PolicyName="MyPolicy")]` use the applied authorization attribute rather than the fallback authorization policy.

RequireAuthenticatedUser adds DenyAnonymousAuthorizationRequirement to the current instance, which enforces that the current user is authenticated.

Static assets under `wwwroot` are publicly accessible because the default Static File Middleware (`app.UseStaticFiles();`) is called before `UseAuthentication`. Static assets in the ***MyStaticFiles*** folder require authentication. The sample code demonstrates this.

An alternative approach to serve files based on authorization is to:

- Store them outside of `wwwroot` and any directory accessible to the Static File Middleware.
- Serve them via an action method to which authorization is applied and return a FileResult object:

C#

```
[Authorize]
public class BannerImageModel : PageModel
{
    private readonly IWebHostEnvironment _env;

    public BannerImageModel(IWebHostEnvironment env) =>
        _env = env;

    public PhysicalFileResult OnGet()
    {
        var filePath = Path.Combine(
                _env.ContentRootPath, "MyStaticFiles", "images", "red-
rose.jpg");

        return PhysicalFile(filePath, "image/jpeg");
    }
}
```

The preceding approach requires a page or endpoint per file. The following code returns files or uploads files for authenticated users:

C#

```
app.MapGet("/files/{fileName}",  IResult (string fileName) =>
    {
        var filePath = GetOrCreateFilePath(fileName);

        if (File.Exists(filePath))
        {
           return TypedResults.PhysicalFile(filePath, fileDownloadName: $"
{fileName}");
        }

        return TypedResults.NotFound("No file found with the supplied file
name");
    })
    .WithName("GetFileByName")
    .RequireAuthorization("AuthenticatedUsers");

app.MapPost("/files",
       async (IFormFile file, LinkGenerator linker, HttpContext context) =>
    {
        // Don't rely on the file.FileName as it is only metadata that can
be
        // manipulated by the end-user. See the `Utilities.IsFileValid`
method that
        // takes an IFormFile and validates its signature within the
        // AllowedFileSignatures

        var fileSaveName = Guid.NewGuid().ToString("N")
```

```
                            + Path.GetExtension(file.FileName);
        await SaveFileWithCustomFileName(file, fileSaveName);

        context.Response.Headers.Append("Location",
                                        linker.GetPathByName(context,
"GetFileByName",
                                        new { fileName = fileSaveName}));
        return TypedResults.Ok("File Uploaded Successfully!");
    })
    .RequireAuthorization("AdminsOnly");

app.Run();
```

IFormFile in the preceding sample uses memory buffer for uploading. For handling large file use streaming. See Upload large files with streaming.

See the StaticFileAuth GitHub folder for the complete sample.

Directory browsing

Directory browsing allows directory listing within specified directories.

Directory browsing is disabled by default for security reasons. For more information, see Security considerations for static files.

Enable directory browsing with AddDirectoryBrowser and UseDirectoryBrowser:

C#

```
using Microsoft.AspNetCore.StaticFiles;
using Microsoft.Extensions.FileProviders;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();
builder.Services.AddControllersWithViews();

builder.Services.AddDirectoryBrowser();

var app = builder.Build();

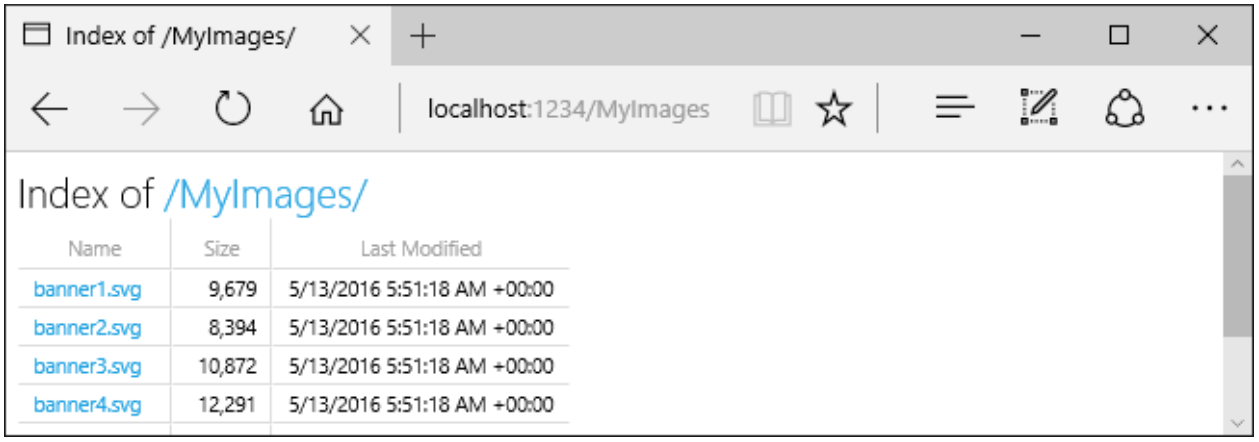
if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();

app.MapStaticAssets();
```

```
var fileProvider = new
PhysicalFileProvider(Path.Combine(builder.Environment.WebRootPath,
"images"));
var requestPath = "/MyImages";

// Enable displaying browser links.
app.UseStaticFiles(new StaticFileOptions
{
    FileProvider = fileProvider,
    RequestPath = requestPath
});



app.UseDirectoryBrowser(new DirectoryBrowserOptions
{
    FileProvider = fileProvider,
    RequestPath = requestPath
});

app.UseAuthorization();

app.MapDefaultControllerRoute().WithStaticAssets();
app.MapRazorPages().WithStaticAssets();

app.Run();
```

The preceding code allows directory browsing of the *wwwroot/images* folder using the URL `https://<hostname>/MyImages`, with links to each file and folder:

`AddDirectoryBrowser` adds services required by the directory browsing middleware, including HtmlEncoder. These services may be added by other calls, such as AddRazorPages, but we recommend calling `AddDirectoryBrowser` to ensure the services are added in all apps.

Serve default documents

Setting a default page provides visitors a starting point on a site. To serve a default file from `wwwroot` without requiring the request URL to include the file's name, call the UseDefaultFiles method:

```
C#

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();
builder.Services.AddControllersWithViews();

var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();

app.UseDefaultFiles();

app.UseStaticFiles();
app.UseAuthorization();

app.MapDefaultControllerRoute().WithStaticAssets();
app.MapRazorPages().WithStaticAssets();

app.Run();
```

`UseDefaultFiles` must be called before `UseStaticFiles` to serve the default file. `UseDefaultFiles` is a URL rewriter that doesn't serve the file.

With `UseDefaultFiles`, requests to a folder in `wwwroot` search for:

- `default.htm`
- `default.html`
- `index.htm`
- `index.html`

The first file found from the list is served as though the request included the file's name. The browser URL continues to reflect the URI requested. For example, in the sample app, a request to `https://localhost:<port>/def/` serves `default.html` from `wwwroot/def`.

The following code changes the default file name to `mydefault.html`:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();
builder.Services.AddControllersWithViews();

var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();

var options = new DefaultFilesOptions();
options.DefaultFileNames.Clear();
options.DefaultFileNames.Add("mydefault.html");
app.UseDefaultFiles(options);

app.UseStaticFiles();

app.UseAuthorization();

app.MapDefaultControllerRoute().WithStaticAssets();
app.MapRazorPages().WithStaticAssets();

app.Run();
```

UseFileServer for default documents

UseFileServer combines the functionality of `UseStaticFiles`, `UseDefaultFiles`, and optionally `UseDirectoryBrowser`.

Call `app.UseFileServer` to enable the serving of static files and the default file. Directory browsing isn't enabled:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();
builder.Services.AddControllersWithViews();

var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
```

```
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();

app.UseFileServer();

app.UseAuthorization();

app.MapDefaultControllerRoute().WithStaticAssets();
app.MapRazorPages().WithStaticAssets();

app.Run();
```

The following code enables the serving of static files, the default file, and directory browsing:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();
builder.Services.AddControllersWithViews();

builder.Services.AddDirectoryBrowser();

var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();

app.UseFileServer(enableDirectoryBrowsing: true);

app.UseRouting();

app.UseAuthorization();

app.MapDefaultControllerRoute().WithStaticAssets();
app.MapRazorPages().WithStaticAssets();

app.Run();
```

Consider the following directory hierarchy:

- `wwwroot`

    - `css`
    - `images`
    - `js`
- `MyStaticFiles`
    - `defaultFiles`
        - `default.html`
        - `image3.png`
    - `images`
        - `MyImage.jpg`

The following code enables the serving of static files, the default file, and directory browsing of `MyStaticFiles`:

C#

```
using Microsoft.Extensions.FileProviders;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();
builder.Services.AddControllersWithViews();

builder.Services.AddDirectoryBrowser();

var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();

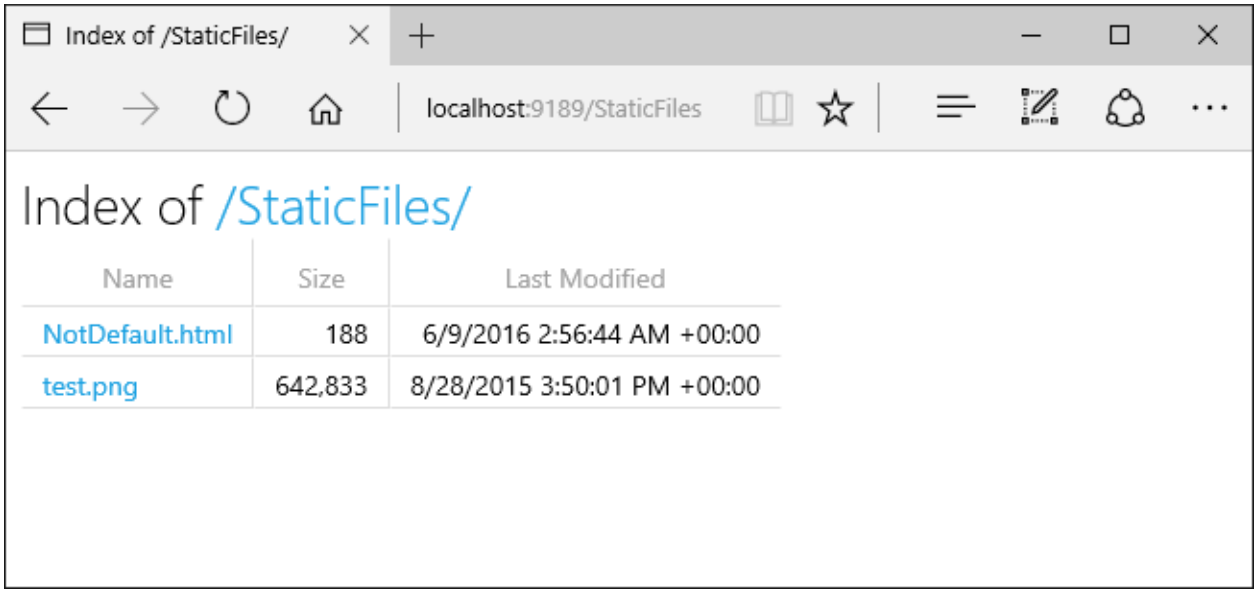
app.UseStaticFiles();

app.UseFileServer(new FileServerOptions
{
    FileProvider = new PhysicalFileProvider(
           Path.Combine(builder.Environment.ContentRootPath,
"MyStaticFiles")),
    RequestPath = "/StaticFiles",
    EnableDirectoryBrowsing = true
});

app.UseAuthorization();

app.MapDefaultControllerRoute().WithStaticAssets();
app.MapRazorPages().WithStaticAssets();
```

```
app.Run();
```



AddDirectoryBrowser must be called when the `EnableDirectoryBrowsing` property value is `true`.

Using the preceding file hierarchy and code, URLs resolve as follows:

Expand table

URI	Response
`https://<hostname>/StaticFiles/images/MyImage.jpg`	`MyStaticFiles/images/MyImage.jpg`
`https://<hostname>/StaticFiles`	directory listing
`https://<hostname>/StaticFiles/defaultFiles`	`MyStaticFiles/defaultFiles/default.html`
`https://<hostname>/StaticFiles/defaultFiles/image3.png`	`MyStaticFiles/defaultFiles//image3.png`

If no default-named file exists in the *MyStaticFiles* directory, `https://<hostname>/StaticFiles` returns the directory listing with clickable links:

UseDefaultFiles and UseDirectoryBrowser perform a client-side redirect from the target URI without a trailing `/` to the target URI with a trailing `/`. For example, from `https://<hostname>/StaticFiles` to `https://<hostname>/StaticFiles/`. Relative URLs within the *StaticFiles* directory are invalid without a trailing slash (`/`) unless the RedirectToAppendTrailingSlash option of DefaultFilesOptions is used.

FileExtensionContentTypeProvider

The FileExtensionContentTypeProvider class contains a Mappings property that serves as a mapping of file extensions to MIME content types. In the following sample, several file extensions are mapped to known MIME types. The *.rtf* extension is replaced, and *.mp4* is removed:

C#

```
using Microsoft.AspNetCore.StaticFiles;
using Microsoft.Extensions.FileProviders;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();
builder.Services.AddControllersWithViews();

var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();

// Set up custom content types - associating file extension to MIME type
var provider = new FileExtensionContentTypeProvider();
// Add new mappings
provider.Mappings[".myapp"] = "application/x-msdownload";
provider.Mappings[".htm3"] = "text/html";
provider.Mappings[".image"] = "image/png";
// Replace an existing mapping
provider.Mappings[".rtf"] = "application/x-msdownload";
// Remove MP4 videos.
provider.Mappings.Remove(".mp4");

app.UseStaticFiles(new StaticFileOptions
{
    ContentTypeProvider = provider
});

app.UseAuthorization();

app.MapDefaultControllerRoute().WithStaticAssets();
app.MapRazorPages().WithStaticAssets();

app.Run();
```

See MIME content types.

Non-standard content types

The Static File Middleware understands almost 400 known file content types. If the user requests a file with an unknown file type, the Static File Middleware passes the request to the next middleware in the pipeline. If no middleware handles the request, a *404 Not Found* response is returned. If directory browsing is enabled, a link to the file is displayed in a directory listing.

The following code enables serving unknown types and renders the unknown file as an image:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();
builder.Services.AddControllersWithViews();

var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();

 app.UseStaticFiles(new StaticFileOptions
 {
     ServeUnknownFileTypes = true,
     DefaultContentType = "image/png"
 });

app.UseAuthorization();

app.MapDefaultControllerRoute().WithStaticAssets();
app.MapRazorPages().WithStaticAssets();

app.Run();
```

With the preceding code, a request for a file with an unknown content type is returned as an image.

> ⚠ **Warning**
>
> Enabling ServeUnknownFileTypes is a security risk. It's disabled by default, and its use is discouraged. FileExtensionContentTypeProvider provides a safer alternative

to serving files with non-standard extensions.

Serve files from multiple locations

Consider the following Razor page which displays the `/MyStaticFiles/image3.png` file:

CSHTML

```
@page

<p> Test /MyStaticFiles/image3.png</p>

<img src="~/image3.png" class="img" asp-append-version="true" alt="Test">
```

`UseStaticFiles` and `UseFileServer` default to the file provider pointing at `wwwroot`. Additional instances of `UseStaticFiles` and `UseFileServer` can be provided with other file providers to serve files from other locations. The following example calls `UseStaticFiles` twice to serve files from both `wwwroot` and `MyStaticFiles`:

C#

```
app.UseStaticFiles();
app.UseStaticFiles(new StaticFileOptions
{
    FileProvider = new PhysicalFileProvider(
        Path.Combine(builder.Environment.ContentRootPath, "MyStaticFiles"))
});
```

Using the preceding code:

- The `/MyStaticFiles/image3.png` file is displayed.
- The Image Tag Helpers AppendVersion is not applied because the Tag Helpers depend on WebRootFileProvider. `WebRootFileProvider` has not been updated to include the `MyStaticFiles` folder.

The following code updates the `WebRootFileProvider`, which enables the Image Tag Helper to provide a version:

C#

```
var webRootProvider = new
PhysicalFileProvider(builder.Environment.WebRootPath);
var newPathProvider = new PhysicalFileProvider(
  Path.Combine(builder.Environment.ContentRootPath, "MyStaticFiles"));
```

```
var compositeProvider = new CompositeFileProvider(webRootProvider,
                                                   newPathProvider);

// Update the default provider.
app.Environment.WebRootFileProvider = compositeProvider;

app.MapStaticAssets();
```

> ⓘ **Note**
>
> The preceding approach applies to Razor Pages and MVC apps. For guidance that applies to Blazor Web Apps, see ASP.NET Core Blazor static files.

Security considerations for static files

> ⚠ **Warning**
>
> `UseDirectoryBrowser` and `UseStaticFiles` can leak secrets. Disabling directory browsing in production is highly recommended. Carefully review which directories are enabled via `UseStaticFiles` or `UseDirectoryBrowser`. The entire directory and its sub-directories become publicly accessible. Store files suitable for serving to the public in a dedicated directory, such as `<content_root>/wwwroot`. Separate these files from MVC views, Razor Pages, configuration files, etc.

- The URLs for content exposed with `UseDirectoryBrowser`, `UseStaticFiles`, and `MapStaticAssets` are subject to the case sensitivity and character restrictions of the underlying file system. For example, Windows is case insensitive, but macOS and Linux aren't.
- ASP.NET Core apps hosted in IIS use the ASP.NET Core Module to forward all requests to the app, including static file requests. The IIS static file handler isn't used and has no chance to handle requests.
- Complete the following steps in IIS Manager to remove the IIS static file handler at the server or website level:

    1. Navigate to the **Modules** feature.
    2. Select **StaticFileModule** in the list.
    3. Click **Remove** in the **Actions** sidebar.

> ⚠ **Warning**
>
> If the IIS static file handler is enabled **and** the ASP.NET Core Module is configured incorrectly, static files are served. This happens, for example, if the *web.config* file isn't deployed.

- Place code files, including `.cs` and `.cshtml`, outside of the app project's web root. A logical separation is therefore created between the app's client-side content and server-based code. This prevents server-side code from being leaked.

Serve files outside wwwroot by updating IWebHostEnvironment.WebRootPath

When IWebHostEnvironment.WebRootPath is set to a folder other than `wwwroot`:

- In the development environment, static assets found in both `wwwroot` and the updated `IWebHostEnvironment.WebRootPath` are served from `wwwroot`.
- In any environment other than development, duplicate static assets are served from the updated `IWebHostEnvironment.WebRootPath` folder.

Consider a web app created with the empty web template:

- Containing an `Index.html` file in `wwwroot` and `wwwroot-custom`.
- With the following updated `Program.cs` file that sets `WebRootPath = "wwwroot-custom"`:

C#

```
var builder = WebApplication.CreateBuilder(new WebApplicationOptions
{
    Args = args,
    // Look for static files in "wwwroot-custom"
    WebRootPath = "wwwroot-custom"
});

var app = builder.Build();

app.UseDefaultFiles();
app.MapStaticAssets();

app.Run();
```

In the preceding code, requests to `/`:

- In the development environment return `wwwroot/Index.html`
- In any environment other than development return `wwwroot-custom/Index.html`

To ensure assets from `wwwroot-custom` are returned, use one of the following approaches:

- Delete duplicate named assets in `wwwroot`.
- Set `"ASPNETCORE_ENVIRONMENT"` in `Properties/launchSettings.json` to any value other than `"Development"`.
- Completely disable static web assets by setting `<StaticWebAssetsEnabled>false</StaticWebAssetsEnabled>` in the project file. ***WARNING, disabling static web assets disables Razor Class Libraries***.
- Add the following XML to the project file:

  XML

  ```xml
  <ItemGroup>
      <Content Remove="wwwroot\**" />
  </ItemGroup>
  ```

The following code updates `IWebHostEnvironment.WebRootPath` to a non development value, guaranteeing duplicate content is returned from `wwwroot-custom` rather than `wwwroot`:

C#

```
var builder = WebApplication.CreateBuilder(new WebApplicationOptions
{
    Args = args,
    // Examine Hosting environment: logging value
    EnvironmentName = Environments.Staging,
    WebRootPath = "wwwroot-custom"
});

var app = builder.Build();

app.Logger.LogInformation("ASPNETCORE_ENVIRONMENT: {env}",
      Environment.GetEnvironmentVariable("ASPNETCORE_ENVIRONMENT"));

app.Logger.LogInformation("app.Environment.IsDevelopment(): {env}",
      app.Environment.IsDevelopment().ToString());

app.UseDefaultFiles();
```

```
app.MapStaticAssets();

app.Run();
```

dotnet-scaffold telemetry

Article • 11/11/2024

The `dotnet-scaffold` command includes a telemetry feature that collects usage data. This feature helps the `dotnet-scaffold` team understand how the tool is used so it can be improved.

How to opt out

The `dotnet-scaffold` telemetry feature is enabled by default. To opt out of the telemetry feature, set the `DOTNET_SCAFFOLD_TELEMETRY_OPTOUT` environment variable to `1` or `true`.

Disclosure

When you run the `dotnet-scaffold` tool the first time, it displays output similar to the following example. The text may vary slightly depending on the version of the tool you're running. This "first run" experience is how Microsoft notifies you about data collection.

Console

```
dotnet-scaffold collects usage data in order to help us improve your
experience. The data is collected by Microsoft and shared with the
community. You can opt-out of telemetry by setting the
DOTNET_SCAFFOLD_TELEMETRY_OPTOUT environment variable to '1' or 'true' using
your favorite shell.

Read more about dotnet-scaffold telemetry:
https://aka.ms/dotnet-scaffold/telemetry
Read more about .NET CLI Tools telemetry:
https://aka.ms/dotnet-cli-telemetry
```

To suppress the "first run" experience text, set the `DOTNET_SCAFFOLD_SKIP_FIRST_TIME_EXPERIENCE` environment variable to `1` or `true`.

Data points

The telemetry feature doesn't collect:

- Personal data, such as usernames, email addresses, or URLs.
- Any project data.

The data is sent securely to Microsoft servers and held under restricted access.

Protecting your privacy is important to us. If you suspect the telemetry feature is collecting sensitive data or the data is being insecurely or inappropriately handled, take one of the following actions:

- File an issue in the dotnet/scaffolding repository.
- Send an email to dotnet@microsoft.com for investigation.

The telemetry feature collects the following data.

Expand table

.NET SDK versions	Data
>=8.0	Timestamp of invocation.
>=8.0	Three-octet IP address used to determine the geographical location.
>=8.0	Operating system and version.
>=8.0	Runtime ID (RID) the tool is running on.
>=8.0	Whether the tool is running in a container.
>=8.0	Hashed Media Access Control (MAC) address: a cryptographically (SHA256) hashed and unique ID for a machine.
>=8.0	Kernel version.
>=8.0	dotnet-scaffold version.
>=8.0	Hashed tool information (tool name, tool version, tool package name, tool package version, chosen scaffolder category, related scaffolding categories)
>=8.0	Tool level (global or local tool)
>=8.0	Hashed command invoked (for example, `mvccontroller`) and whether it succeeded.
>=8.0	dotnet-scaffold-aspnet scaffolder name, step names, and whether they succeeded.
>=8.0	dotnet-scaffold-aspire scaffolder name and whether it succeeded.
>=8.0	dotnet-scaffold aspnet scaffolder validation method name and whether they succeed.
>=8.0	dotnet-scaffold aspire scaffolder validation method name and whether they succeed.

Choose an ASP.NET Core web UI

Article • 10/21/2024

ASP.NET Core is a complete UI framework. Choose which functionalities to combine that fit the app's web UI needs.

For new project development, we recommend ASP.NET Core Blazor.

ASP.NET Core Blazor

Blazor is a full-stack web UI framework and is recommended for most web UI scenarios.

Benefits of using Blazor:

- Reusable component model.
- Efficient diff-based component rendering.
- Flexibly render components from the server or client via WebAssembly.
- Build rich interactive web UI components in C#.
- Render components statically from the server.
- Progressively enhance server rendered components for smoother navigation and form handling and to enable streaming rendering.
- Share code for common logic on the client and server.
- Interop with JavaScript.
- Integrate components with existing MVC, Razor Pages, or JavaScript based apps.

For a complete overview of Blazor, its architecture and benefits, see ASP.NET Core Blazor and ASP.NET Core Blazor hosting models. To get started with your first Blazor app, see Build your first Blazor app.

ASP.NET Core Razor Pages

Razor Pages is a page-based model for building server rendered web UI. Razor pages UI are dynamically rendered on the server to generate the page's HTML and CSS in response to a browser request. The page arrives at the client ready to display. Support for Razor Pages is built on ASP.NET Core MVC.

Razor Pages benefits:

- Quickly build and update UI. Code for the page is kept with the page, while keeping UI and business logic concerns separate.
- Testable and scales to large apps.

- Keep your ASP.NET Core pages organized in a simpler way than ASP.NET MVC:
  - View specific logic and view models can be kept together in their own namespace and directory.
  - Groups of related pages can be kept in their own namespace and directory.

To get started with your first ASP.NET Core Razor Pages app, see Tutorial: Get started with Razor Pages in ASP.NET Core. For a complete overview of ASP.NET Core Razor Pages, its architecture and benefits, see: Introduction to Razor Pages in ASP.NET Core.

ASP.NET Core MVC

ASP.NET Core MVC renders UI on the server and uses a Model-View-Controller (MVC) architectural pattern. The MVC pattern separates an app into three main groups of components: models, views, and controllers. User requests are routed to a controller. The controller is responsible for working with the model to perform user actions or retrieve results of queries. The controller chooses the view to display to the user and provides it with any model data it requires.

ASP.NET Core MVC benefits:

- Based on a scalable and mature model for building large web apps.
- Clear separation of concerns for maximum flexibility.
- The Model-View-Controller separation of responsibilities ensures that the business model can evolve without being tightly coupled to low-level implementation details.

To get started with ASP.NET Core MVC, see Get started with ASP.NET Core MVC. For an overview of ASP.NET Core MVC's architecture and benefits, see Overview of ASP.NET Core MVC.

ASP.NET Core Single Page Applications (SPA) with frontend JavaScript frameworks

Build client-side logic for ASP.NET Core apps using popular JavaScript frameworks, like Angular, React, and Vue. ASP.NET Core provides project templates for Angular, React, and Vue, and it can be used with other JavaScript frameworks as well.

Benefits of ASP.NET Core SPA with JavaScript Frameworks, in addition to the client rendering benefits previously listed:

- The JavaScript runtime environment is already provided with the browser.
- Large community and mature ecosystem.

- Build client-side logic for ASP.NET Core apps using popular JS frameworks, like Angular, React, and Vue.

Downsides:

- More coding languages, frameworks, and tools required.
- Difficult to share code so some logic may be duplicated.

To get started, see:

- Create an ASP.NET Core app with Angular
- Create an ASP.NET Core app with React
- Create an ASP.NET Core app with Vue
- JavaScript and TypeScript in Visual Studio

Combine multiple web UI solutions: ASP.NET Core MVC or Razor Pages plus Blazor

MVC, Razor Pages, and Blazor are part of the ASP.NET Core framework and are designed to be used together. Razor components can be integrated into Razor Pages and MVC apps. When a view or page is rendered, components can be prerendered at the same time.

Benefits for MVC or Razor Pages plus Blazor, in addition to MVC or Razor Pages benefits:

- Prerendering executes Razor components on the server and renders them into a view or page, which improves the perceived load time of the app.
- Add interactivity to existing views or pages with the Component Tag Helper.

To get started with ASP.NET Core MVC or Razor Pages plus Blazor, see Integrate ASP.NET Core Razor components into ASP.NET Core apps.

Introduction to Razor Pages in ASP.NET Core

Article • 09/27/2024

By Rick Anderson, Dave Brock, and Kirk Larkin

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

Razor Pages can make coding page-focused scenarios easier and more productive than using controllers and views.

If you're looking for a tutorial that uses the Model-View-Controller approach, see Get started with ASP.NET Core MVC.

This document provides an introduction to Razor Pages. It's not a step by step tutorial. If you find some of the sections too advanced, see Get started with Razor Pages. For an overview of ASP.NET Core, see the Introduction to ASP.NET Core.

Prerequisites

Visual Studio

- Visual Studio 2022 with the **ASP.NET and web development** workload.
- .NET 6.0 SDK

Create a Razor Pages project

Visual Studio

See Get started with Razor Pages for detailed instructions on how to create a Razor Pages project.

Razor Pages

Razor Pages is enabled in `Program.cs`:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();

var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseRouting();

app.UseAuthorization();

app.MapRazorPages();

app.Run();
```

In the preceding code:

- AddRazorPages adds services for Razor Pages to the app.
- MapRazorPages adds endpoints for Razor Pages to the IEndpointRouteBuilder.

Consider a basic page:

CSHTML

```
@page

<h1>Hello, world!</h1>
<h2>The time on the server is @DateTime.Now</h2>
```

The preceding code looks a lot like a Razor view file used in an ASP.NET Core app with controllers and views. What makes it different is the @page directive. `@page` makes the file into an MVC action, which means that it handles requests directly, without going through a controller. `@page` must be the first Razor directive on a page. `@page` affects the behavior of other Razor constructs. Razor Pages file names have a `.cshtml` suffix.

A similar page, using a `PageModel` class, is shown in the following two files. The `Pages/Index2.cshtml` file:

CSHTML

```
@page
@using RazorPagesIntro.Pages
@model Index2Model

<h2>Separate page model</h2>
<p>
    @Model.Message
</p>
```

The `Pages/Index2.cshtml.cs` page model:

C#

```
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.Extensions.Logging;
using System;

namespace RazorPagesIntro.Pages
{
    public class Index2Model : PageModel
    {
        public string Message { get; private set; } = "PageModel in C#";

        public void OnGet()
        {
            Message += $" Server time is { DateTime.Now }";
        }
    }
}
```

By convention, the `PageModel` class file has the same name as the Razor Page file with `.cs` appended. For example, the previous Razor Page is `Pages/Index2.cshtml`. The file containing the `PageModel` class is named `Pages/Index2.cshtml.cs`.

The associations of URL paths to pages are determined by the page's location in the file system. The following table shows a Razor Page path and the matching URL:

Expand table

File name and path	matching URL
`/Pages/Index.cshtml`	`/` or `/Index`

File name and path	matching URL
`/Pages/Contact.cshtml`	`/Contact`
`/Pages/Store/Contact.cshtml`	`/Store/Contact`
`/Pages/Store/Index.cshtml`	`/Store` or `/Store/Index`

Notes:

- The runtime looks for Razor Pages files in the *Pages* folder by default.
- `Index` is the default page when a URL doesn't include a page.

Write a basic form

Razor Pages is designed to make common patterns used with web browsers easy to implement when building an app. Model binding, Tag Helpers, and HTML helpers work with the properties defined in a Razor Page class. Consider a page that implements a basic "contact us" form for the `Contact` model:

For the samples in this document, the `DbContext` is initialized in the Program.cs file.

The in memory database requires the `Microsoft.EntityFrameworkCore.InMemory` NuGet package.

C#

```
using Microsoft.EntityFrameworkCore;
using RazorPagesContacts.Data;
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();

builder.Services.AddDbContext<CustomerDbContext>(options =>
    options.UseInMemoryDatabase("name"));

var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseRouting();
```

```
app.UseAuthorization();

app.MapRazorPages();

app.Run();
```

The data model:

C#

```
using System.ComponentModel.DataAnnotations;

namespace RazorPagesContacts.Models
{
    public class Customer
    {
        public int Id { get; set; }

        [Required, StringLength(10)]
        public string? Name { get; set; }
    }
}
```

The db context:

C#

```
using Microsoft.EntityFrameworkCore;

namespace RazorPagesContacts.Data
{
    public class CustomerDbContext : DbContext
    {
        public CustomerDbContext (DbContextOptions<CustomerDbContext>
options)
            : base(options)
        {
        }

        public DbSet<RazorPagesContacts.Models.Customer> Customer =>
Set<RazorPagesContacts.Models.Customer>();
    }
}
```

The `Pages/Customers/Create.cshtml` view file:

CSHTML

```
@page
@model RazorPagesContacts.Pages.Customers.CreateModel
@addTagHelper *, Microsoft.AspNetCore.Mvc.TagHelpers

<p>Enter a customer name:</p>

<form method="post">
    Name:
    <input asp-for="Customer!.Name" />
    <input type="submit" />
</form>
```

The `Pages/Customers/Create.cshtml.cs` page model:

C#

```
public class CreateModel : PageModel
{
    private readonly Data.CustomerDbContext _context;

    public CreateModel(Data.CustomerDbContext context)
    {
        _context = context;
    }

    public IActionResult OnGet()
    {
        return Page();
    }

    [BindProperty]
    public Customer? Customer { get; set; }

    public async Task<IActionResult> OnPostAsync()
    {
        if (!ModelState.IsValid)
        {
            return Page();
        }

        if (Customer != null) _context.Customer.Add(Customer);
        await _context.SaveChangesAsync();

        return RedirectToPage("./Index");
    }
}
```

By convention, the `PageModel` class is called `<PageName>Model` and is in the same namespace as the page.

The `PageModel` class allows separation of the logic of a page from its presentation. It defines page handlers for requests sent to the page and the data used to render the page. This separation allows:

- Managing of page dependencies through dependency injection.
- Unit testing

The page has an `OnPostAsync` *handler method*, which runs on `POST` requests (when a user posts the form). Handler methods for any HTTP verb can be added. The most common handlers are:

- `OnGet` to initialize state needed for the page. In the preceding code, the `OnGet` method displays the `Create.cshtml` Razor Page.
- `OnPost` to handle form submissions.

The `Async` naming suffix is optional but is often used by convention for asynchronous functions. The preceding code is typical for Razor Pages.

If you're familiar with ASP.NET apps using controllers and views:

- The `OnPostAsync` code in the preceding example looks similar to typical controller code.
- Most of the MVC primitives like model binding, validation, and action results work the same with Controllers and Razor Pages.

The previous `OnPostAsync` method:

C#

```
[BindProperty]
public Customer? Customer { get; set; }

public async Task<IActionResult> OnPostAsync()
{
    if (!ModelState.IsValid)
    {
        return Page();
    }

    if (Customer != null) _context.Customer.Add(Customer);
    await _context.SaveChangesAsync();

    return RedirectToPage("./Index");
}
```

The basic flow of `OnPostAsync`:

Check for validation errors.

- If there are no errors, save the data and redirect.
- If there are errors, show the page again with validation messages. In many cases, validation errors would be detected on the client, and never submitted to the server.

The `Pages/Customers/Create.cshtml` view file:

CSHTML

```
@page
@model RazorPagesContacts.Pages.Customers.CreateModel
@addTagHelper *, Microsoft.AspNetCore.Mvc.TagHelpers

<p>Enter a customer name:</p>

<form method="post">
    Name:
    <input asp-for="Customer!.Name" />
    <input type="submit" />
</form>
```

The rendered HTML from `Pages/Customers/Create.cshtml`:

HTML

```
<p>Enter a customer name:</p>

<form method="post">
    Name:
    <input type="text" data-val="true"
           data-val-length="The field Name must be a string with a maximum
length of 10."
           data-val-length-max="10" data-val-required="The Name field is
required."
           id="Customer_Name" maxlength="10" name="Customer.Name" value=""
/>
    <input type="submit" />
    <input name="__RequestVerificationToken" type="hidden"
           value="<Antiforgery token here>" />
</form>
```

In the previous code, posting the form:

- With valid data:
  - The `OnPostAsync` handler method calls the RedirectToPage helper method. `RedirectToPage` returns an instance of RedirectToPageResult. `RedirectToPage`:

    - Is an action result.
    - Is similar to `RedirectToAction` or `RedirectToRoute` (used in controllers and views).
    - Is customized for pages. In the preceding sample, it redirects to the root Index page (`/Index`). `RedirectToPage` is detailed in the URL generation for Pages section.

- With validation errors that are passed to the server:
    - The `OnPostAsync` handler method calls the Page helper method. `Page` returns an instance of PageResult. Returning `Page` is similar to how actions in controllers return `View`. `PageResult` is the default return type for a handler method. A handler method that returns `void` renders the page.
    - In the preceding example, posting the form with no value results in ModelState.IsValid returning false. In this sample, no validation errors are displayed on the client. Validation error handling is covered later in this document.

```
C#

[BindProperty]
public Customer? Customer { get; set; }

public async Task<IActionResult> OnPostAsync()
{
    if (!ModelState.IsValid)
    {
        return Page();
    }

    if (Customer != null) _context.Customer.Add(Customer);
    await _context.SaveChangesAsync();

    return RedirectToPage("./Index");
}
```

- With validation errors detected by client side validation:
    - Data is **not** posted to the server.
    - Client-side validation is explained later in this document.

The `Customer` property uses [BindProperty] attribute to opt in to model binding:

```
C#

[BindProperty]
public Customer? Customer { get; set; }
```

```
public async Task<IActionResult> OnPostAsync()
{
    if (!ModelState.IsValid)
    {
        return Page();
    }

    if (Customer != null) _context.Customer.Add(Customer);
    await _context.SaveChangesAsync();

    return RedirectToPage("./Index");
}
```

`[BindProperty]` should **not** be used on models containing properties that should not be changed by the client. For more information, see Overposting.

Razor Pages, by default, bind properties only with non-`GET` verbs. Binding to properties removes the need to writing code to convert HTTP data to the model type. Binding reduces code by using the same property to render form fields (`<input asp-for="Customer.Name">`) and accept the input.

> ⚠ **Warning**
>
> For security reasons, you must opt in to binding `GET` request data to page model properties. Verify user input before mapping it to properties. Opting into `GET` binding is useful when addressing scenarios that rely on query string or route values.
>
> To bind a property on `GET` requests, set the [BindProperty] attribute's `SupportsGet` property to `true`:
>
> C#
>
> ```
> [BindProperty(SupportsGet = true)]
> ```
>
> For more information, see ASP.NET Core Community Standup: Bind on GET discussion (YouTube).

Reviewing the `Pages/Customers/Create.cshtml` view file:

CSHTML

```
@page
@model RazorPagesContacts.Pages.Customers.CreateModel
@addTagHelper *, Microsoft.AspNetCore.Mvc.TagHelpers
```

```
<p>Enter a customer name:</p>

<form method="post">
    Name:
    <input asp-for="Customer!.Name" />
    <input type="submit" />
</form>
```

- In the preceding code, the input tag helper `<input asp-for="Customer.Name" />` binds the HTML `<input>` element to the `Customer.Name` model expression.
- @addTagHelper makes Tag Helpers available.

The home page

`Index.cshtml` is the home page:

CSHTML

```
@page
@model RazorPagesContacts.Pages.Customers.IndexModel
@addTagHelper *, Microsoft.AspNetCore.Mvc.TagHelpers

<h1>Contacts home page</h1>
<form method="post">
    <table class="table">
        <thead>
            <tr>
                <th>ID</th>
                <th>Name</th>
                <th></th>
            </tr>
        </thead>
        <tbody>
        @if (Model.Customers != null)
        {
            foreach (var contact in Model.Customers)
            {
                <tr>
                    <td> @contact.Id </td>
                    <td>@contact.Name</td>
                    <td>
                        <!-- <snippet_Edit> -->
                        <a asp-page="./Edit" asp-route-
id="@contact.Id">Edit</a> |
                        <!-- </snippet_Edit> -->
                        <!-- <snippet_Delete> -->
                        <button type="submit" asp-page-handler="delete" asp-
route-id="@contact.Id">delete</button>
                        <!-- </snippet_Delete> -->
                    </td>
```

```
                </tr>
            }
        }
        </tbody>
    </table>
    <a asp-page="Create">Create New</a>
</form>
```

The associated `PageModel` class (`Index.cshtml.cs`):

C#

```
public class IndexModel : PageModel
{
    private readonly Data.CustomerDbContext _context;
    public IndexModel(Data.CustomerDbContext context)
    {
        _context = context;
    }

    public IList<Customer>? Customers { get; set; }

    public async Task OnGetAsync()
    {
        Customers = await _context.Customer.ToListAsync();
    }

    public async Task<IActionResult> OnPostDeleteAsync(int id)
    {
        var contact = await _context.Customer.FindAsync(id);

        if (contact != null)
        {
            _context.Customer.Remove(contact);
            await _context.SaveChangesAsync();
        }

        return RedirectToPage();
    }
}
```

The `Index.cshtml` file contains the following markup:

CSHTML

```
<a asp-page="./Edit" asp-route-id="@contact.Id">Edit</a> |
```

The `<a /a>` Anchor Tag Helper used the `asp-route-{value}` attribute to generate a link to the Edit page. The link contains route data with the contact ID. For example,

`https://localhost:5001/Edit/1`. Tag Helpers enable server-side code to participate in creating and rendering HTML elements in Razor files.

The `Index.cshtml` file contains markup to create a delete button for each customer contact:

CSHTML

```
<button type="submit" asp-page-handler="delete" asp-route-
id="@contact.Id">delete</button>
```

The rendered HTML:

HTML

```
<button type="submit" formaction="/Customers?
id=1&amp;handler=delete">delete</button>
```

When the delete button is rendered in HTML, its formaction includes parameters for:

- The customer contact ID, specified by the `asp-route-id` attribute.
- The `handler`, specified by the `asp-page-handler` attribute.

When the button is selected, a form `POST` request is sent to the server. By convention, the name of the handler method is selected based on the value of the `handler` parameter according to the scheme `OnPost[handler]Async`.

Because the `handler` is `delete` in this example, the `OnPostDeleteAsync` handler method is used to process the `POST` request. If the `asp-page-handler` is set to a different value, such as `remove`, a handler method with the name `OnPostRemoveAsync` is selected.

C#

```
public async Task<IActionResult> OnPostDeleteAsync(int id)
{
    var contact = await _context.Customer.FindAsync(id);

    if (contact != null)
    {
        _context.Customer.Remove(contact);
        await _context.SaveChangesAsync();
    }

    return RedirectToPage();
}
```

The `OnPostDeleteAsync` method:

- Gets the `id` from the query string.
- Queries the database for the customer contact with `FindAsync`.
- If the customer contact is found, it's removed and the database is updated.
- Calls RedirectToPage to redirect to the root Index page (`/Index`).

The Edit.cshtml file

CSHTML

```
@page "{id:int}"
@model RazorPagesContacts.Pages.Customers.EditModel

@{
    ViewData["Title"] = "Edit";
}

<h1>Edit</h1>

<h4>Customer</h4>
<hr />
<div class="row">
    <div class="col-md-4">
        <form method="post">
            <div asp-validation-summary="ModelOnly" class="text-danger">
</div>
            <input type="hidden" asp-for="Customer!.Id" />
            <div class="form-group">
                <label asp-for="Customer!.Name" class="control-label">
</label>
                <input asp-for="Customer!.Name" class="form-control" />
                <span asp-validation-for="Customer!.Name" class="text-
danger"></span>
            </div>
            <div class="form-group">
                <input type="submit" value="Save" class="btn btn-primary" />
            </div>
        </form>
    </div>
</div>

<div>
    <a asp-page="./Index">Back to List</a>
</div>

@section Scripts {
    @{await Html.RenderPartialAsync("_ValidationScriptsPartial");}
}
```

The first line contains the `@page "{id:int}"` directive. The routing constraint `"{id:int}"` tells the page to accept requests to the page that contain `int` route data. If a request to the page doesn't contain route data that can be converted to an `int`, the runtime returns an HTTP 404 (not found) error. To make the ID optional, append `?` to the route constraint:

CSHTML

```
@page "{id:int?}"
```

The `Edit.cshtml.cs` file:

C#

```
public class EditModel : PageModel
{
    private readonly RazorPagesContacts.Data.CustomerDbContext _context;

    public EditModel(RazorPagesContacts.Data.CustomerDbContext context)
    {
        _context = context;
    }

    [BindProperty]
    public Customer? Customer { get; set; }

    public async Task<IActionResult> OnGetAsync(int? id)
    {
        if (id == null)
        {
            return NotFound();
        }

        Customer = await _context.Customer.FirstOrDefaultAsync(m => m.Id ==
id);

        if (Customer == null)
        {
            return NotFound();
        }
        return Page();
    }

    // To protect from overposting attacks, enable the specific properties
you want to bind to.
    // For more details, see https://aka.ms/RazorPagesCRUD.
    public async Task<IActionResult> OnPostAsync()
    {
        if (!ModelState.IsValid)
        {
            return Page();
```

```
        }

        if (Customer != null)
        {
            _context.Attach(Customer).State = EntityState.Modified;

            try
            {
                await _context.SaveChangesAsync();
            }
            catch (DbUpdateConcurrencyException)
            {
                if (!CustomerExists(Customer.Id))
                {
                    return NotFound();
                }
                else
                {
                    throw;
                }
            }
        }

        return RedirectToPage("./Index");
    }

    private bool CustomerExists(int id)
    {
        return _context.Customer.Any(e => e.Id == id);
    }
}
```

Validation

Validation rules:

- Are declaratively specified in the model class.
- Are enforced everywhere in the app.

The System.ComponentModel.DataAnnotations namespace provides a set of built-in validation attributes that are applied declaratively to a class or property. DataAnnotations also contains formatting attributes like [DataType] that help with formatting and don't provide any validation.

Consider the `Customer` model:

C#

```
using System.ComponentModel.DataAnnotations;
```

```
namespace RazorPagesContacts.Models
{
    public class Customer
    {
        public int Id { get; set; }

        [Required, StringLength(10)]
        public string? Name { get; set; }
    }
}
```

Using the following `Create.cshtml` view file:

CSHTML

```
@page
@model RazorPagesContacts.Pages.Customers.CreateModel
@addTagHelper *, Microsoft.AspNetCore.Mvc.TagHelpers

<p>Validation: customer name:</p>

<form method="post">
    <div asp-validation-summary="ModelOnly"></div>
    <span asp-validation-for="Customer!.Name"></span>
    Name:
    <input asp-for="Customer!.Name" />
    <input type="submit" />
</form>

<script src="~/lib/jquery/dist/jquery.js"></script>
<script src="~/lib/jquery-validation/dist/jquery.validate.js"></script>
<script src="~/lib/jquery-validation-
unobtrusive/jquery.validate.unobtrusive.js"></script>
```

The preceding code:

- Includes jQuery and jQuery validation scripts.
- Uses the `<div />` and `<span />` Tag Helpers to enable:
  - Client-side validation.
  - Validation error rendering.
- Generates the following HTML:

  HTML

  ```
  <p>Enter a customer name:</p>

  <form method="post">
      Name:
  ```

```
    <input type="text" data-val="true"
           data-val-length="The field Name must be a string with a
maximum length of 10."
           data-val-length-max="10" data-val-required="The Name field
is required."
           id="Customer_Name" maxlength="10" name="Customer.Name"
value="" />
    <input type="submit" />
    <input name="__RequestVerificationToken" type="hidden"
           value="<Antiforgery token here>" />
</form>

<script src="/lib/jquery/dist/jquery.js"></script>
<script src="/lib/jquery-validation/dist/jquery.validate.js"></script>
<script src="/lib/jquery-validation-
unobtrusive/jquery.validate.unobtrusive.js"></script>
```

Posting the Create form without a name value displays the error message "The Name field is required." on the form. If JavaScript is enabled on the client, the browser displays the error without posting to the server.

The `[StringLength(10)]` attribute generates `data-val-length-max="10"` on the rendered HTML. `data-val-length-max` prevents browsers from entering more than the maximum length specified. If a tool such as Fiddler is used to edit and replay the post:

- With the name longer than 10.
- The error message "The field Name must be a string with a maximum length of 10." is returned.

Consider the following `Movie` model:

C#

```
using System;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace RazorPagesMovie.Models
{
    public class Movie
    {
        public int ID { get; set; }

        [StringLength(60, MinimumLength = 3)]
        [Required]
        public string Title { get; set; }

        [Display(Name = "Release Date")]
        [DataType(DataType.Date)]
        public DateTime ReleaseDate { get; set; }
```

```
        [Range(1, 100)]
        [DataType(DataType.Currency)]
        [Column(TypeName = "decimal(18, 2)")]
        public decimal Price { get; set; }

        [RegularExpression(@"^[A-Z]+[a-zA-Z\s]*$")]
        [Required]
        [StringLength(30)]
        public string Genre { get; set; }

        [RegularExpression(@"^[A-Z]+[a-zA-Z0-9""'\s-]*$")]
        [StringLength(5)]
        [Required]
        public string Rating { get; set; }
    }
}
```

The validation attributes specify behavior to enforce on the model properties they're applied to:

- The `Required` and `MinimumLength` attributes indicate that a property must have a value, but nothing prevents a user from entering white space to satisfy this validation.
- The `RegularExpression` attribute is used to limit what characters can be input. In the preceding code, "Genre":
  - Must only use letters.
  - The first letter is required to be uppercase. White space, numbers, and special characters are not allowed.
- The `RegularExpression` "Rating":
  - Requires that the first character be an uppercase letter.
  - Allows special characters and numbers in subsequent spaces. "PG-13" is valid for a rating, but fails for a "Genre".
- The `Range` attribute constrains a value to within a specified range.
- The `StringLength` attribute sets the maximum length of a string property, and optionally its minimum length.
- Value types (such as `decimal`, `int`, `float`, `DateTime`) are inherently required and don't need the `[Required]` attribute.

The Create page for the `Movie` model shows displays errors with invalid values:

For more information, see:

- Add validation to the Movie app
- Model validation in ASP.NET Core.

CSS isolation

Isolate CSS styles to individual pages, views, and components to reduce or avoid:

- Dependencies on global styles that can be challenging to maintain.
- Style conflicts in nested content.

To add a *scoped CSS file* for a page or view, place the CSS styles in a companion `.cshtml.css` file matching the name of the `.cshtml` file. In the following example, an `Index.cshtml.css` file supplies CSS styles that are only applied to the `Index.cshtml` page or view.

`Pages/Index.cshtml.css` (Razor Pages) or `Views/Index.cshtml.css` (MVC):

```css
h1 {
    color: red;
}
```

CSS isolation occurs at build time. The framework rewrites CSS selectors to match markup rendered by the app's pages or views. The rewritten CSS styles are bundled and produced as a static asset, `{APP ASSEMBLY}.styles.css`. The placeholder `{APP ASSEMBLY}` is the assembly name of the project. A link to the bundled CSS styles is placed in the app's layout.

In the `<head>` content of the app's `Pages/Shared/_Layout.cshtml` (Razor Pages) or `Views/Shared/_Layout.cshtml` (MVC), add or confirm the presence of the link to the bundled CSS styles:

```HTML
<link rel="stylesheet" href="~/{APP ASSEMBLY}.styles.css" />
```

In the following example, the app's assembly name is `WebApp`:

```HTML
<link rel="stylesheet" href="WebApp.styles.css" />
```

The styles defined in a scoped CSS file are only applied to the rendered output of the matching file. In the preceding example, any `h1` CSS declarations defined elsewhere in the app don't conflict with the `Index`'s heading style. CSS style cascading and inheritance rules remain in effect for scoped CSS files. For example, styles applied directly to an `<h1>` element in the `Index.cshtml` file override the scoped CSS file's styles in `Index.cshtml.css`.

> **Note**
>
> In order to guarantee CSS style isolation when bundling occurs, importing CSS in Razor code blocks isn't supported.
>
> CSS isolation only applies to HTML elements. CSS isolation isn't supported for Tag Helpers.

Within the bundled CSS file, each page, view, or Razor component is associated with a scope identifier in the format `b-{STRING}`, where the `{STRING}` placeholder is a ten-character string generated by the framework. The following example provides the style for the preceding `<h1>` element in the `Index` page of a Razor Pages app:

```css
/* /Pages/Index.cshtml.rz.scp.css */
h1[b-3xxtam6d07] {
    color: red;
}
```

In the `Index` page where the CSS style is applied from the bundled file, the scope identifier is appended as an HTML attribute:

```HTML
<h1 b-3xxtam6d07>
```

The identifier is unique to an app. At build time, a project bundle is created with the convention `{STATIC WEB ASSETS BASE PATH}/Project.lib.scp.css`, where the placeholder `{STATIC WEB ASSETS BASE PATH}` is the static web assets base path.

If other projects are utilized, such as NuGet packages or Razor class libraries, the bundled file:

- References the styles using CSS imports.
- Isn't published as a static web asset of the app that consumes the styles.

CSS preprocessor support

CSS preprocessors are useful for improving CSS development by utilizing features such as variables, nesting, modules, mixins, and inheritance. While CSS isolation doesn't natively support CSS preprocessors such as Sass or Less, integrating CSS preprocessors is seamless as long as preprocessor compilation occurs before the framework rewrites the CSS selectors during the build process. Using Visual Studio for example, configure existing preprocessor compilation as a **Before Build** task in the Visual Studio Task Runner Explorer.

Many third-party NuGet packages, such as AspNetCore.SassCompiler, can compile SASS/SCSS files at the beginning of the build process before CSS isolation occurs, and no additional configuration is required.

CSS isolation configuration

CSS isolation permits configuration for some advanced scenarios, such as when there are dependencies on existing tools or workflows.

Customize scope identifier format

In this section, the `{Pages|Views}` placeholder is either `Pages` for Razor Pages apps or `Views` for MVC apps.

By default, scope identifiers use the format `b-{STRING}`, where the `{STRING}` placeholder is a ten-character string generated by the framework. To customize the scope identifier format, update the project file to a desired pattern:

XML

```
<ItemGroup>
  <None Update="{Pages|Views}/Index.cshtml.css" CssScope="custom-scope-
identifier" />
</ItemGroup>
```

In the preceding example, the CSS generated for `Index.cshtml.css` changes its scope identifier from `b-{STRING}` to `custom-scope-identifier`.

Use scope identifiers to achieve inheritance with scoped CSS files. In the following project file example, a `BaseView.cshtml.css` file contains common styles across views. A `DerivedView.cshtml.css` file inherits these styles.

XML

```
<ItemGroup>
  <None Update="{Pages|Views}/BaseView.cshtml.css" CssScope="custom-scope-
identifier" />
  <None Update="{Pages|Views}/DerivedView.cshtml.css" CssScope="custom-
scope-identifier" />
</ItemGroup>
```

Use the wildcard (`*`) operator to share scope identifiers across multiple files:

XML

```
<ItemGroup>
  <None Update="{Pages|Views}/*.cshtml.css" CssScope="custom-scope-
```

```
identifier" />
</ItemGroup>
```

Change base path for static web assets

The scoped CSS file is generated at the root of the app. In the project file, use the `StaticWebAssetBasePath` property to change the default path. The following example places the scoped CSS file, and the rest of the app's assets, at the `_content` path:

XML

```
<PropertyGroup>
  <StaticWebAssetBasePath>_content/$(PackageId)</StaticWebAssetBasePath>
</PropertyGroup>
```

Disable automatic bundling

To opt out of how framework publishes and loads scoped files at runtime, use the `DisableScopedCssBundling` property. When using this property, other tools or processes are responsible for taking the isolated CSS files from the `obj` directory and publishing and loading them at runtime:

XML

```
<PropertyGroup>
  <DisableScopedCssBundling>true</DisableScopedCssBundling>
</PropertyGroup>
```

Razor class library (RCL) support

When a Razor class library (RCL) provides isolated styles, the `<link>` tag's `href` attribute points to `{STATIC WEB ASSET BASE PATH}/{PACKAGE ID}.bundle.scp.css`, where the placeholders are:

- `{STATIC WEB ASSET BASE PATH}`: The static web asset base path.
- `{PACKAGE ID}`: The library's package identifier. The package identifier defaults to the project's assembly name if the package identifier isn't specified in the project file.

In the following example:

- The static web asset base path is `_content/ClassLib`.
- The class library's assembly name is `ClassLib`.

`Pages/Shared/_Layout.cshtml` (Razor Pages) or `Views/Shared/_Layout.cshtml` (MVC):

HTML

```
<link href="_content/ClassLib/ClassLib.bundle.scp.css" rel="stylesheet">
```

For more information on RCLs, see the following articles:

- Reusable Razor UI in class libraries with ASP.NET Core
- Consume ASP.NET Core Razor components from a Razor class library (RCL)

For information on Blazor CSS isolation, see ASP.NET Core Blazor CSS isolation.

Handle HEAD requests with an OnGet handler fallback

`HEAD` requests allow retrieving the headers for a specific resource. Unlike `GET` requests, `HEAD` requests don't return a response body.

Ordinarily, an `OnHead` handler is created and called for `HEAD` requests:

C#

```
public void OnHead()
{
    HttpContext.Response.Headers.Add("Head Test", "Handled by OnHead!");
}
```

Razor Pages falls back to calling the `OnGet` handler if no `OnHead` handler is defined.

XSRF/CSRF and Razor Pages

Razor Pages are protected by Antiforgery validation. The FormTagHelper injects antiforgery tokens into HTML form elements.

Using Layouts, partials, templates, and Tag Helpers with Razor Pages

Pages work with all the capabilities of the Razor view engine. Layouts, partials, templates, Tag Helpers, `_ViewStart.cshtml`, and `_ViewImports.cshtml` work in the same way they do for conventional Razor views.

Let's declutter this page by taking advantage of some of those capabilities.

Add a layout page to `Pages/Shared/_Layout.cshtml`:

CSHTML

```
<!DOCTYPE html>
<html>
<head>
    <title>RP Sample</title>
    <link rel="stylesheet" href="~/lib/bootstrap/dist/css/bootstrap.css" />
</head>
<body>
    <a asp-page="/Index">Home</a>
    <a asp-page="/Customers/Create">Create</a>
    <a asp-page="/Customers/Index">Customers</a> <br />

    @RenderBody()
    <script src="~/lib/jquery/dist/jquery.js"></script>
    <script src="~/lib/jquery-validation/dist/jquery.validate.js"></script>
    <script src="~/lib/jquery-validation-
unobtrusive/jquery.validate.unobtrusive.js"></script>
</body>
</html>
```

The Layout:

- Controls the layout of each page (unless the page opts out of layout).
- Imports HTML structures such as JavaScript and stylesheets.
- The contents of the Razor page are rendered where `@RenderBody()` is called.

For more information, see layout page.

The Layout property is set in `Pages/_ViewStart.cshtml`:

CSHTML

```
@{
    Layout = "_Layout";
}
```

The layout is in the *Pages/Shared* folder. Pages look for other views (layouts, templates, partials) hierarchically, starting in the same folder as the current page. A layout in the *Pages/Shared* folder can be used from any Razor page under the *Pages* folder.

The layout file should go in the *Pages/Shared* folder.

We recommend you **not** put the layout file in the *Views/Shared* folder. *Views/Shared* is an MVC views pattern. Razor Pages are meant to rely on folder hierarchy, not path conventions.

View search from a Razor Page includes the *Pages* folder. The layouts, templates, and partials used with MVC controllers and conventional Razor views *just work*.

Add a `Pages/_ViewImports.cshtml` file:

CSHTML

```
@namespace RazorPagesContacts.Pages
@addTagHelper *, Microsoft.AspNetCore.Mvc.TagHelpers
```

`@namespace` is explained later in the tutorial. The `@addTagHelper` directive brings in the built-in Tag Helpers to all the pages in the *Pages* folder.

The `@namespace` directive set on a page:

CSHTML

```
@page
@namespace RazorPagesIntro.Pages.Customers

@model NameSpaceModel

<h2>Name space</h2>
<p>
    @Model.Message
</p>
```

The `@namespace` directive sets the namespace for the page. The `@model` directive doesn't need to include the namespace.

When the `@namespace` directive is contained in `_ViewImports.cshtml`, the specified namespace supplies the prefix for the generated namespace in the Page that imports the `@namespace` directive. The rest of the generated namespace (the suffix portion) is the dot-separated relative path between the folder containing `_ViewImports.cshtml` and the folder containing the page.

For example, the `PageModel` class `Pages/Customers/Edit.cshtml.cs` explicitly sets the namespace:

C#

```
namespace RazorPagesContacts.Pages
{
    public class EditModel : PageModel
    {
        private readonly AppDbContext _db;

        public EditModel(AppDbContext db)
        {
            _db = db;
        }

        // Code removed for brevity.
```

The `Pages/_ViewImports.cshtml` file sets the following namespace:

CSHTML

```
@namespace RazorPagesContacts.Pages
@addTagHelper *, Microsoft.AspNetCore.Mvc.TagHelpers
```

The generated namespace for the `Pages/Customers/Edit.cshtml` Razor Page is the same as the `PageModel` class.

`@namespace` *also works with conventional Razor views.*

Consider the `Pages/Customers/Create.cshtml` view file:

CSHTML

```
@page
@model RazorPagesContacts.Pages.Customers.CreateModel
@addTagHelper *, Microsoft.AspNetCore.Mvc.TagHelpers

<p>Validation: customer name:</p>

<form method="post">
    <div asp-validation-summary="ModelOnly"></div>
    <span asp-validation-for="Customer!.Name"></span>
    Name:
    <input asp-for="Customer!.Name" />
    <input type="submit" />
</form>

<script src="~/lib/jquery/dist/jquery.js"></script>
<script src="~/lib/jquery-validation/dist/jquery.validate.js"></script>
<script src="~/lib/jquery-validation-
unobtrusive/jquery.validate.unobtrusive.js"></script>
```

The updated `Pages/Customers/Create.cshtml` view file with `_ViewImports.cshtml` and the preceding layout file:

CSHTML

```
@page
@model CreateModel

<p>Enter a customer name:</p>

<form method="post">
    Name:
    <input asp-for="Customer!.Name" />
    <input type="submit" />
</form>
```

In the preceding code, the `_ViewImports.cshtml` imported the namespace and Tag Helpers. The layout file imported the JavaScript files.

The Razor Pages starter project contains the `Pages/_ValidationScriptsPartial.cshtml`, which hooks up client-side validation.

For more information on partial views, see Partial views in ASP.NET Core.

URL generation for Pages

The `Create` page, shown previously, uses `RedirectToPage`:

C#

```
public class CreateModel : PageModel
{
    private readonly Data.CustomerDbContext _context;

    public CreateModel(Data.CustomerDbContext context)
    {
        _context = context;
    }

    public IActionResult OnGet()
    {
        return Page();
    }

    [BindProperty]
    public Customer? Customer { get; set; }

    public async Task<IActionResult> OnPostAsync()
    {
```

```
            if (!ModelState.IsValid)
            {
                return Page();
            }

            if (Customer != null) _context.Customer.Add(Customer);
            await _context.SaveChangesAsync();

            return RedirectToPage("./Index");
        }
    }
```

The app has the following file/folder structure:

- */Pages*
  - `Index.cshtml`
  - `Privacy.cshtml`
  - */Customers*
    - `Create.cshtml`
    - `Edit.cshtml`
    - `Index.cshtml`

The `Pages/Customers/Create.cshtml` and `Pages/Customers/Edit.cshtml` pages redirect to `Pages/Customers/Index.cshtml` after success. The string `./Index` is a relative page name used to access the preceding page. It is used to generate URLs to the `Pages/Customers/Index.cshtml` page. For example:

- `Url.Page("./Index", ...)`
- `<a asp-page="./Index">Customers Index Page</a>`
- `RedirectToPage("./Index")`

The absolute page name `/Index` is used to generate URLs to the `Pages/Index.cshtml` page. For example:

- `Url.Page("/Index", ...)`
- `<a asp-page="/Index">Home Index Page</a>`
- `RedirectToPage("/Index")`

The page name is the path to the page from the root */Pages* folder including a leading `/` (for example, `/Index`). The preceding URL generation samples offer enhanced options and functional capabilities over hard-coding a URL. URL generation uses routing and

can generate and encode parameters according to how the route is defined in the destination path.

URL generation for pages supports relative names. The following table shows which Index page is selected using different `RedirectToPage` parameters in `Pages/Customers/Create.cshtml`.

Expand table

RedirectToPage(x)	Page
RedirectToPage("/Index")	*Pages/Index*
RedirectToPage("./Index");	*Pages/Customers/Index*
RedirectToPage("../Index")	*Pages/Index*
RedirectToPage("Index")	*Pages/Customers/Index*

`RedirectToPage("Index")`, `RedirectToPage("./Index")`, and `RedirectToPage("../Index")` are *relative names*. The `RedirectToPage` parameter is *combined* with the path of the current page to compute the name of the destination page.

Relative name linking is useful when building sites with a complex structure. When relative names are used to link between pages in a folder:

- Renaming a folder doesn't break the relative links.
- Links are not broken because they don't include the folder name.

To redirect to a page in a different Area, specify the area:

```
C#

RedirectToPage("/Index", new { area = "Services" });
```

For more information, see Areas in ASP.NET Core and Razor Pages route and app conventions in ASP.NET Core.

ViewData attribute

Data can be passed to a page with ViewDataAttribute. Properties with the `[ViewData]` attribute have their values stored and loaded from the ViewDataDictionary.

In the following example, the `AboutModel` applies the `[ViewData]` attribute to the `Title` property:

C#

```
public class AboutModel : PageModel
{
    [ViewData]
    public string Title { get; } = "About";

    public void OnGet()
    {
    }
}
```

In the About page, access the `Title` property as a model property:

CSHTML

```
<h1>@Model.Title</h1>
```

In the layout, the title is read from the ViewData dictionary:

CSHTML

```
<!DOCTYPE html>
<html lang="en">
<head>
    <title>@ViewData["Title"] - WebApplication</title>
    ...
```

TempData

ASP.NET Core exposes the TempData. This property stores data until it's read. The Keep and Peek methods can be used to examine the data without deletion. `TempData` is useful for redirection, when data is needed for more than a single request.
